Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Video Contents

Volume One:

Chapter 15: Skin graft

15.1: Harvesting a split-thickness skin graft
Dennis P. Orgill

Chapter 34: Robotics in plastic surgery

34.1: Robotic microsurgery
34.2: Robotic rectus abdominis muscle flap harvest
34.3: Trans-oral robotic surgery
34.4: Robotic latissimus dorsi muscle harvest
34.5: Robotic lymphovenous bypass
Jesse C. Selber

Volume Two:

Chapter 6.2: Facelift: Principles of and surgical approaches to facelift

6.2.1: Parotid masseteric fascia
6.2.2: Anterior incision
6.2.3: Posterior incision
6.2.4: Facelift skin flap
6.2.5: Facial fat injection
Richard J. Warren

6.2.6: Anthropometry, cephalometry, and orthognathic surgery
Jonathon S. Jacobs, Jordan M. S. Jacobs, and Daniel I. Taub

Chapter 6.3: Facelift: Platysma-SMAS plication

6.3.1: Platysma-SMAS plication
Dai M. Davies and Miles G. Berry

Chapter 6.4: Facelift: Facial rejuvenation with loop sutures – the MACS lift and its derivatives

6.4.1: Loop sutures MACS facelift
Patrick L. Tonnard
From Aston SJ, Steinbrech DS, Walden JL, eds. Aesthetic Plastic Surgery, Saunders Elsevier; 2009; with permission from Elsevier

Chapter 6.7: Facelift: SMAS with skin attached – the "high SMAS" technique

6.7.1: The high SMAS technique with septal reset
Fritz E. Barton Jr.
© Fritz E. Barton Jr.

Chapter 6.8: Facelift: Subperiosteal midface lift

6.8.1: Subperiosteal midface lift: Endoscopic temporo-midface
Oscar M. Ramirez

Chapter 9: Blepharoplasty

9.1: Periorbital rejuvenation
Julius Few Jr. and Marco Ellis
© Julius Few Jr.

Chapter 11: Asian facial cosmetic surgery

1.1: Medial epicanthoplasty
11.2: Eyelidplasty: Non-incisional method
11.3: Rhinoplasty
11.4: Subclinical ptosis correction (total)
11.5: Secondary rhinoplasty: Septal extension graft and costal cartilage strut fixed with K-wire
Kyung S. Koh, Jong Woo Choi, and Clyde H. Ishii

Chapter 12: Neck rejuvenation

12.1: Anterior lipectomy
James E. Zins, Colin M. Morrison, and C. J. Langevin

Chapter 13: Structural fat grafting

13.1: Structural fat grafting of the face
Sydney R. Coleman and Alesia P. Saboeiro

Chapter 14: Skeletal augmentation

14.1: Chin implant
Michael J. Yarumchuk
© Mesa J, Havlik R, Mackay D, Buchman S, Losee J, eds. Atlas of Operative Craniofacial Surgery, CRC Press, 2019.

14.2: Mandibular angle implant
14.3: Midface skeletal augmentation and rejuvenation
Michael J. Yarumchuk
© Michael J. Yaremchuk

Chapter 16: Open technique rhinoplasty

16.1: Open technique rhinoplasty
Allen L. Van Beek

Chapter 20: Otoplasty and ear reduction

20.1: Setback otoplasty
Leila Kasrai

Chapter 23: Abdominoplasty procedures

23.1: Abdominoplasty
Dirk F. Richter and Alexander Stoff

Chapter 24: Lipoabdominoplasty

24.1: Lipoabdominoplasty (including secondary lipo)
Osvaldo Saldanha, Sérgio Fernando Dantas de Azevedo, Osvaldo Ribeiro Saldanha Filho, Cristianna Bonnetto Saldanha, and Luis Humberto Uribe Morelli

Chapter 26.2: Buttock augmentation: Buttock augmentation with implants

26.2.1: Buttock augmentation
Terrence W. Bruner, Jose Abel De la Peña Salcedo, Constantino G. Mendieta, and Thomas L. Roberts III

Chapter 27: Upper limb contouring

27.1: Brachioplasty
27.2: Upper limb contouring
Joseph F. Capella, Matthew J. Trovato, and Scott Woehrle

Chapter 28: Post-bariatric reconstruction

28.1: Post-bariatric reconstruction – bodylift procedure
J. Peter Rubin and Jonathan W. Toy
© J. Peter Rubin

Volume Three:

Chapter 6: Aesthetic nasal reconstruction

6.1: The three-stage folded forehead flap for cover and lining
6.2: First-stage transfer and intermediate operation
Frederick J. Menick

Chapter 7: Auricular construction

7.1: Total auricular construction
Akira Yamada

Chapter 8: Acquired cranial and facial bone deformities

8.1: Removal of venous malformation enveloping intraconal optic nerve
Renee M. Burke, Robert J. Morin, and S. Anthony Wolfe

Chapter 13: Facial paralysis

13.1: Facial paralysis
Eyal Gur

13.2: Facial paralysis
13.3: Cross facial nerve graft
13.4: Gracilis harvest
Peter C. Neligan

Chapter 14: Pharyngeal and esophageal reconstruction

14.1: Reconstruction of pharyngoesophageal defects with the anterolateral thigh flap
Peirong Yu

Chapter 15: Tumors of the facial skeleton: Fibrous dysplasia

15.1: Surgical approaches to the facial skeleton
Yu-Ray Chen, You-Wei Cheong, and Alberto Córdova-Aguilar

Chapter 17: Local flaps for facial coverage

17.1: Facial artery perforator flap
17.2: Local flaps for facial coverage
Peter C. Neligan

Chapter 21.2: Rotation advancement cheiloplasty

21.2.1: Repair of unilateral cleft lip
Philip Kuo-Ting Chen, M. Samuel Noordhoff, Frank Chun-Shin, Chang, and Fuan Chiang Chan

21.2.2: Unilateral cleft lip repair – anatomic subunit approximation technique
David M. Fisher

Chapter 24: Alveolar clefts

24.1: Unilateral cleft alveolar bone graft
24.2: Mobilized premaxilla after vomer osteotomy prior to setback and splint application
Richard A. Hopper and Gerhard S. Mundinger

Chapter 26: Velopharyngeal dysfunction

26.1: Velopharyngeal incompetence – 1
26.2: Velopharyngeal incompetence – 2
26.3: Velopharyngeal incompetence – 3
Richard E. Kirschner and Adriane L. Baylis

Chapter 27: Secondary deformities of the cleft lip, nose, and palate

27.1: Abbé flap
27.2: Alveolar bone grafting
27.3: Complete takedown
27.4: Definitive rhinoplasty
Evan M. Feldman, John C. Koshy, Larry H. Hollier Jr., and Samuel Stal

27.5: Thick lip and buccal sulcus deformities
Evan M. Feldman and John C. Koshy

Chapter 36: Pierre Robin Sequence

36.1: Mandibular distraction
Arun K. Gosain and Chad A. Purnell

Chapter 39: Vascular anomalies

39.1: Lip hemangioma
Arin K. Greene

Chapter 43: Reconstruction of urogenital defects: Congenital

43.1: First-stage hypospadias repair with free inner preputial graft
43.2: Second-stage hypospadias repair with tunica vaginalis flap
Mohan S. Gundeti and Michael C. Large

Volume Four:

Chapter 2: Management of lower extremity trauma

2.1: Anterolateral thigh flap harvest
Michel Saint-Cyr

Chapter 3: Lymphatic reconstruction of the extremities

3.1: End-to-side lymphovenous bypass technique
© Cheng M-H, Chang D, Patel K. Principles and Practice of Lymphedema Surgery, Elsevier; 2015.

3.2: Recipient site preparation for vascularized lymph node transfer – axilla
© Cheng M-H, Chang D, Patel K. Principles and Practice of Lymphedema Surgery, Elsevier; 2015.

3.3: Indocyanine green lymphography
David W. Chang

3.4: Charles procedure
Peter C. Neligan

Chapter 6: Diagnosis and treatment of painful neuroma and nerve compression in the lower extremity

6.1: Diagnosis and treatment of painful neuroma and of nerve compression in the lower extremity 1
6.2: Diagnosis and treatment of painful neuroma and of nerve compression in the lower extremity 2

6.3: Diagnosis and treatment of painful neuroma and of nerve compression in the lower extremity 3
A. Lee Dellon

Chapter 7: Skeletal reconstruction

7.1: Medial femoral condyle/medial geniculate artery osteocutaneous free flap dissection for scaphoid nonunion
Stephen J. Kovach III and L. Scott Levin

Chapter 10: Reconstruction of the chest

10.1: Sternal rigid fixation
David H. Song and Michelle C. Roughton

Chapter 12: Abdominal wall reconstruction

12.1: Component separation innovation
Peter C. Neligan

Chapter 13: Reconstruction of male genital defects

13.1: Complete and partial penile reconstruction
Stan Monstrey, Peter Ceulemans, Nathalie Roche, Philippe Houtmeyers, Nicolas Lumen, and Piet Hoebeke

Volume Five:

Chapter 6: Mastopexy options and techniques

6.1: Circumareolar mastopexy
Kenneth C. Shestak

Chapter 7: One- and two-stage considerations for augmentation mastopexy

7.1: Preoperative markings for a single-stage augmentation mastopexy
W. Grant Stevens

Chapter 10: Reduction mammaplasty with short scar techniques

10.1: SPAIR technique
Dennis C. Hammond

Chapter 11: Gynecomastia surgery

11.1: Ultrasound-assisted liposuction
Charles M. Malata

Chapter 15: One- and two-stage prosthetic reconstruction in nipple-sparing mastectomy

15.1: Pectoralis muscle elevation
15.2: Acellular dermal matrix
15.3: Sizer
Amy S. Colwell

Chapter 16: Skin-sparing mastectomy: Planned two-stage and direct-to-implant breast reconstruction

16.1: Mastectomy and expander insertion: First stage
16.2: Mastectomy and expander insertion: Second stage
Maurizio B. Nava, Giuseppe Catanuto, Angela Pennati, Valentina Visintini Cividin, and Andrea Spano

Chapter 19: Latissimus dorsi flap breast reconstruction

19.1: Latissimus dorsi flap technique
Scott L. Spear†

19.2: Markings
19.3: Intraoperative skin paddles
19.4: Tendon division
19.5: Transposition and skin paddles
19.6: Inset and better skin paddle explanation
Neil A. Fine and Michael S. Gart

Chapter 20.2: The deep inferior epigastric artery perforator (DIEAP) flap

20.2.1: The Deep Inferior Epigastric Artery Perforator (DIEAP) flap breast reconstruction
Phillip N. Blondeel and Robert J. Allen, Sr

Chapter 21.2: Gluteal free flaps for breast reconstruction

21.2.1: Superior Gluteal Artery Perforator (SGAP) flap
21.2.2: Inferior Gluteal Artery Perforator (IGAP) flap
Peter C. Neligan

Chapter 21.3: Medial thigh flaps for breast reconstruction

21.3.1: Transverse Upper Gracilis (TUG) flap 1
Peter C. Neligan

21.3.2: Transverse Upper Gracilis (TUG) flap 2
Venkat V. Ramakrishnan

Chapter 23.2: Partial breast reconstruction using reduction and mastopexy techniques

23.2.1: Partial breast reconstruction using reduction mammoplasty
Maurice Y. Nahabedian

23.2.2: Partial breast reconstruction with a latissimus dorsi flap
Neil A. Fine

23.2.3: Partial breast reconstruction with a pedicle TRAM
Maurice Y. Nahabedian

Volume Six:

Chapter 1: Anatomy and biomechanics of the hand

1.1: The extensor tendon compartments
1.2: The contribution of the interosseous and lumbrical muscles to the lateral bands
1.3: Extrinsic flexors and surrounding vasculonervous elements, from superficial to deep
1.4: The lumbrical plus deformity
1.5: The sensory and motor branches of the median nerve in the hand
James Chang, Vincent R. Hentz, Robert A. Chase, and Anais Legrand

Chapter 2: Examination of the upper extremity

2.1: Flexor profundus test in a normal long finger
2.2: Flexor sublimis test in a normal long finger
2.3: Extensor pollicis longus test in a normal person
2.4: Test for the Extensor Digitorum Communis (EDC) muscle in a normal hand
2.5: Test for assessing thenar muscle function
2.6: The “cross fingers” sign
2.7: Static Two-Point Discrimination Test (s-2PD Test)
2.8: Moving 2PD Test (m-2PD Test) performed on the radial or ulnar aspect of the finger

2.9: Semmes–Weinstein monofilament test: The patient should sense the pressure produced by bending the filament
2.10: Allen's test in a normal person
2.11: Digital Allen's test
2.12: Scaphoid shift test
2.13: Dynamic tenodesis effect in a normal hand
2.14: The milking test of the fingers and thumb in a normal hand
2.15: Eichhoff test
2.16: Adson test
2.17: Roos test
Ryosuke Kakinoki

Chapter 3: Diagnostic imaging of the hand and wrist

3.1: Scaphoid lunate dislocation
Alphonsus K. Chong and David M. K. Tan

3.2: Right wrist positive midcarpal catch up clunk
Alphonsus K. Chong

Chapter 4: Anesthesia for upper extremity surgery

4.1: Supraclavicular block
Subhro K. Sen

Chapter 5: Principles of internal fixation as applied to the hand and wrist

5.1: Dynamic compression plating and lag screw technique
Christopher Cox

5.2: Headless compression screw
5.3: Locking vs. non-locking plates
Jeffrey Yao and Jason R. Kang

Chapter 7: Hand fractures and joint injuries

7.1: Bennett reduction
7.2: Hemi-Hamate arthroplasty
Warren C. Hammert

Chapter 9: Flexor tendon injury and reconstruction

9.1: Zone II flexor tendon repair
9.2: Incision and feed tendon forward
9.3: Distal tendon exposure
9.4: Six-strand M-tang repair
9.5: Extension–flexion test – wide awake
Jin Bo Tang

Chapter 10: Extensor tendon injuries

10.1: Sagittal band reconstruction
10.2: Setting the tension in extensor indicis transfer
Kai Megerle

Chapter 11: Replantation and revascularization

11.1: Hand replantation
James Chang

Chapter 12: Reconstructive surgery of the mutilated hand

12.1: Debridement technique
James Chang

Chapter 13: Thumb reconstruction: Non-microsurgical techniques

13.1: Osteoplastic thumb reconstruction
13.2: First Dorsal Metacarpal Artery (FDMA) flap
Jeffrey B. Friedrich

Chapter 14: Thumb reconstruction: Microsurgical techniques

14.1: Trimmed great toe
14.2: Second toe for index finger
14.3: Combined second and third toe for metacarpal hand
Nidal F. Al Deek

Chapter 19: Rheumatologic conditions of the hand and wrist

19.1: Extensor tendon rupture and end–side tendon transfer
James Chang

19.2: Silicone metacarpophalangeal arthroplasty
Kevin C. Chung and Evan Kowalski

Chapter 20: Osteoarthritis in the hand and wrist

20.1: Ligament reconstruction tendon interposition arthroplasty of the thumb carpometacarpal joint
James W. Fletcher

Chapter 21: The stiff hand and the spastic hand

21.1: Flexor pronator slide
David T. Netscher

Chapter 22: Ischemia of the hand

22.1: Radial artery sympathectomy
Hee Chang Ahn and Neil F. Jones

22.2: Interposition arterial graft and sympathectomy
Hee Chang Ahn

Chapter 24: Nerve entrapment syndromes

24.1: The manual muscle testing algorithm
24.2: Scratch collapse test – carpal tunnel
Elisabet Hagert

24.3: Injection technique for carpal tunnel surgery
24.4: Wide awake carpal tunnel surgery
Donald Lalonde

24.5: Clinical exam and surgical technique – lacertus syndrome
Elisabet Hagert

24.6: Injection technique for cubital tunnel surgery
24.7: Wide awake cubital tunnel surgery
Donald Lalonde

24.8: Clinical exam and surgical technique – radial tunnel syndrome
24.9: Clinical exam and surgical technique – lateral intermuscular syndrome
24.10: Clinical exam and surgical technique – axillary nerve entrapment
Elisabet Hagert

24.11: Carpal tunnel and cubital tunnel releases in the same patient in one procedure with field sterility: Part 1 – local anesthetic injection for carpal tunnel
24.12: Carpal tunnel and cubital tunnel releases in the same patient in one procedure with field sterility: Part 2 – local anesthetic injection for cubital tunnel
Donald Lalonde and Michael Bezuhly

Chapter 25: Congenital hand I: Embryology, classification, and principles

25.1: Pediatric trigger thumb release
James Chang

Chapter 27: Congenital hand III: Thumb hypoplasia

27.1: Thumb hypoplasia
Joseph Upton III and Amir Taghinia

Chapter 30: Growth considerations in pediatric upper extremity trauma and reconstruction

30.1: Epiphyseal transplant harvesting technique
Marco Innocenti and Carla Baldrighi

Chapter 31: Vascular anomalies of the upper extremity

31.1: Excision of venous malformation
Joseph Upton III and Amir Taghinia

Chapter 32: Peripheral nerve injuries of the upper extremity

32.1: Suture repair of the cut digital nerve
32.2: Suture repair of the median nerve
Simon Farnebo and Johan Thorfinn

Chapter 35: Free-functioning muscle transfer in the upper extremity

35.1: Gracilis functional muscle harvest
Gregory H. Borschel

Chapter 36: Brachial plexus injuries: Adult and pediatric

36.1: Pediatric: shoulder correct and biceps-to-triceps transfer with preserving intact brachialis
36.2: Adult: results of one-stage surgery for C5 rupture, C6–T1 root avulsion 10 years after
36.3: Nerve transfer results 1
36.4: Nerve transfer results 2
36.5: Nerve transfer results 3
36.6: Nerve transfer results 4
36.7: Nerve transfer results 5
David Chwei-Chin Chuang

Chapter 37: Restoration of upper extremity function in tetraplegia

37.1: The single-stage grip and release procedure
37.2: Postoperative results after single-stage grip release procedure in OCu3–5 patients
Carina Reinholdt and Catherine Curtin

Chapter 38: Upper extremity vascularized composite allotransplantation

38.1: Upper extremity composite tissue allotransplantation
W. P. Andrew Lee and Vijay S. Gorantla

Chapter 39: Hand therapy

39.1: Goniometric measurement
39.2: Threshold testing
Christine B. Novak and Rebecca L. Neiduski

Lecture Video Contents

Volume One:

Chapter 1: Plastic surgery and innovation in medicine

Plastic surgery and innovation in medicine

Peter C. Neligan

Chapter 7: Digital imaging in plastic surgery

Digital imaging in plastic surgery

Daniel Z. Liu

Chapter 15: Skin graft

Skin graft

Peter C. Neligan

Chapter 19: Repair and grafting of peripheral nerve

Nerve injury and repair

Kirsty Usher Boyd, Andrew Yee, and Susan E. Mackinnon

Chapter 20: Reconstructive fat grafting

Reconstructive fat grafting

J. Peter Rubin

Chapter 21: Vascular territories

Vascular territories

Steven F. Morris

Chapter 22: Flap classification and applications

Flap classification and applications

Joon Pio Hong

Chapter 23: Flap pathophysiology and pharmacology

Flap pathophysiology and pharmacology

Cho Y. Pang and Peter C. Neligan

Chapter 24: Principles and techniques of microvascular surgery

Principles and techniques of microvascular surgery

Fu-Chan Wei, Nidal F. Al Deek, and Sherilyn Keng Lin Tay

Chapter 25: Principles and applications of tissue expansion

Principles and applications of tissue expansion

Ivo Alexander Pestana, Louis C. Argenta, and Malcolm W. Marks

Chapter 26: Principles of radiation

Therapeutic radiation: principles, effects, and complications

Gabrielle M. Kane

Chapter 28: Benign and malignant nonmelanocytic tumors of the skin and soft tissue

Benign and malignant nonmelanocytic tumors of the skin and soft tissue

Rei Ogawa

Chapter 31: Facial prosthetics in plastic surgery

Facial prosthetics in plastic surgery

Gordon H. Wilkes

Volume Two:

Chapter 4: Skincare and nonsurgical skin rejuvenation

Skincare and nonsurgical skin rejuvenation

Leslie Baumann and Edmund Weisberg

Chapter 5.2: Injectables and resurfacing techniques: Soft-tissue fillers

Soft-tissue fillers

Trevor M. Born, Lisa E. Airan, and Daniel Suissa

Chapter 5.3: Injectables and resurfacing techniques: Botulinum toxin (BoNT-A)

Botulinum toxin

Michael A. C. Kane

Chapter 5.4: Injectables and resurfacing techniques: Laser resurfacing

Laser resurfacing

Steven R. Cohen, Ahmad N. Saad, Tracy Leong, and E. Victor Ross

Chapter 5.5: Injectables and resurfacing techniques: Chemical peels

Chemical peels

Suzan Obagi

Chapter 6.1: Facelift: Facial anatomy and aging

Anatomy of the aging face

Bryan Mendelson and Chin-Ho Wong

Chapter 6.2: Facelift: Principles of and surgical approaches to facelift

Principles of and surgical approaches to facelift

Richard J. Warren

Chapter 6.3: Facelift: Platysma-SMAS plication

Platysma-SMAS plication

Miles G. Berry

Chapter 6.4: Facelift: Facial rejuvenation with loop sutures – the MACS lift and its derivatives

Facial rejuvenation with loop sutures – the MACS lift and its derivatives

Mark Laurence Jewell

Chapter 6.5: Facelift: Lateral SMASectomy facelift

Lateral SMASectomy facelift

Daniel C. Baker and Steven M. Levine

Chapter 6.6: Facelift: The extended SMAS technique in facial rejuvenation

The extended SMAS technique in facelift

James M. Stuzin

Chapter 6.7: Facelift: SMAS with skin attached – the "high SMAS" technique

SMAS with skin attached – the high SMAS technique

Fritz E. Barton Jr.

Chapter 6.8: Facelift: Subperiosteal midface lift

Subperiosteal midface lift

Alan Yan and Michael J. Yaremchuk

Chapter 6.9: Facelift: Male facelift

Male facelift

Timothy J. Marten and Dino Elyassnia

Chapter 6.10: Facelift: Secondary deformities and the secondary facelift

Secondary deformities and the secondary facelift

Timothy J. Marten and Dino Elyassnia

Chapter 7: Forehead rejuvenation

Forehead rejuvenation

Richard J. Warren

Chapter 8: Endoscopic brow lifting

Endoscopic brow lift

Renato Saltz and Alyssa Lolofie

Chapter 9: Blepharoplasty

Blepharoplasty

Julius Few Jr. and Marco Ellis

Chapter 11: Asian facial cosmetic surgery

Asian facial cosmetic surgery

Clyde H. Ishii

Chapter 12: Neck rejuvenation

Neck rejuvenation

James E. Zins, Joshua T. Waltzman, and Rafael A. Couto

Chapter 13: Structural fat grafting

Structural fat grafting

Sydney R. Coleman and Alesia P. Saboeiro

Chapter 15: Nasal analysis and anatomy

Nasal analysis and anatomy

Rod J. Rohrich

Chapter 19: Secondary rhinoplasty

Secondary rhinoplasty

Ronald P. Gruber, Simeon H. Wall Jr., David L. Kaufman, and David M. Kahn

Chapter 21: Hair restoration

Hair restoration

Jack Fisher

Chapter 22.1: Liposuction: A comprehensive review of techniques and safety

Liposuction

Phillip J. Stephan, Phillip Dauwe, and Jeffrey Kenkel

Chapter 22.2: Correction of liposuction deformities with the SAFE liposuction technique

SAFE liposuction technique

Simeon H. Wall Jr. and Paul N. Afrooz

Chapter 23: Abdominoplasty procedures

Abdominoplasty

Dirk F. Richter and Nina Schwaiger

Chapter 25.2: Circumferential approaches to truncal contouring: Belt lipectomy

Belt lipectomy

Al S. Aly, Khalid Al-Zahrani, and Albert Cram

Chapter 25.3: Circumferential approaches to truncal contouring: The lower lipo-bodylift

Circumferential lower bodylift

Dirk F. Richter and Nina Schwaiger

Chapter 25.4: Circumferential approaches to truncal contouring: Autologous buttocks augmentation with purse string gluteoplasty

Purse string gluteoplasty

Joseph P. Hunstad and Nicholas A. Flugstad

Chapter 25.5: Circumferential approaches to truncal contouring: Lower bodylift with autologous gluteal flaps for augmentation and preservation of gluteal contour

Lower bodylift with gluteal flaps

Robert F. Centeno and Jazmina M. Gonzalez

Chapter 26.3: Buttock augmentation: Buttock shaping with fat grafting and liposuction

Buttock shaping with fat grafting and liposuction

Constantino G. Mendieta, Thomas L. Roberts III, and Terrence W. Bruner

Chapter 27: Upper limb contouring

Upper limb contouring

Joseph F. Capella, Matthew J. Trovato, and Scott Woehrle

Chapter 30: Aesthetic genital surgery

Aesthetic genital surgery

Gary J. Alter

Volume Three:

Chapter 10.3: Midface reconstruction: The M. D. Anderson approach

Midfacial reconstruction: The M. D. Anderson approach
Matthew M. Hanasono and Roman Skoracki

Chapter 12: Lip reconstruction

Lip reconstruction
Peter C. Neligan and Lawrence J. Gottlieb

Chapter 14: Pharyngeal and esophageal reconstruction

Pharyngoesophageal reconstruction
Peirong Yu

Chapter 15: Tumors of the facial skeleton: Fibrous dysplasia

Fibrous dysplasia
Alberto Córdova-Aguilar and Yu-Ray Chen

Chapter 17: Local flaps for facial coverage

Local flaps for facial coverage
David W. Mathes

Chapter 19: Facial transplant

Facial transplant
Michael Sosin and Eduardo D. Rodriguez

Chapter 32: Nonsyndromic craniosynostosis

Nonsyndromic craniosynostosis
Patrick A. Gerety, Jesse A. Taylor, and Scott P. Bartlett

Chapter 36: Pierre Robin Sequence

Pierre Robin sequence
Chad A. Purnell and Arun K. Gosain

Chapter 39: Vascular anomalies

Vascular anomalies
Arin K. Greene and John B. Mulliken

Volume Four:

Chapter 2: Management of lower extremity trauma

Management of lower extremity trauma
Yoo Joon Sur, Shannon M. Colohan, and Michel Saint-Cyr

Chapter 15: Surgery for gender identity disorder

Surgery for gender identity disorder
Loren S. Schechter

Chapter 16: Pressure sores

Pressure sores
Robert Kwon, Juan L. Rendon, and Jeffrey E. Janis

Chapter 17: Perineal reconstruction

Perineal reconstruction
Hakim K. Said and Otway Louie

Volume Five:

Chapter 5: Breast augmentation with autologous fat grafting

Breast augmentation with autologous fat grafting
E. Delay

Chapter 6: Mastopexy options and techniques

Mastopexy
Robert Cohen

Chapter 9: Reduction mammaplasty with inverted-T techniques

Reduction mammaplasty with inverted-T techniques
Maurice Y. Nahabedian

Chapter 15: One- and two-stage prosthetic reconstruction in nipple-sparing mastectomy

Prosthetic reconstruction in nipple-sparing mastectomy
Amy S. Colwell

Chapter 20.1: Abdominally based free flaps: Introduction

Abdominally-based autologous breast reconstruction
Maurice Y. Nahabedian, Phillip N. Blondeel, and David H. Song

Chapter 20.2: The deep inferior epigastric artery perforator (DIEAP) flap

Abdominally-based autologous breast reconstruction
Maurice Y. Nahabedian, Phillip N. Blondeel, and David H. Song

Chapter 20.3: The superficial inferior epigastric artery (SIEA) flap

Abdominally-based autologous breast reconstruction
Maurice Y. Nahabedian, Phillip N. Blondeel, and David H. Song

Chapter 20.4: The free TRAM flap

Abdominally-based autologous breast reconstruction
Maurice Y. Nahabedian, Phillip N. Blondeel, and David H. Song

Chapter 25: Radiation therapy considerations in the setting of breast reconstruction

Radiation therapy in breast reconstruction
Steven Kronowitz

Volume Six:

Chapter 7: Hand fractures and joint injuries

Hand fractures and joint injuries
Joseph S. Khouri and Warren C. Hammert

Chapter 13: Thumb reconstruction: Non-microsurgical techniques

Thumb reconstruction
Nicholas B. Vedder and Jeffrey B. Friedrich

Chapter 21: The stiff hand and the spastic hand

The stiff hand
David T. Netscher, Kenneth W. Donohue, and Dang T. Pham

Chapter 24: Nerve entrapment syndromes

Tips and pearls on common nerve compressions

Elisabet Hagert and Donald Lalonde

Chapter 30: Growth considerations in pediatric upper extremity trauma and reconstruction

Growth considerations in pediatric upper extremity trauma and reconstruction

Marco Innocenti and Carla Baldrighi

Chapter 33: Nerve transfers

Nerve injury and repair

Kirsty Usher Boyd, Andrew Yee, and Susan E. Mackinnon

Chapter 37: Restoration of upper extremity function in tetraplegia

Restoration of upper extremity function in tetraplegia

Carina Reinholdt and Catherine Curtin

Preface to the Fourth Edition

When I wrote the preface to the 3rd edition of this book, I remarked how honored and unexpectedly surprised I was to be the Editor of this great series. This time 'round, I'm equally grateful to carry this series forward. When Elsevier called me and suggested it was time to prepare the 4th edition, my initial reaction was that this was way too soon. What could possibly have changed in Plastic Surgery since the 3rd edition was launched in 2012? As it transpires, there have been many developments and I hope we have captured them in this edition.

We have an extraordinary specialty. A recent article by Chadra, Agarwal and Agarwal entitled "Redefining Plastic Surgery" appeared in *Plastic and Reconstructive Surgery—Global Open*. In it they gave the following definition: "Plastic surgery is a specialized branch of surgery, which deals with deformities, defects and abnormalities of the organs of perception, organs of action and the organs guarding the external passages, besides innovation, implantation, replantation and transplantation of tissues, and aims at restoring and improving their form, function and the esthetic appearances." This is an all-encompassing but very apt definition and captures the enormous scope of the specialty.[1]

In the 3rd edition, I introduced volume editors for each of the areas of the specialty because the truth is that one person can no longer be an expert in all areas of this diverse specialty, and I'm certainly not. I think this worked well because the volume editors not only had the expertise to present their area of subspecialty in the best light, but they were tuned in to what was new and who was doing it. We have continued this model in this new edition. Four of the seven volume editors from the previous edition have again helped to bring the latest and the best to this edition: Drs Gurtner, Song, Rodriguez, Losee, and Chang have revised and updated their respective volumes with some chapters remaining, some extensively revised, some added, and some deleted. Dr. Peter Rubin has replaced Dr. Rick Warren to compile the Aesthetic volume (Vol. 2). Dr. Warren did a wonderful job in corralling this somewhat disparate, yet vitally important, part of our specialty into the Aesthetic volume in the 3rd edition but felt that the task of doing it again, though a labor of love, was more than he wanted to take on. Similarly, Dr. Jim Grotting who did a masterful job in the last edition on the Breast volume, decided that doing a major revision should be undertaken by someone with a fresh perspective and Dr. Maurice Nahabedian stepped into that breach. I hope you will like the changes you see in both of these volumes.

Dr. Allen Van Beek was the video editor for the last edition and he compiled an impressive array of movies to complement the text. This time around, we wanted to go a step further and though we've considerably expanded the list of videos accompanying the text (there are over 170), we also added the idea of lectures accompanying selected chapters. What we've done here is to take selected key chapters and include the images from that chapter, photos and artwork, and create a narrated presentation that is available online; there are annotations in the text to alert the reader that this is available. Dr. Daniel Liu, who has taken over from Dr. Van Beek as multimedia editor (rather than video editor) has done an amazing job in making all of this happen. There are over 70 presentations of various key chapters online, making it as easy as possible for you, the reader, to get as much knowledge as you can, in the easiest way possible from this edition. Many of these presentations have been done by the authors of the chapters; the rest have been compiled by Dr. Liu and myself from the content of the individual chapters. I hope you find them useful.

The reader may wonder how this all works. To plan this edition, the Elsevier team, headed by Belinda Kuhn, and I, convened a face-to-face meeting in San Francisco. The volume editors, as well as the London based editorial team, were present. We went through the 3rd edition, volume by volume, chapter by chapter, over an entire weekend. We decided what needed to stay, what needed to be added, what needed to be revised, and what needed to be changed. We also decided who should write the various chapters, keeping many existing authors, replacing others, and adding some new ones; we did this so as to really reflect the changes occurring within the specialty. We also decided on practical changes that needed to be made. As an example, you will notice that we have omitted the complete index for the 6 Volume set from Volumes 2-6 and highlighted only the table of contents for that particular volume. The complete index is of course available in Volume 1 and fully searchable online. This allowed us to save several hundred pages per volume, reducing production costs and diverting those dollars to the production of the enhanced online content.

In my travels around the world since the 3rd edition was published, I've been struck by what an impact this publication has had on the specialty and, more particularly, on training. Everywhere I go, I'm told how the text is an important part of didactic teaching and a font of knowledge. It is gratifying to see that the 3rd edition has been translated into Portuguese, Spanish, and Chinese. This is enormously encouraging. I hope this 4th edition continues to contribute to the specialty, remains a resource for practicing surgeons, and continues to prepare our trainees for their future careers in Plastic Surgery.

Peter C. Neligan

List of Editors

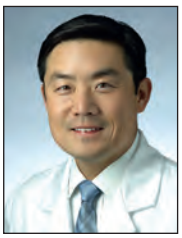
Editor-in-Chief
Peter C. Neligan, MB, FRCS(I), FRCSC, FACS
Professor of Surgery
Department of Surgery, Division of Plastic Surgery
University of Washington
Seattle, WA, USA

Volume 1: Principles
Geoffrey C. Gurtner, **MD, FACS**
Johnson and Johnson Distinguished Professor of Surgery and Vice Chairman,
Department of Surgery (Plastic Surgery)
Stanford University
Stanford, CA, USA

Volume 2: Aesthetic
J. Peter Rubin, **MD, FACS**
UPMC Professor of Plastic Surgery
Chair, Department of Plastic Surgery
Professor of Bioengineering
University of Pittsburgh
Pittsburgh, PA, USA

Volume 3: Craniofacial, Head and Neck Surgery
Eduardo D. Rodriguez, MD, DDS
Helen L. Kimmel Professor of Reconstructive Plastic Surgery
Chair, Hansjörg Wyss Department of Plastic Surgery
NYU School of Medicine
NYU Langone Medical Center
New York, NY, USA

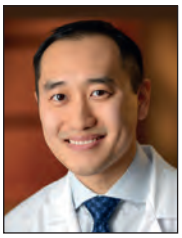
Volume 3: Pediatric Plastic Surgery
Joseph E. Losee, MD
Ross H. Musgrave Professor of Pediatric Plastic Surgery
Department of Plastic Surgery
University of Pittsburgh Medical Center;
Chief Division of Pediatric Plastic Surgery
Children's Hospital of Pittsburgh
Pittsburgh, PA, USA



Volume 4: Lower Extremity, Trunk, and Burns
David H. Song, **MD, MBA, FACS**
Regional Chief, MedStar Health
Plastic and Reconstructive Surgery
Professor and Chairman
Department of Plastic Surgery
Georgetown University School of Medicine
Washington, DC, USA

Volume 5: Breast
Maurice Y. Nahabedian, **MD, FACS**
Professor and Chief
Section of Plastic Surgery
MedStar Washington Hospital Center
Washington, DC, USA;
Vice Chairman
Department of Plastic Surgery
MedStar Georgetown University Hospital
Washington, DC, USA

Volume 6: Hand and Upper Extremity
James Chang, MD
Johnson & Johnson Distinguished Professor and Chief
Division of Plastic and Reconstructive Surgery
Stanford University Medical Center
Stanford, CA, USA



Multimedia editor
Daniel Z. Liu, MD
Plastic and Reconstructive Surgeon
Cancer Treatment Centers of America at Midwestern Regional Medical Center
Zion, IL, USA

List of Contributors

The editors would like to acknowledge and offer grateful thanks for the input of all previous editions' contributors, without whom this new edition would not have been possible.

VOLUME ONE

Hatem Abou-Sayed, MD, MBA
Vice President
Physician Engagement
Interpreta, Inc.
San Diego, CA, USA

Paul N. Afrooz, MD
Resident
Plastic and Reconstructive Surgery
University of Pittsburgh Medical Center
Pittsburgh, PA, USA

Foad Nahai, MD
Professor of Surgery
Division of Plastic and Reconstructive Surgery
Department of Surgery
Emory University School of Medicine
Emory Aesthetic Center at Paces
Atlanta, Georgia, USA

Suzan Obagi, MD
Associate Professor of Dermatology
Dermatology
University of Pittsburgh;
Associate Professor of Plastic Surgery
Plastic Surgery
University of Pittsburgh
Pittsburgh, PA, USA

Sabina Aparecida Alvarez de Paiva, MD
Resident of Plastic Surgery
Plastic Surgery Service Dr. Ewaldo Bolivar de Souza Pinto
São Paulo, Brazil

Galen Perdikis, MD
Assistant Professor of Surgery
Division of Plastic Surgery
Emory University School of Medicine
Atlanta, GA, USA

Jason Posner, MD, FACS
Private Practice
Boca Raton, FL, USA

Dirk F. Richter, MD, PhD
Clinical Professor of Plastic Surgery
University of Bonn
Director and Chief
Dreifaltigkeits-Hospital
Wesseling, Germany

Thomas L. Roberts III, FACS
Plastic Surgery Center of the Carolinas
Spartanburg, SC, USA

Jocelyn Celeste Ledezma Rodriguez, MD
Private Practice
Guadalajara, Jalisco, Mexico

Rod J. Rohrich, MD
Clinical Professor and Founding Chair
Department of Plastic Surgery
Distinguished Teaching Professor
University of Texas Southwestern Medical Center
Founding Partner
Dallas Plastic Surgery Institute
Dallas, TX, USA

E. Victor Ross, MD
Director of Laser and Cosmetic Dermatology
Scripps Clinic
San Diego, CA, USA

J. Peter Rubin, MD, FACS
Chief
Plastic and Reconstructive Surgery
University of Pittsburgh Medical Center;
Associate Professor
Department of Surgery
University of Pittsburgh
Pittsburgh, PA, USA

Ahmad N. Saad, MD
Private Practice
FACES+ Plastic Surgery
Skin and Laser Center
La Jolla, CA, USA

Alesia P. Saboeiro, MD
Attending Physician
Private Practice
New York, NY, USA

Cristianna Bonnetto Saldanha, MD
Plastic Surgery Service Dr. Osvaldo Saldanha
São Paulo, Brazil

Osvaldo Saldanha, MD, PhD
Director of Plastic Surgery Service Dr. Osvaldo Saldanha;
Professor of Plastic Surgery Department
Universidade Metropolitana de Santos - UNIMES
São Paulo, Brazil

Renato Saltz, MD, FACS
Saltz Plastic Surgery
President
International Society of Aesthetic Plastic Surgery
Adjunct Professor of Surgery
University of Utah
Past-President, American Society for Aesthetic Plastic Surgery
Salt Lake City and Park City, UT, USA

Paulo Rodamilans Sanjuan MD
Chief Resident of Plastic Surgery
Plastic Surgery Service Dr. Ewaldo Boliar de Souza Pinto
São Paulo, Brazil

Nina Schwaiger, MD
Senior Specialist in Plastic and Aesthetic Surgery
Department of Plastic Surgery
Dreifaltigkeits-Hospital Wesseling
Wesseling, Germany

Douglas S. Steinbrech, MD, FACS
Gotham Plastic Surgery
New York, NY, USA

Phillip J. Stephan, MD
Clinical Faculty
Plastic Surgery
UT Southwestern Medical School;
Plastic Surgeon
Texoma Plastic Surgery
Wichita Falls, TX, USA

David Gonzalez Sosa, MD
Plastic and Reconstructive Surgery
Hospital Quirónsalud Torrevieja
Alicante, Spain

James M. Stuzin, MD
Associate Professor of Surgery
(Plastic) Voluntary
University of Miami Leonard M. Miller School of Medicine
Miami, FL, USA

Daniel Suissa, MD, MSc
Clinical Instructor
Section of Plastic and Reconstructive Surgery
Yale University
New Haven, CT, USA

Charles H. Thorne, MD
Associate Professor of Plastic Surgery
Department of Plastic Surgery
NYU School of Medicine
New York, NY, USA

Ali Totonchi, MD
Assistant Professor
Plastic Surgery
Case Western Reserve University;
Medical Director Craniofacial Deformity Clinic
Plastic Surgery
MetroHealth Medical center
Cleveland, OH, USA

Jonathan W. Toy, MD, FRCSC
Program Director, Plastic Surgery Residency
Program Assistant Clinical Professor
University of Alberta
Edmonton, Alberta, Canada

Matthew J. Trovato, MD
Dallas Plastic Surgery Institute
Dallas, TX, USA

Simeon H. Wall Jr., MD, FACS
Director
The Wall Center for Plastic Surgery;
Assistant Clinical Professor
Plastic Surgery
LSU Health Sciences Center at Shreveport
Shreveport, LA, USA

Joshua T. Waltzman, MD, MBA
Private Practice
Waltzman Plastic and Reconstructive Surgery
Long Beach, CA, USA

Richard J. Warren, MD, FRCSC
Clinical Professor
Division of Plastic Surgery
University of British Columbia
Vancouver, British Columbia, Canada

Edmund Weisberg, MS, MBE
University of Pennsylvania
Philadelphia, PA, USA

Scott Woehrle, MS BS
Physician Assistant
Department of Plastic Surgery
Jospeh Capella Plastic Surgery
Ramsey, NJ, USA

Chin-Ho Wong, MBBS, MRCS, MMed(Surg), FAMS(Plast Surg)
W Aesthetic Plastic Surgery
Mt Elizabeth Novena Specialist Center
Singapore

Alan Yan, MD
Former Fellow
Adult Reconstructive and Aesthetic Craniomaxillofacial Surgery
Division of Plastic and Reconstructive Surgery
Massachusetts General Hospital
Boston, MA, USA

Michael J. Yaremchuk, MD
Chief of Craniofacial Surgery
Massachusetts General Hospital;
Clinical Professor of Surgery
Harvard Medical School;
Program Director
Harvard Plastic Surgery Residency Program
Boston, MA, USA

James E. Zins, MD
Chairman
Department of Plastic Surgery
Dermatology and Plastic Surgery Institute
Cleveland Clinic
Cleveland, OH, USA

VOLUME THREE

Neta Adler, MD
Senior Surgeon
Department of Plastic and Reconstructive Surgery
Hadassah University Hospital
Jerusalem, Israel

Ahmed M. Afifi, MD
Assistant Professor of Plastic Surgery
Department of Surgery
University of Wisconsin
Madison, WI, USA;
Associate Professor
Department of Plastic Surgery
Cairo University
Cairo, Egypt

Marta Alvarado, DDS, MS
Department of Orthodontics
Facultad de Odontología
Universidad de San Carlos de Guatemala
Guatemala

Eric Arnaud, MD
Pediatric Neurosurgeon and Co-Director
Unité de Chirurgie Craniofaciale
Hôpital Necker Enfants Malades
Paris, France

Stephen B. Baker, MD, DDS
Associate Professor and Program Director
Co-Director Inova Hospital for Children
Craniofacial Clinic
Department of Plastic Surgery
Georgetown University Hospital
Georgetown, WA, USA

Scott P. Bartlett, MD
Professor of Surgery
Surgery
University of Pennsylvania;
Chief Division of Plastic Surgery
Surgery
Children's Hospital of Philadelphia
Philadelphia, PA, USA

Bruce S. Bauer, MD
Chief
Division of Plastic Surgery
NorthShore University HealthSystem
Highland Park;
Clinical Professor of Surgery
Department of Surgery
University of Chicago Pritzker School of Medicine
Chicago, IL, USA

Adriane L. Baylis, PhD
Speech Scientist
Section of Plastic and Reconstructive Surgery
Nationwide Children's Hospital
Columbus, OH, USA

Mike Bentz, MD, FAAP, FACS
Interim Chairman
Department of Surgery
University of Wisconsin;
Chairman Division of Plastic Surgery
Department of Surgery
University of Wisconsin
Madison, WI, USA

Craig Birgfeld, MD, FACS
Associate Professor, Pediatric Plastic and Craniofacial Surgery
Seattle Children's Hospital
Seattle, WA, USA

William R. Boysen, MD
Resident Physician, Urology
University of Chicago Medicine
Chicago, IL, USA

James P. Bradley, MD
Professor and Chief
Section of Plastic and Reconstructive Surgery
Temple University
Philadelphia, PA, USA

Edward P. Buchanan, MD
Division of Plastic Surgery
Baylor College of Medicine
Houston, TX, USA

Michael R. Bykowski, MD, MS
Plastic Surgery Resident
Plastic Surgery
University of Pittsburgh Medical Center
Pittsburgh, PA, USA

Edward J. Caterson, MD, PhD
Director of Craniofacial Surgery
Division of Plastic Surgery
Brigham and Women's Hospital
Boston, MA, USA

Rodney K. Chan, MD
Chief Plastic and Reconstructive Surgery
Clinical Division and Burn Center
United States Army Institute of Surgical Research
Joint Base San Antonio, TX, USA

Edward I. Chang, MD
Assistant Professor
Department of Plastic Surgery
The University of Texas M. D. Anderson Cancer Center
Houston, TX, USA

Constance M. Chen, MD, MPH
Director of Microsurgery
Plastic and Reconstructive Surgery
New York Eye and Ear Infirmary of Mt Sinai;
Clinical Assistant Professor
Plastic and Reconstructive Surgery
Weil Medical College of Cornell University;
Clinical Assistant Professor
Plastic and Reconstructive Surgery
Tulane University School of Medicine
New York, NY, USA

Yu-Ray Chen, MD
Professor of Surgery
Plastic and Reconstructive Surgery
Chang Gung Memorial Hospital
Taoyuan City, Taiwan

Philip Kuo-Ting Chen, MD
Professor
Craniofacial Center
Chang Gung Memorial Hospital
Taoyuan City, Taiwan

Ming-Huei Cheng, MD, MBA
Professor
Division of Reconstructive Microsurgery
Department of Plastic and Reconstructive Surgery
Chang Gung Memorial Hospital
Taoyuan City, Taiwan

Gerson R. Chinchilla, DDS MS
Director
Department of Orthodontics
Facultad de Odontología
Universidad de San Carlos de Guatemala
Guatemala

Peter G. Cordeiro, MD
Chief
Plastic and Reconstructive Surgery
Memorial Sloan Kettering Cancer Center;
Professor of Surgery
Surgery
Weil Medical College of Cornell University
New York, NY, USA

Alberto Córdova-Aguilar, MD, MPH
Attending Plastic Surgeon
Surgery
Faculty of Medicine Ricardo Palma University
Lima, Peru

Edward H. Davidson, MA(Cantab), MBBS
Resident Plastic Surgeon
Department of Plastic Surgery
University of Pittsburgh
Pittsburgh, PA, USA

Sara R. Dickie, MD
Clinician Educator
Surgery
University of Chicago Hospital Pritzker School of Medicine;
Attending Surgeon
Section of Plastic and Reconstructive Surgery
NorthShore University HealthSystem
Northbrook, IL, USA

Risal S. Djohan, MD
Microsurgery Fellowship Program Director
Plastic Surgery
Cleveland Clinic;
Surgery ASC Quality Improvement Officer
Plastic Surgery
Cleveland Clinic
Cleveland, OH, USA

Amir H. Dorafshar, MBChB, FACS, FAAP
Associate Professor
Plastic and Reconstructive Surgery
Johns Hopkins Medical Institute;
Assistant Professor
Plastic Surgery
R Adams Cowley Shock Trauma Center
Baltimore, MD, USA

Jeffrey A. Fearon, MD
Director
The Craniofacial Center
Dallas, TX, USA

Alexander L. Figueroa, DMD
Craniofacial Orthodontist
Rush Craniofacial Center
Rush University Medical Center
Chicago, IL, USA

Alvaro A. Figueroa, DDS, MS
Co-Director
Rush Craniofacial Center
Rush University Medical Center
Chicago, IL, USA

David M. Fisher, MB, BCh, FRCSC, FACS
Medical Director Cleft Lip and Palate Program
Plastic Surgery
Hospital for Sick Children;
Associate Professor
Surgery
University of Toronto
Toronto, Ontario, Canada

Roberto L. Flores, MD
Associate Professor of Plastic Surgery
Director of Cleft Lip and Palate
Hansjörg Wyss Department of Plastic Surgery
NYU Langone Medical Center
New York, NY, USA

Andrew Foreman, B. Physio, BMBS(Hons), PhD, FRACS
Consultant Surgeon, Department of Otolaryngology - Head and Neck Surgery
University of Adelaide,
Royal Adelaide Hospital,
Adelaide, SA, Australia

Patrick A. Gerety, MD
Assistant Professor of Surgery
Division of Plastic and Reconstructive Surgery
Indiana University and Riley Hospital for Children
Philadelphia, PA, USA

Jesse A. Goldstein, MD
Chief Resident
Department of Plastic Surgery
Georgetown University Hospital
Washington, DC, USA

Arun K. Gosain, MD
Chief
Division of Plastic Surgery
Ann and Robert H. Lurie Children's Hospital of Chicago
Chicago, IL, USA

Lawrence J. Gottlieb, MD
Professor of Surgery
Department of Surgery
Section of Plastic and Reconstructive Surgery
University of Chicago
Chicago, IL, USA

Arin K. Greene, MD, MMSc
Department of Plastic and Oral Surgery
Boston Children's Hospital;
Associate Professor of Surgery
Harvard Medical School
Boston, MA, USA

Patrick J. Gullane, MD, FRCS
Wharton Chair in Head and Neck Surgery
Professor of Surgery, Department of Otolaryngology - Head and Neck Surgery
University of Toronto
Toronto, Ontario, Canada

Mohan S. Gundeti, MB, MCh, FEBU, FRCS(Urol), FEAPU
Associate Professor of Urology in Surgery and Pediatrics, Director Pediatric Urology, Director Centre for Pediatric Robotics and Minimal Invasive Surgery
University of Chicago and Pritzker Medical School Comer Children's Hospital
Chicago, IL, USA

Eyal Gur, MD
Professor of Surgery, Chief
Department of Plastic and Reconstructive Surgery
The Tel Aviv Sourasky Medical Center
Tel Aviv, Israel

Bahman Guyuron, MD, FCVS
Editor in Chief, Aesthetic Plastic Surgery Journal;
Emeritus Professor of Plastic Surgery
Case School of Medicine
Cleveland, OH, USA

Matthew M. Hanasono, MD
Associate Professor
Department of Plastic Surgery
The University of Texas MD Anderson Cancer Center
Houston, TX, USA

Toshinobu Harada, PhD
Professor in Engineering
Department of Systems Engineering
Faculty of Systems Engineering
Wakayama University
Wakayama, Japan

Jill A. Helms, DDS, PhD
Professor
Surgery
Stanford University
Stanford, CA, USA

David L. Hirsch, MD, DDS
Director of Oral Oncology and Reconstruction
Lenox Hill Hospital/Northwell Health
New York, NY, USA

Jung-Ju Huang, MD
Associate Professor
Division of Microsurgery
Plastic and Reconstructive Surgery
Chang Gung Memorial Hospital
Taoyuan, Taiwan

William Y. Hoffman, MD
Professor and Chief
Division of Plastic and Reconstructive Surgery
UCSF
San Francisco, CA, USA

Larry H. Hollier Jr., MD
Division of Plastic Surgery
Baylor College of Medicine
Houston, TX, USA

Richard A. Hopper, MD, MS
Chief
Division of Craniofacial Plastic Surgery
Seattle Children's Hospital;
Surgical Director
Craniofacial Center
Seattle Children's Hospital;
Associate Professor
Department of Surgery
University of Washington
Seattle, WA, USA

Gazi Hussain, MBBS, FRACS
Clinical Senior Lecturer
Macquarie University
Sydney, Australia

Oksana Jackson, MD
Assistant Professor
Plastic Surgery
Perelman School of Medicine at the University of Pennsylvania;
Assistant Professor
Plastic Surgery
The Children's Hospital of Philadelphia
Philadelphia, PA, USA

Syril James, MD
Clinic Marcel Sembat
Boulogne-Billancourt
Paris, France

Professor of Plastic Surgery, Neurosurgery, Neurology, and Surgery;
Executive Vice Chairman, Department of Plastic Surgery;
Chief of Plastic Surgery, University Hospitals
Ohio State University Wexner Medical Center
Columbus, OH, USA

Leila Jazayeri, MD
Microsurgery Fellow
Plastic and Reconstructive Surgery
Memorial Sloan Kettering Cancer Center
New York, NY, USA

Grant M. Kleiber, MD
Assistant Professor of Surgery
Division of Plastic and Reconstructive Surgery
Washington University School of Medicine
St. Louis, MO, USA

Stephen J. Kovach III, MD
Assistant Professor
Division of Plastic Surgery
University of Pennsylvania
Philadelphia, PA, USA

Robert Kwon, MD
Southwest Hand and Microsurgery
3108 Midway Road, Suite 103
Plano, TX, USA

Raphael C. Lee, MS, MD, ScD, FACS, FAIMBE
Paul and Allene Russell Professor
Plastic Surgery, Dermatology, Anatomy and Organismal Biology, Molecular Medicine
University of Chicago
Chicago, IL, USA

L. Scott Levin, MD, FACS
Chairman of Orthopedic Surgery
Department of Orthopaedic Surgery
University of Pennsylvania School of Medicine
Philadelphia, PA, USA

Otway Louie, MD
Associate Professor
Surgery
University of Washington Medical Center
Seattle, WA, USA

Nicolas Lumen, MD, PhD
Head of Clinic
Urology
Ghent University Hospital
Ghent, Belgium

Alessandro Masellis, MD
Plastic Surgeon
Euro-Mediterranean Council for Burns and Fire Disasters
Palermo, Italy

Michele Masellis, MD
Former Chief of Department of Plastic and Reconstructive Surgery and Burn Therapy
Department of Plastic and Reconstructive Surgery and Burn Therapy - ARNAS Ospedale Civico e Benfratelli
Palermo, Italy

Stephen M. Milner, MB BS, BDS
Professor of Plastic Surgery
Surgery
Johns Hopkins School of Medicine
Baltimore, MD, USA

Arash Momeni, MD
Fellow, Reconstructive Microsurgery
Division of Plastic Surgery
University of Pennsylvania Health System
Philadelphia, PA, USA

Stan Monstrey, MD, PhD
Department of Plastic and Reconstructive Surgery
Ghent University Hospital
Ghent, Belgium

Venkateshwaran N, MBBS, MS, DNB, MCh, MRCS(Intercollegiate)
Consultant Plastic Surgeon
Jupiter Hospital
Thane, India

Rajiv P. Parikh, MD, MPHS
Resident Physician
Department of Surgery, Division of Plastic and Reconstructive Surgery
Washington University School of Medicine
St. Louis, MO, USA

Mônica Sarto Piccolo, MD, MSc, PhD
Director
Pronto Socorro para Queimaduras
Goiânia, Goiás, Brazil

Nelson Sarto Piccolo, MD
Chief
Division of Plastic Surgery
Pronto Socorro para Queimaduras
Goiânia, Goiás, Brazil

Maria Thereza Sarto Piccolo, MD, PhD
Scientific Director
Pronto Socorro para Queimaduras
Goiânia, Goiás, Brazil

Vinita Puri, MS, MCh
Professor and Head
Department of Plastic, Reconstructive Surgery and Burns
Seth G S Medical College and KEM Hospital
Mumbai, Maharashtra, India

Andrea L. Pusic, MD, MHS, FACS
Associate Professor
Plastic and Reconstructive Surgery
Memorial Sloan Kettering Cancer Center
New York, NY, USA

Division of Plastic Surgery
Northwestern Feinberg School of Medicine
Chicago, IL, USA

Juan L. Rendon, MD, PhD
Clinical Instructor Housestaff
Department of Plastic Surgery
The Ohio State University Wexner Medical Center
Columbus, OH, USA

Michelle C. Roughton, MD
Assistant Professor
Division of Plastic and Reconstructive Surgery
University of North Carolina at Chapel Hill
Chapel Hill, NC, USA

Hakim K. Said, MD, FACS
Associate Professor
Division of Plastic surgery
University of Washington
Seattle, WA, USA

Michel Saint-Cyr, MD, FRSC(C)
Professor
Plastic Surgery
Mayo Clinic
Rochester, MN, USA

Michael Sauerbier, MD, PhD
Professor, Chair
Department for Plastic, Hand, and Reconstructive Surgery
Academic Hospital Goethe University Frankfurt am Main
Frankfurt am Main, Germany

Loren S. Schechter, MD
Associate Professor and Chief
Division of Plastic Surgery
Chicago Medical School
Morton Grove, IL, USA

David H. Song, MD, MBA, FACS
Regional Chief, MedStar Health
Plastic and Reconstructive Surgery
Professor and Chairman
Department of Plastic Surgery
Georgetown University School of Medicine
Washington, DC, USA

Yoo Joon Sur, MD, PhD
Associate Professor
Department of Orthopedic Surgery
The Catholic University of Korea, College of Medicine
Seoul, Korea

Chad M. Teven, MD
Resident
Section of Plastic and Reconstructive Surgery
University of Chicago
Chicago, IL, USA

VOLUME FIVE

Jamil Ahmad, MD, FRCSC
Director of Research and Education
The Plastic Surgery Clinic
Mississauga, Ontario, Canada;
Assistant Professor of Surgery
University of Toronto
Toronto, Ontario, Canada

Robert J. Allen Sr., MD
Clinical Professor of Plastic Surgery
Department of Plastic Surgery
New York University Medical Center
Charleston, NC, USA

Ryan E. Austin, MD, FRCSC
Plastic Surgeon
The Plastic Surgery Clinic
Mississauga, ON, Canada

Brett Beber, BA, MD, FRCSC
Plastic and Reconstructive Surgeon
Lecturer, Department of Surgery
University of Toronto
Toronto, Ontario, Canada

Philip N. Blondeel, MD
Professor of Plastic Surgery
Department of Plastic Surgery
University Hospital Ghent
Ghent, Belgium

Benjamin J. Brown, MD
Gulf Coast Plastic Surgery
Pensacola, FL, USA

Mitchell H. Brown, MD, MEd, FRCSC
Plastic and Reconstructive Surgeon
Associate Professor, Department of Surgery
University of Toronto
Toronto, Ontario, Canada

M. Bradley Calobrace, MD, FACS
Plastic Surgeon
Calobrace and Mizuguchi Plastic Surgery Center
Departments of Surgery, Divisions of Plastic Surgery
Clinical Faculty, University of Louisville and University of Kentucky
Louisville, KY, USA

Grant W. Carlson, MD
Wadley R. Glenn Professor of Surgery
Emory University
Atlanta, GA, USA

Bernard W. Chang, MD
Chief of Plastic and Reconstructive Surgery
Mercy Medical Center
Baltimore, MD, USA

Mark W. Clemens II, MD, FACS
Assistant Professor Plastic Surgery
M. D. Anderson Cancer Center
Houston, TX, USA

Robert Cohen MD, FACS
Medical Director
Plastic Surgery
Scottsdale Center for Plastic Surgery
Paradise Valley, AZ and;
Santa Monica, CA, USA

Amy S. Colwell, MD
Associate Professor
Harvard Medical School
Massachusetts General Hospital
Boston, MA, USA

Edward H. Davidson, MA(Cantab), MB, BS
Resident Plastic Surgeon
Department of Plastic Surgery
University of Pittsburgh Medical Center
Pittsburgh, PA, USA

Emmanuel Delay, MD, PhD
Unité de Chirurgie Plastique et Reconstructrice
Centre Léon Bérard
Lyon, France

Francesco M. Egro, MB ChB, MSc, MRCS
Department of Plastic Surgery
University of Pittsburgh Medical Center
Pittsburgh, PA, USA

Neil A. Fine, MD
President
Northwestern Specialists in Plastic Surgery;
Associate Professor (Clinical) Surgery/Plastics
Northwestern University Fienberg School of Medicine
Chicago, IL, USA

Jaime Flores, MD

Acknowledgments

My wife, Gabrielle Kane, has always been my rock. She not only encourages me in my work but gives constructive criticism bolstered by her medical expertise as well as by her knowledge and training in education. I can never repay her. The editorial team at Elsevier have made this series possible. Belinda Kuhn leads the group of Alexandra Mortimer, Louise Cook, and the newest addition to the team, Sam Crowe. The Elsevier production team has also been vital in moving this project along. The volume editors, Geoff Gurtner, Peter Rubin, Ed Rodriguez, Joe Losee, David Song, Mo Nahabedian, Jim Chang, and Dan Liu have shaped and refined this edition, making vital changes to keep the series relevant and up-to-date. My colleagues in the University of Washington, headed by Nick Vedder, have provided continued encouragement and support. Finally, and most importantly, the residents and fellows who pass through our program keep us on our toes and ensure that we give them the best possible solutions to their questions.

Peter C. Neligan, MB, FRCS(I), FRCSC, FACS

This completely updated volume represents this generation's brightest minds in hand and microvascular surgery. I am indebted to my colleagues and friends from around the globe for their hard work and eloquent writing, and to our talented staff at Elsevier. It is our hope that this text will continue to serve as a guide for the optimal treatment of all our patients. I am fortunate to have two families to thank: the students, residents, fellows, and faculty at Stanford University who stimulate and enrich me intellectually; and my own loved ones, my wife Dr. Harriet Walker Roeder, and girls Julia, Kathleen, and Cecilia, who sustain me in every way.

James Chang, MD

Dedicated to future plastic surgeons. Take up the torch and lead us forward!

Introduction

Plastic surgery contributions to hand surgery

James Chang

Although references to surgery of the hand date back to Hippocrates in ancient Greece, the dedicated specialty of hand surgery is relatively young. The Second World War is thought to be the major driving event for the development of hand surgery as a separate surgical discipline. This modern specialty was founded by a combination of general surgeons, plastic surgeons, orthopedic surgeons, vascular surgeons, and neurosurgeons. Hand surgery has remained unique in that it is a regional specialty instead of a tissue specialty – its practitioners are ideally trained in managing problems affecting all component tissues of the hand. This introduction chronicles the role plastic surgery has played in the development of hand surgery as a surgical specialty. Furthermore, it predicts how plastic surgery will influence the future direction of hand surgery.

Origins of hand surgery

Henry C. Marble, in Flynn's classic textbook, *Hand Surgery*, found the earliest references to surgery of the hand by Hippocrates (460–377 BC) in ancient Greece.[1] In his writings, Hippocrates described methods to reduce wrist fractures and also highlighted the importance of well-fitting, clean dressings to the hand. A later Greek physician, Heliodorus, described his technique for amputation of a finger with specific reference to dissecting adequate skin flaps with which to cover the remaining bone. While Galen (131–201 AD) confused tendons with nerves and cautioned against suturing tendons for fear of "nervous spasms",[2] Avicenna (981–1038 AD),[3] an Arabian physician, wrote detailed descriptions of tendon repair in medieval times. Other references to hand surgery have been found in history, but comprehensive care of the hand was not truly developed until the 20th century.

An understanding of human anatomy has been critical to both plastic surgery and hand surgery, and therefore, the history of anatomy has paralleled the development of these two surgical disciplines. J. William Littler reviewed the influence of famed anatomists on hand surgery.[4] Perhaps these anatomists were drawn to the hand as the most intricate of body parts – the ultimate challenge to their craft. In the Renaissance period, Leonardo da Vinci (1452–1519) used his artistic genius to create extraordinarily accurate representations of the hand. His knowledge of anatomy was acquired from over 100 human dissections and ultimately resulted in a collection of 779 anatomical drawings.[5]

Andreas Vesalius (1514–1564) (Figs. 0.1 & 0.2) published his monumental work *De Corporis Humani Fabrica* in 1543 with many engravings dedicated to the hand.[5] Like da Vinci, Vesalius relied on his own dissections of cadavers rather than accepting the dogma found in previous medical texts. His observations refuted the inaccuracies found in the earlier writings of Galen and his disciples. Modern-day hand surgeons J. William Littler and Robert A. Chase have both credited Sir Charles Bell (1774–1842) as the foremost anatomist of the hand.[6] His *Fourth Bridgewater Treatise – The Hand: Its Mechanism and Vital Endowments as Evincing Design* (1834) remains a classic essay on the anatomic and functional aspects of the hand.[7]

In addition to anatomy, two more recent achievements allowed hand surgery to develop into a unique specialty in the modern era. On October 16, 1846 at the Massachusetts General Hospital, Dr. William Morton delivered sulfuric ether fumes to a patient undergoing excision of a neck mass by Dr. John Collins Warren.[8] For the first time, adequate anesthesia was performed, thus allowing the possibility of more complex reconstructive procedures in both plastic surgery and hand surgery.

The second major achievement was an understanding of microbiology with resulting advances in sterile technique and antibiotics.[9] In the 1860s, Louis Pasteur's work with fermentation introduced the field of bacteriology. Semmelweis, in Vienna, and Lister, in Britain, developed antiseptic surgery with the early use of carbolic acid as a disinfectant. In the 20th century, several Nobel Prizes marked the importance of the development of antibiotics. Paul Ehrlich a German

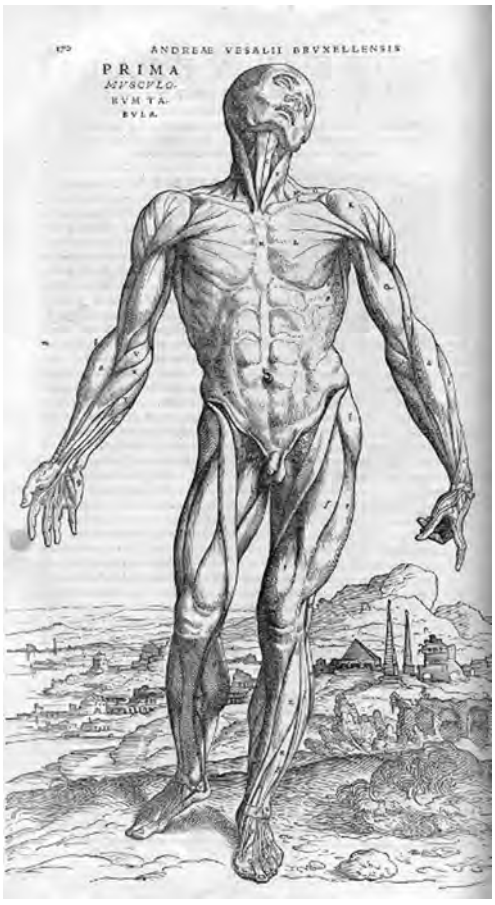

Fig. 0.2 An example of the anatomic illustrations of Stephan van Calcar in the monumental text of Vesalius, *De Humani Corporis Fabrica* (1543). *(Reproduced from Vesalius A.* De Humani Corporis Fabrica*. 1543. Reproduced with permission from the British Library.)*

bacteriologist, developed the principle of "antimicrobial chemotherapy" and received the Nobel Prize in 1908. Another German, Gerhard Domagk, received the Nobel Prize in 1939 for discovering the antibacterial effects of sulfa drugs. Finally, Alexander Fleming shared the Nobel Prize in 1945 for discovering the ability of a mold, *Penicillium notatum* to halt the growth of staphylococcus bacteria. With penicillin and later antibiotics, plastic surgeons and hand surgeons had an armamentarium of agents to control infections.

Over the course of this history, how has plastic surgery contributed to the development and progress of hand surgery? Like hand surgery, plastic surgery became a separate surgical specialty in the US only in the 20th century with the founding of the American Association of Oral and Plastic Surgeons (later shortened to the American Association of Plastic Surgeons) in 1921. The American Board of Plastic Surgery was not established until 1938. However, plastic surgery has profoundly influenced hand surgery, and this influence has predated formal associations and boards. In other words, surgeons throughout history have used plastic surgery principles before they were known as "plastic surgeons". Therefore, early plastic surgery contributions to hand surgery are best chronicled by reviewing the development of plastic surgery principles and how they have been applied to hand surgery.

Principles of plastic surgery and their application to hand surgery

Sushruta, a Hindu surgeon in India around the first century AD, performed reconstruction of the nose using pedicled flaps from the face – either forehead or cheek. He described the operation as follows:

> *The physician should take the leaf of a tree the same size as the nose and apply it to the cheek in such a way that a stem is still adherent. Then he stitches the cheek with needle and thread, scarifies the stump of the nose and quickly but carefully places the flap in the nose. After the transplanted piece has grown, the stem is cut off. In like manner the flap might be turned up from the upper or lower arm and attached to the nose – with the arm over the head.*[1]

This description included the basic plastic surgery principles of precise patterning of the defect, preparation of the recipient bed, and the use of local and distant flaps, all which have had obvious applicability to soft-tissue reconstruction of the hand.

Another famed surgeon, Ambrose Paré (1510–1590), offered principles that allowed for optimal care of battlefield wounds, including the upper extremity: "to enlarge the wound for drainage; to remove bone splinters and foreign bodies from wounds; to control hemorrhage with ligatures; not to encourage suppuration; and to amputate through sound tissues."[1] Paré's use of ligatures during amputation controlled hemorrhage and saved countless lives on the battlefield (Figs. 0.3 & 0.4). His principles of wound care would later be applied directly to the enormous number of battlefield casualties of World War II. In addition, Paré popularized the anatomic drawings of Vesalius amongst surgeons, and even designed elaborate prostheses for upper extremity amputees, victims of the French wars of the 1500s. Paré was perhaps the quintessential upper extremity trauma surgeon.

Fig. 0.3 Ambrose Paré applying a ligature during battlefield amputation. Wood engraving by C. Maurand. *(Reproduced with permission from The Wellcome Trust L0018530.)*

Gaspare Tagliacozzi (1545–1599) did not invent the Italian method of nasal reconstruction, which has been generally attributed to Branca. However, Tagliacozzi, a professor of medicine and anatomy in Bologna, did popularize this technique of attaching a medial upper arm skin flap to the nasal defect. In addition, specialized leather band contraptions were devised to immobilize the patient during the period of flap revascularization (Fig. 0.5). His detailed textbook, *De Chirurgia Curtorum per Insitionem*, was published in 1597 and allowed later generations of surgeons to learn techniques for the transfer of distant pedicled flaps.[5]

As plastic surgeons became more adept at tissue transfer, these innovations were applied to reconstruction of the hand. Carl Nicoladoni (1849–1903) pioneered work on reconstruction of the thumb. Nicoladoni reported on a case of total skin avulsion of the thumb that he treated by a skin flap from the patient's left pectoral region – similar to the thoracoepigastric or random pattern chest flaps still used today.[6] In 1903, his

paper, "Further experience with thumb reconstruction", described the pedicled toe transfer to the thumb that continues to bear his name. Microsurgeons today have obviated the need for the uncomfortable positioning of this transfer; nevertheless, Nicoladoni deserves credit for the ingenuity behind the toe-to-hand transfer. Plastic surgeon George H. Monks (1853–1933) transferred a composite skin island flap from the forehead on the superficial temporal arteriovenous pedicle to a lower-eyelid defect.[6] The use of island flaps would later be applied to the hand with the neurovascular island flaps of Littler, and, more recently, with the dorsal metacarpal artery flaps. Even Sir Harold Gillies (1882–1960) who, with Millard, codified the principles of plastic surgery and was one of history's most influential plastic surgeons, turned from the head and neck to the hand and devised a method to lengthen the stump of a thumb, the Gillies "cocked-hat" flap.[10]

Vilray P. Blair (1871–1955) was one of the founding fathers of American plastic surgery.[11] In addition to a large body of work in cleft lip repair and maxillofacial surgery, Blair made two significant contributions to plastic surgery that translated directly to hand surgery. Blair helped redefine the delay phenomenon of Tagliacozzi in a 1921 article, "The delayed transfer of long pedicled flaps in plastic surgery". Blair and his disciple, James Barrett Brown (1899–1971), described a new technique of harvesting skin for skin grafting in a paper published in *Surgery, Gynecology, and Obstetrics* entitled "The use and uses of large split skin grafts of intermediate thickness".[12] This simple and reproducible method of harvesting split-thickness skin improved on the previous techniques of Thiersch and would have a tremendous impact on the reconstruction of hand burns and other wounds in World War II.

Origins of modern hand surgery

With this historical background in wound management, flap transfer, and skin grafting, plastic surgeons were poised to contribute to the founding of modern hand surgery. World War II was the crucible in which hand surgery became a separate specialty. Prior to the outbreak of this war, two surgeons were instrumental in hand surgery's early development. In 1939, Allen B. Kanavel published his *Infections of the Hand*,[13] and for the first time, a comprehensive approach to the myriad of hand infections and treatments was described. Even at that early time, Kanavel stressed the importance of hospitalization for hand infections, intravenous hydration, and placing the hand at rest.

Sterling Bunnell (1882–1957) has been widely regarded as the father of hand surgery. The first edition of Bunnell's comprehensive textbook, *Surgery of the Hand*,[14] was published in 1944, and remained the classic reference for many years. He was a general surgeon but believed in the importance of plastic surgery principles, and as the consummate hand surgeon, was able to apply plastic, orthopedic, and vascular principles equally to hand surgery. Marble recounted Bunnell's mastery:

He insisted on all of the teachings of the past masters, stressing particularly the gentle handling of the tissues. He called this atraumatic surgery. He exercised his skill also in plastic, bone, tendon, nerve, blood vessel, and muscle surgery to reconstruct crippled hands. He showed that tendons could be grafted to substitute for lost ones, and could be transferred to give function to useless digits or joints. He taught that nerves could be grafted and that whole fingers could be moved about for better function. Thus he opened the door for the complete reconstruction of the injured hand.[1]

The specialty of hand surgery in the US really developed in the field hospitals and regional medical referral centers established during the Second World War. During those years, massive numbers of surviving casualties with upper extremity injuries, an organized resuscitation and transportation service, and increasing sophistication within the fields of general surgery, plastic surgery, orthopedic surgery, vascular surgery, and neurosurgery together formed the critical mass necessary for accelerated technical and educational development.

The high volume of hand injuries requiring care in World War II was unprecedented. Unlike the trench warfare of World War I when head and neck wounds were common, World War II involved open warfare with rapid movements and grenades, leading to a greater likelihood of upper extremity injuries. In the early years of the war, soldiers with injured hands and upper extremities were placed into individual hospitals and distributed somewhat arbitrarily on to orthopedic, general surgery, plastic surgery, and neurosurgery wards depending on the nature of the injury and the availability of beds. It became evident that specialized interdisciplinary care of the hand patient was necessary. In a masterpiece of organizational effort, regional hand referral centers were established in US military hospitals. Colonel J.J. Reddy and Colonel F.V. Kilgore together established the first ward designated for hand surgery at Cushing General Hospital in Framingham, Massachusetts.[15] Plastic surgeon Captain (later Major) J. William Littler was assigned to this ward and supervised the first service specifically dedicated to care of the injured hand. Joint conferences involving plastic surgery, orthopedic surgery, and neurosurgery were established and, within a short time, four complete wards dedicated to hand surgery were in operation.

Dr. Littler's unit was used as a model by Surgeon General Norman T. Kirk to establish nine military referral centers throughout the US.[15] Sterling Bunnell served as civilian surgical consultant to the Secretary of War and visited each referral center to teach hand surgery.

Simultaneously, advances in plastic surgery had provided effective and reliable methods of wound coverage ranging from split- and full-thickness skin grafts to local and distant pedicled flaps. This ability to cover wounds was critical to the development of hand surgery. Because wound coverage was a priority, the regional hand centers established across the US were situated in hospitals that had been already designated as plastic surgery centers.

Plastic surgeons were instrumental in this early phase of development in American hand surgery because of their expertise in wound care and trauma reconstruction. In March 1945, Lieutenant Colonel Eugene M. Bricker outlined in an Army memorandum the principles of plastic surgery relevant to hand surgery:

1. Conservative, careful and thorough debridement of the primary wound is essential. Primary closure is not advised in an evacuation hospital, but skin flaps can be dressed back into place.
2. Splint purposefully, maintaining the palmar arch and flexion of the metacarpophalangeal joints.
3. Bring about delayed closure as early as possible, preferably on the third or fourth day, by simple closure, split graft or pedicle graft, according to the necessities of the case.
4. Use traction only when it is urgently indicated, and then for a minimum length of time.
5. Concentrate on maintenance of such function as remains following certain severe types of injury. Restoration of the injured part should not be attempted, and healing should be accomplished as rapidly as possible. Amputation of an irreparably damaged finger is justified.
6. Institute active motion as early as possible, and supplement by occupational therapy when healing has occurred.
7. Try to prevent edema and infection in open wounds. Proper debridement, proper dressings, proper splinting, and effective elevation of the hand will prevent this development.
8. Manage an open wound aseptically as long as it remains open. Aseptic management implies the use of masks and of instruments or gloves, whether or not the wound is infected.[16] These principles served as the foundation for acute treatment of traumatic hand injuries.

Developments after World War II

Immediately after World War II, plastic surgeons continued to have a profound influence on hand surgery. In 1946, plastic

surgeon Darrel T. Shaw and general surgeon Robert Lee Payne published a landmark paper entitled, "One stage tubed abdominal flaps".[17] This paper described an axial flap based on the superficial inferior epigastric vessels for composite tissue transfer to the hand. The development of reliable composite tissue transfer allowed early coverage of extensive hand and upper extremity defects. Sir Archibald McIndoe, a disciple of Gillies, established several burn facilities in England and refined techniques in burn excision and reconstruction of the hand.[18]

The patients wounded during the battles of World War II returned to the US for further reconstructive surgery by an increasingly better-trained cadre of hand surgeons. In order to coordinate this explosive growth in hand surgery, representatives from general surgery, plastic surgery, and orthopedic surgery combined to form the American Society for Surgery of the Hand in 1946.[19] The first annual meeting was held on January 20, 1946 at the Blackstone Hotel in Chicago, Illinois, with Sterling Bunnell as the first president. Plastic surgeons figured prominently – of the 35 founding members, 13 (37%) came from plastic surgery backgrounds.[20]

Hand surgery underwent another period of accelerated productivity during the Korean War. By that time, the US military had experience in organizing regional referral centers for reconstruction of the hand. Dr. J William Littler took on Bunnell's former role and was appointed as Hand Surgery Civilian Consultant to the Military.[6] Littler's unrivaled experience from World War II and then the Korean conflict allowed him to become perhaps the most famous of plastic hand surgeons. His achievements have included the Littler digital neurovascular transfer and countless other surgical innovations bearing his name, in addition to his legendary anatomic sketches of the hand and long list of trainees who have become distinguished hand surgeons themselves. Other plastic surgeons who were involved in the Korean War effort included Robert A. Chase and Earle Peacock. Robert A. Chase returned from his military duty to embark on a lifelong effort of developing educational aids related to functional anatomy of the hand. Earle Peacock contributed original laboratory work on wound healing, particularly related to flexor tendon wound healing.

The era of microsurgery

Hand surgery underwent an intense period of laboratory and clinical activity in the 1960s and 1970s devoted to microsurgery and free tissue transfer. In 1963, Goldwyn *et al.* presented their work on abdominal free flaps in dogs, based on the inferior epigastric vessels.[21] This investigative work was further developed by Krizek *et al.* in 1965.[22] Together, these plastic surgeons, along with O'Brien,[23] Taylor *et al.*[24] and many others throughout the world, established the possibility of free tissue transfer that liberated the hand surgeon from the anatomic limitations of local tissue transfer.

Replantation of fingers and other body parts came into reality via an international effort of plastic surgeons, orthopedic surgeons, and general surgeons. The first successful replantation of an upper arm amputation by Malt and McKhann was carried out in 1962, and the first successful replantation of an amputated thumb was performed in 1968 by Komatsu and Tamai. Since then, replantation teams have been organized in major hospitals, and microsurgical techniques have become an integral part of the training of hand surgeons. The techniques of replantation in the upper extremity have been extrapolated to successful replantation of other parts of the body, including the lower limb, the scalp, the ear, portions of the lip and nose, and the penis, and have led directly to the further evolution of elective microsurgical free tissue transfer. In addition, plastic surgeons have devised innovations to improve the success rates of replantation, including the use of Y-shaped interposition vein grafts in multiple-digit replantations[25] and replantation of fingers distal to the proximal interphalangeal joint.[26]

Plastic surgeon Harry J. Buncke helped pioneer the toe-to-thumb transplant in animal models, and eventually in humans. His efforts in the past 40 years have made him one of the fathers of American microsurgery.[27] Beyond the earlier work of Littler on thumb reconstruction, plastic surgeons have continued to contribute greatly to the refinement of various operations, including the toe-to-hand transfer[28,29] and the great-toe wraparound free flap of Morrison *et al.*[30]

Critical to reconstruction of the hand with both pedicled flaps and free flaps has been a detailed knowledge of anatomy as it relates to vascular distributions to muscle and skin. McCraw *et al.* popularized the use of musculocutaneous flaps[31] and Mathes and Nahai developed an atlas of these muscle and musculocutaneous flaps, which has been an invaluable reference for the reconstructive surgeon.[32] Ian Taylor and his plastic surgery colleagues have described the vascular territories of skin flaps. Taylor's angiosome theory, where the body is divided into different vascular territories to the skin, originating from deeper source arteries, has allowed surgeons to design flaps with reliable perfusion. In addition, second-generation flaps, based on smaller vessels, may be possible with an understanding of this intricate anatomy.

Plastic surgeons have also continued to be involved in the political and educational development of hand surgery. In 1970, a second hand organization – the American Association for Hand Surgery (AAHS) – was founded.[33] By the fall of 1971, there were 65 full members. As in the American Society for Surgery of the Hand, plastic surgeons played an instrumental role. The first meeting in 1971 immediately preceded the annual American Society of Plastic and Reconstructive Surgeons meeting. This arrangement symbolized the influence and participation of plastic surgeons in the AAHS that continues today.

Recent developments

In recent years, significant contributions to hand surgery have been made by plastic surgeons. One area of intense study in the past several decades has been peripheral nerve repair and reconstruction. Millesi *et al.*[34] published a landmark paper in 1972 on interfascicular nerve grafting of median and ulnar nerves. Since then, nerve grafting, as well as autogenous vein grafting of nerve defects, has helped improve results of nerve reconstruction.[35,36] Mackinnon and Hudson[37] have examined the possibility of immunosuppression for allograft nerve transplantation to bridge extensive defects where autogenous donor nerve may not be sufficient, and more recently pioneered the field of nerve transfers.[38] Several plastic

surgeons, including Terzis *et al.*[39] and Hentz and Narakas,[40] have published reports of their considerable experience on reconstruction of brachial palsy injury. Their dedication to the comprehensive reconstruction and rehabilitation of these devastating injuries has resulted in improved surgical outcomes.

Beyond replantation, more intricate microvascular operations have been undertaken by plastic hand surgeons to restore form and function to the hand. Although the indications are limited, microvascular transfer of a toe metatarsophalangeal joint to recreate a metacarpophalangeal joint has been shown to be possible.[41] Further advances in microsurgical reconstruction of the hand include functional free muscle transfer. Manktelow and McKee's landmark paper in 1978 introduced the concept of a free gracilis or free pectoralis major muscle transfer with motor nerve coaptation to restore active finger flexion.[42]

Plastic surgeons have also been at the forefront of congenital hand surgery.[43] Graham Lister published one of the first significant series of toe-to-hand microvascular transfers in children, ushering in a new era of complex reconstruction for congenital hand problems.[44] Other authors, including Gilbert[45] and Buck-Gramcko,[46] have also published their series. More recently, Neil Jones has added his work on pediatric toe-to-hand transfers to previous contributors, thus refining these technically challenging procedures.[47] In addition, Joseph Upton *et al.*[48] reported on their unrivalled experience with excision and reconstruction of vascular anomalies in the upper extremity.

The plastic surgery techniques of flap dissection have been used to develop newer flaps intrinsic to the hand and upper extremity such as vascularized bone flaps from the distal radius. There is much excitement in using these pedicled bone flaps for revascularization of the scaphoid in scaphoid nonunion and avascular necrosis, or revascularization of the lunate in Kienbock's disease.[49] These second-generation flaps may lead to other intrinsic flaps that will also be useful for bone and ligament reconstruction.

Plastic surgeons know of their legacy of involvement in the field of organ transplantation. Much of the pioneering work on allograft rejection and homograft tolerance by Sir Peter Medawar and others was derived from experimentation with skin grafts in various animal models.[9] Joe Murray, the only plastic surgeon ever to receive the Nobel Prize, received it for his work on transplantation, including the first human kidney transplantation in 1954.[9] With newer immunosuppressive agents and greater acceptance of the risks of transplantation, human hand allograft transplantation has now become a reality.[50] While the ultimate success of these early operations remains to be seen, reaching these new frontiers in hand reconstruction as well as in other forms of composite tissue allotransplantation is now possible.

Future directions

An accomplished hand and plastic surgeon once wrote:

> *I learned about hand surgery's battle against scar adherence and contraction and that the Z-plasty can be a major and intriguing weapon in that battle in other parts of the body as well as in the hand. I thought a lot about the Z-plasties that year and used them often, in multiple parts of the body, always trying to pick the optimum size and the best orientation, trying to decide which of the two parallel sides of the Z-plasty's diamond would be most advantageous for mimicking the wrinkle lines, and trying to avoid running into features not to be moved or, occasionally, to something on or in one of the flaps … Ever since, I have looked upon the Z-plasty as a little bit of magic.*[51]

That surgeon was Leonard T Furlow Jr, who took the Z-plasty from the scarred hand to the cleft palate. It is an excellent example of the intellectual interplay between plastic surgery and hand surgery.

Current plastic surgery research has focused on growth factor technology to inhibit scarring or to augment bone growth, wound healing,[52] and angiogenesis. Tissue engineering may allow formation of ample supplies of bone, cartilage,[53] even muscle, skin, and nerve. Virtual reality surgery will help plastic surgeons model and practice complex reconstructive procedures prior to undertaking them. In the next decade, hand surgeons will acquire an armamentarium that includes bone substitutes, tissue-engineered bone, cartilage and nerve, and three-dimensional computer models for complex intracarpal abnormalities. Throughout the chapters of this hand volume, you will find new, pioneering translational work that shapes the future of hand and upper extremity surgery. As in microsurgery, plastic surgeons will lead the way for this new technical revolution in hand surgery.

Anatomy and biomechanics of the hand

James Chang, Anais Legrand, Francisco Valero-Cuevas, Vincent R. Hentz, and Robert A. Chase

Access video content for this chapter online at expertconsult.com

SYNOPSIS

- The hand is an incredibly designed structure with complex anatomy and precise biomechanics. The hand must be able to produce adequate force to allow performance of activities of daily living. Furthermore, it must ensure coordination of the fingers for precise prehension and fine motor tasks.
- In order to achieve an optimal functional and aesthetic outcome in patients requiring hand surgery, it is thus essential to fully understand the detailed bone, muscle–tendon, aponeurotic, vascular, nerve and lymphatic components.
- Additional challenges arise from the range of possible movements of various articular surfaces, assisted by muscle action and ligamentous support.
- In this chapter, we present the various elements that compose the hand as well as explanations of the biomechanical principles. These are updated according to the latest literature. Additionally, clinical examples will be used to illustrate anatomic principles.

Introduction

During the Renaissance, Vesalius corrected early misconceptions and brought gross anatomy into proper focus. Since that time, many investigators have embellished the basic structural studies with functional, physiologic, and philosophical observations. The forearm and hand have been prominently included in those observations. Sir Charles Bell (1834),[1] in his thought-provoking volume, *The Hand – Its Mechanism and Vital Endowments as Evincing Design*, presented a concept of hand anatomy that places it in proper context with the position of humans in the animal kingdom. Duchenne (1867) carried out detailed analysis of muscular function by isolated electrical stimulation, described in his classic volume, *Physiologie des Mouvements*.[2] Frederick Wood-Jones (1920) probed more extensively into comparative anatomy and anthropology in his excellent work, *The Principles of Anatomy as Seen in the Hand*.[3] Allen B. Kanavel (1925) published his monograph, *Infections of the Hand*, which reported detailed analysis of the spaces and synovial sheaths.[4] *Surgery of the Hand* by Sterling Bunnell (1944) became an indispensable reference during World War II.[5] Emanuel B. Kaplan (1953) produced the nicely illustrated, detailed volume, *Functional and Surgical Anatomy of the Hand*.[6] Detailed studies of the integration of the intrinsic and extrinsic muscles operating the polyarticular digits may be found in the work of Landsmeer,[7–10] Kaplan,[11] Eyler and Markee,[12] Stack,[13] Tubiana and Valentin,[14] and others. More recently, newer flaps intrinsic to the hand and upper extremity have been developed from more detailed investigation into vascular anatomy.[15,16] Lastly, Berger,[17] Viegas *et al.*,[18] and others have expanded our knowledge of the ligamentous anatomy of the wrist.

As a functional puppet, the hand responds to human desires; its motor performance is initiated by the contralateral cerebral cortex. The conscious demands relayed to the hand and forearm from the central nervous controlling mechanism are sent as movement commands. At subconscious levels, such a movement command is broken down, regrouped, coordinated, and sent on as a signal for fixation, graded contraction, or relaxation of a specific muscular unit. The degree of contraction or relaxation is then modified by relayed evidence that the motion created is that desired by the person. The modifying factors arrive centrally from a multiplicity of sensory sources such as the eye, peripheral sensory end organs, and muscle or joint sensory endings.

The surgeon planning reconstructive surgery on the upper extremity must be aware not only of the complex anatomy of the hand and arm, but also of the physiologic interplay of balanced muscular functions under the influence of complex central nervous coordination. The maintenance of physiologic viability by the central and peripheral circulatory and lymphatic systems must also concern the reconstructive surgeon.

This chapter addresses the fundamentals of hand and upper extremity anatomy and highlights clinical pearls, new anatomic descriptions that may aid surgery of the hand, and

the fundamentals of biomechanics relevant to the hand surgeon. New pictures and dissection videos are now available for the reader to review important anatomic concepts.

Skin, subcutaneous tissue, and fascia

There is great disparity in the character of the skin and soft-tissue envelope covering the dorsum of the hand and that covering the palm. Dorsal skin is thin and pliable, anchored to the deep investing fascia by loose, areolar tissue. These characteristics, coupled with the fact that the major venous and lymphatic drainage in the hand courses dorsally, serve to explain why hand edema is first evident dorsally. The prominent, visible veins in the subcutaneous tissue make it the standard site in which to evaluate venous filling and limb venous pressure on physical examination. The same characteristics make the dorsum of the hand vulnerable to skin avulsion injuries.

Palmar skin, in contrast, is characterized by a thick dermal layer and a heavily cornified epithelial surface. The skin is not as pliable as dorsal skin, and it is held tightly to the thick fibrous palmar fascia by diffusely distributed vertical fibers between the fascia and dermis. Stability of palmar skin is critical to hand function. At the same time, if scar fixation or loss of elasticity occurs in palmar skin, contractures and functional loss result. The skin of the palm is laden with a high concentration of specialized sensory end organs and sweat glands. The surgeon must understand the relationship of the palmar skin creases and the underlying joints in order to plan precise placement of skin incisions for exposure of joints and their related structures (Box 1.1 & Fig. 1.1).

Examination of hand skin during normal ranges of motion in various planes is important in planning incisions or geometrically rearranging lacerations that might result in disabling scar contractures. Most loss of elasticity and some longitudinal shortening are compensated for adequately by mobility and elasticity of the uninjured dorsal skin. On the palmar aspect, however, scar shortening and inelasticity of the skin may result in contracture. The nature of palmar skin, its stabilizing fixation to the palmar fascia, and its position on the concave side of the hand are the bases for such contractures. Littler outlined the specific sites in the palm where a longitudinal scar would impede extension.[20] For example, in each digit the geometry has been worked out by noting each joint axis and the kissing surfaces of the palmar skin in full flexion. These diamond-shaped skin surfaces should not be shortened and rendered inelastic by longitudinal scars if limitation of extension is to be avoided (Fig. 1.2).

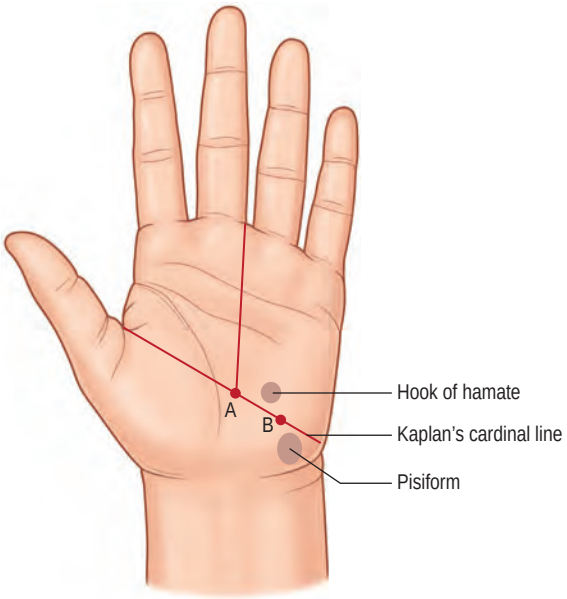

Fig. 1.1 Kaplan's cardinal line, along with lines from the ulnar aspect of the middle finger and the ulnar aspect of the ring finger. Point A corresponds with the motor branch of the median nerve and point B with the motor branch of the ulnar nerve.

The palmar fascia consists of resistant fibrous tissue arranged in longitudinal, transverse, oblique, and vertical fibers (Fig. 1.3). The longitudinal fibers concentrate at the proximal origin of the palmar fascia at the wrist, taking origin from the palmaris longus when it is present (in about 80–85% of individuals). The fascia at this level is separable from the underlying flexor retinaculum/carpal ligament, being identified by the longitudinal orientation of its fibers in contrast to the transverse fibers of the retinaculum. The palmar fascia fibers fan out from this origin, concentrating in flat bundles to each of the digits. Generally, the fibers spread at the base of each digit and send minor fibers to the skin and the bulk of fibers distal into the fingers, where they attach to tissues making up the fibrous flexor sheath of the digits. There are attachments of the fascia to the volar plate and intermetacarpal ligaments at each side of the flexor tendon sheath at the level of the metacarpal heads.

Transverse fibers are concentrated in the midpalm and the web spaces. The midpalmar transverse fibers, although intimately associated with the longitudinal bundles, lie deep to them and are inseparable from the vertical fibers that concentrate into septa between the longitudinally oriented structures passing to the fingers. This system of palmar transverse fibers makes up what Skoog (1967) called the transverse palmar ligament.[21] In fact, the transverse fibers form the roof of tunnels at this point that act as pulleys for the flexor tendons proximal to the level of the digital pulleys. Biomechanical evaluation of the palmar aponeurosis pulley has demonstrated that isolated sectioning did not change the work of flexor tendons or load efficiency.[22] Nevertheless, this pulley has been implicated as contributing to the etiology of trigger finger.[23]

BOX 1.1 Clinical pearl: Kaplan's cardinal line

Hand anatomist Emanuel Kaplan described specific surface lines that would aid surgeons in locating key structures in the palm of the hand. The cardinal line has often been misquoted; therefore we refer to Kaplan's classic hand text, *Functional and Surgical Anatomy of the Hand*.[19] Kaplan's cardinal line is drawn from the apex of the first web space to the distal edge of the pisiform bone (see Fig. 1.1). Two longitudinal lines are drawn from the ulnar aspect of the middle finger and the ulnar aspect of the ring finger. These will cross the cardinal line. The intersection of the cardinal line and the longitudinal line from the ulnar side of the middle finger corresponds to the motor branch of the median nerve. The intersection of the cardinal line and the longitudinal line from the ulnar side of the ring finger corresponds to the hook of the hamate. The motor branch of the ulnar nerve is found on the cardinal line, equidistant between the hamate and pisiform. See Kaplan's original text for additional surface markings.

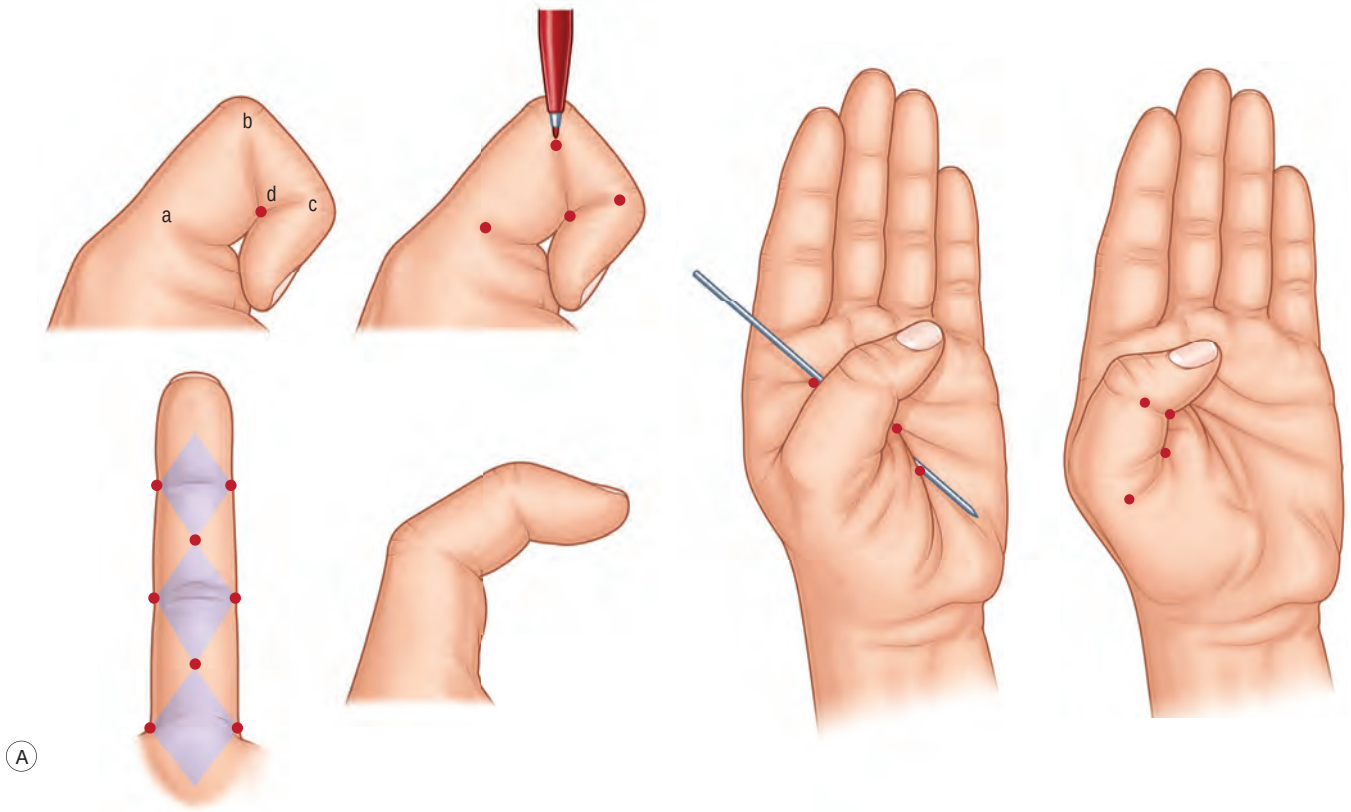

Fig. 1.2 (A,B) Schematic representation of the joint axes. The longitudinal dimensions in the midpalmar and mid-dorsal aspect of the digits change maximally. The midaxial line through the three joint axes does not change in length with flexion and extension. Palmar incisions placed longitudinally produce contracture if they pass across the palmar diamonds delineated by lines joining the joint axes (after Littler). Transverse incisions avoid the occurrence of flexion scar contractures. The same principle applies at the wrist. *(Redrawn after Chase RA.* Atlas of Hand Surgery, *vol 1. Philadelphia: WB Saunders, 1973.)*

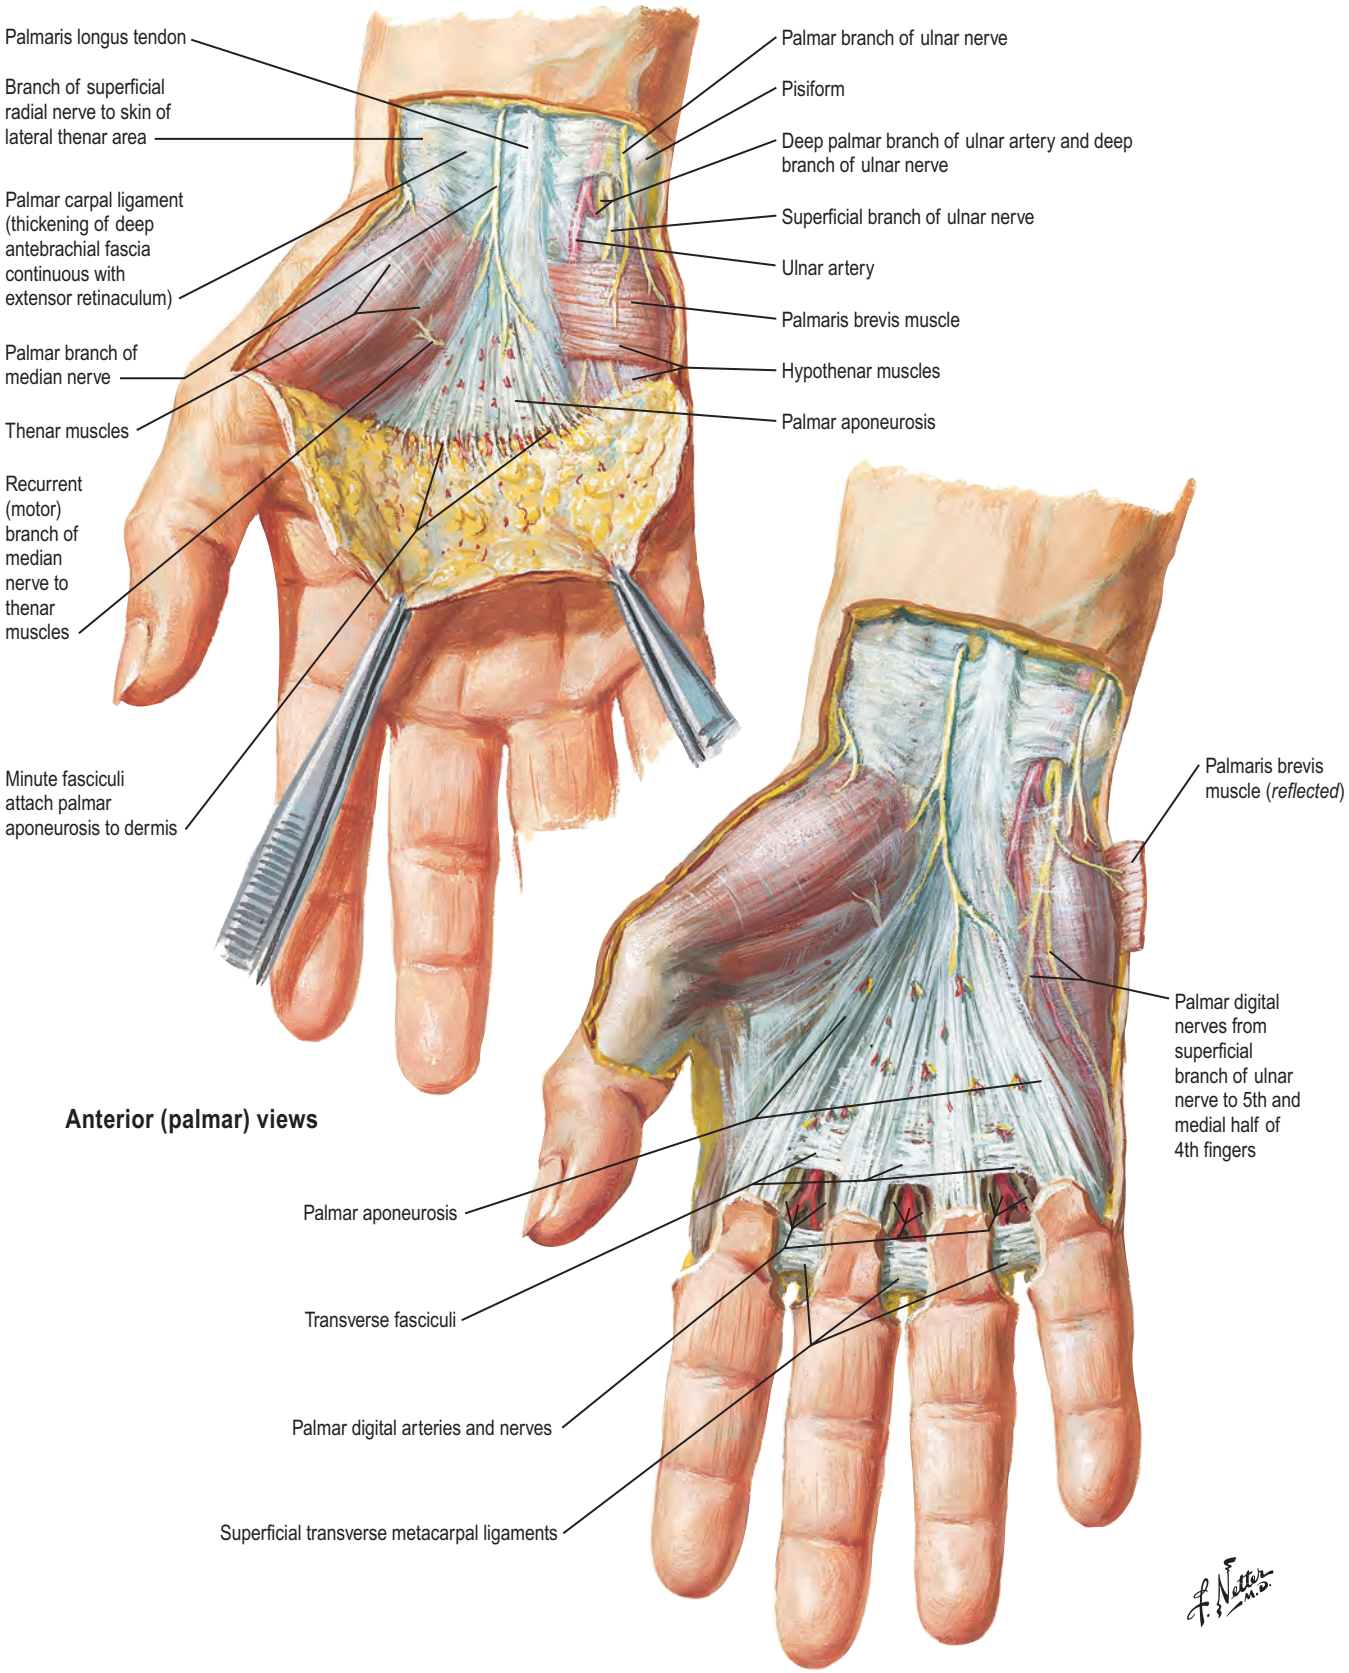

Fig. 1.3 Superficial dissection of the palm, showing orientation of the palmar fascia. *(Reprinted with permission from www.netterimages.com © Elsevier Inc. All Rights Reserved.)*

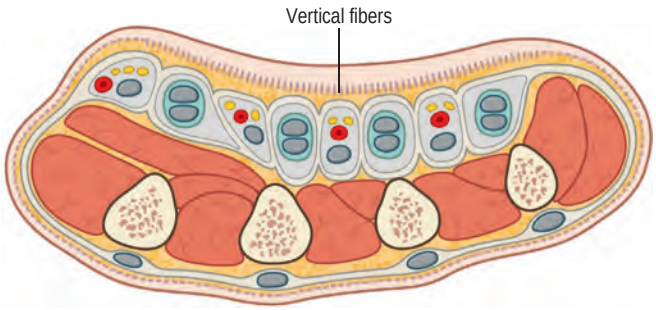

Fig. 1.4 The palmar fascia with its longitudinal, transverse, and vertical fibers. The longitudinal fibers take origin in the palmaris longus (when present). Transverse fibers are concentrated in the distal palm supporting the web skin and in the midpalm as the transverse palmar ligament. Vertical fibers extend superficially as multiple, tiny tethering strands to stabilize the thick palmar skin. The deep vertical components concentrate in septa between the longitudinally oriented structures in the fingers. *(Redrawn after McCarthy JG.* Plastic Surgery. *Philadelphia: WB Saunders, 1990.)*

Longitudinal fibers pass toward the palmar surface of the thumb, but these fibers are generally less numerous and sometimes difficult to identify. The thumb fibers blend into the deep fascia overlying the thenar muscles. The ulnar extreme palmar fascia blends with the hypothenar fascia. The proximal one-third of this border is the attachment site of the palmaris brevis muscle. Laterally, the muscle attaches to the hypothenar skin and hypothenar fascia.

The vertical fibers of the palmar fascia, which lie superficially to the tough triangular membrane made up by the longitudinal and transverse fibers, consist of abundant vertical fibers to the palm dermis (Fig. 1.4). Deep to the palmar fascia, the vertical fibers coalesce into septa, or the "perforating fibers of Legueu and Juvara",[24] forming compartments for flexor tendons to each digit and separate compartments for the neurovascular bundles together with the lumbrical muscles. There are eight such compartments, which extend proximally to about the midpalm. Proximal to this, there is a common central compartment.[25] The marginal septa extend more proximally than the seven intermediate septa closing the central compartment laterally and medially. The major septum between the index flexor tendons and the neurovascular and lumbrical space to the third interspace attaches to the third metacarpal, dividing the thenar or adductor space from the midpalmar space. Knowledge of these vertical compartments aids dissection and identification of structures in operations such as trigger-finger release and Dupuytren's fasciectomy (Fig. 1.5).

In the fingers, two important bands of fascia are named Grayson's ligaments and Cleland's ligaments. Grayson's ligaments are volar to the neurovascular bundles and are quite flimsy. The much stouter Cleland's ligaments are dorsal to the neurovascular bundles. These two fascial sheets help contain and protect the ulnar and radial digital arteries and nerves (Fig. 1.6).

Bones and joints

Hand elements

The ability of the hand to resist and create powerful gross action, combined with its capacity to perform intricate fine movements in multiple planes, reflects the masterful construction of its supporting architecture. Reducing the hand to its supporting skeleton and its restraining ligaments reveals the architectural basis for its varied function. A study of the range of joint motions in the hand and forearm with all motor elements removed discloses the full range and limitations that the skeleton imposes on hand function.

The hand skeleton is divisible into four elements:

1. The fixed unit of the hand, consisting of the second and third metacarpals and the distal carpal row.
2. The thumb and its metacarpal with a wide range of motion at the carpometacarpal joint. Five intrinsic muscles and four extrinsic muscles are specifically influential on thumb positioning and activity.
3. The index digit with independence of action within the range of motion allowed by its joints and ligaments. Three intrinsic and four extrinsic muscles allow such digital independence.
4. The third, fourth, and fifth digits with the fourth and fifth metacarpals. This unit functions as a stabilizing vise to grasp objects for manipulation by the thumb and index finger, or in concert with the other hand units in powerful grasp (Fig. 1.7).

The distal row of carpal bones forms a solid architectural arch with the capitate bone as a keystone. The articulations of the distal carpals with one another, the intercarpal ligaments, and the important transverse carpal ligament (flexor retinaculum) maintain a strong, fixed transverse carpal arch. Projecting distally from the central third of this arch are the fixed central metacarpals, the second and third. Littler called this the "the fixed unit of the hand". It forms a fixed transverse arch of carpal bones and a fixed longitudinal arch created by the anatomic convexity of the metacarpals. As a stable foundation, this unit creates a supporting base for the three other mobile units. This central beam moves as a unit at the wrist under the influence of the prime wrist extensors (the extensor carpi radialis longus and brevis) and the prime wrist flexor, the flexor carpi radialis. These major wrist movers insert on the second and third metacarpals. Thus, the fixed central unit is positioned for activity of the adaptive elements of the hand around it.

The distal row of carpal bones constitutes a fixed transverse arch. At the level of the metacarpal heads, the transverse arch of the hand becomes mobile, which is possible because the first metacarpal moves through a wide range of motion at the saddle-like carpometacarpal joint. The loose capsular ligaments and the shallow saddle articulation between the first metacarpal and the trapezium allow circumduction of the mobile first metacarpal. Its range of motion is checked by these capsular ligaments, including the volar beak ligament, and by its attachment to the fixed hand axis through the adductor pollicis, the first dorsal interosseous, and the fascia and skin of the first web space. The mobile fourth and fifth metacarpal heads move dorsally and palmarly in relation to the central hand axis by limited mobility at the carpometacarpal joints. These metacarpal heads are tethered to the central metacarpals by the intermetacarpal ligaments. The latter unite adjacent metacarpophalangeal volar plates, which are an intimate part of the joint capsules.

When the head of the first metacarpal is palmar-abducted by thenar muscles innervated by the median nerve, and the

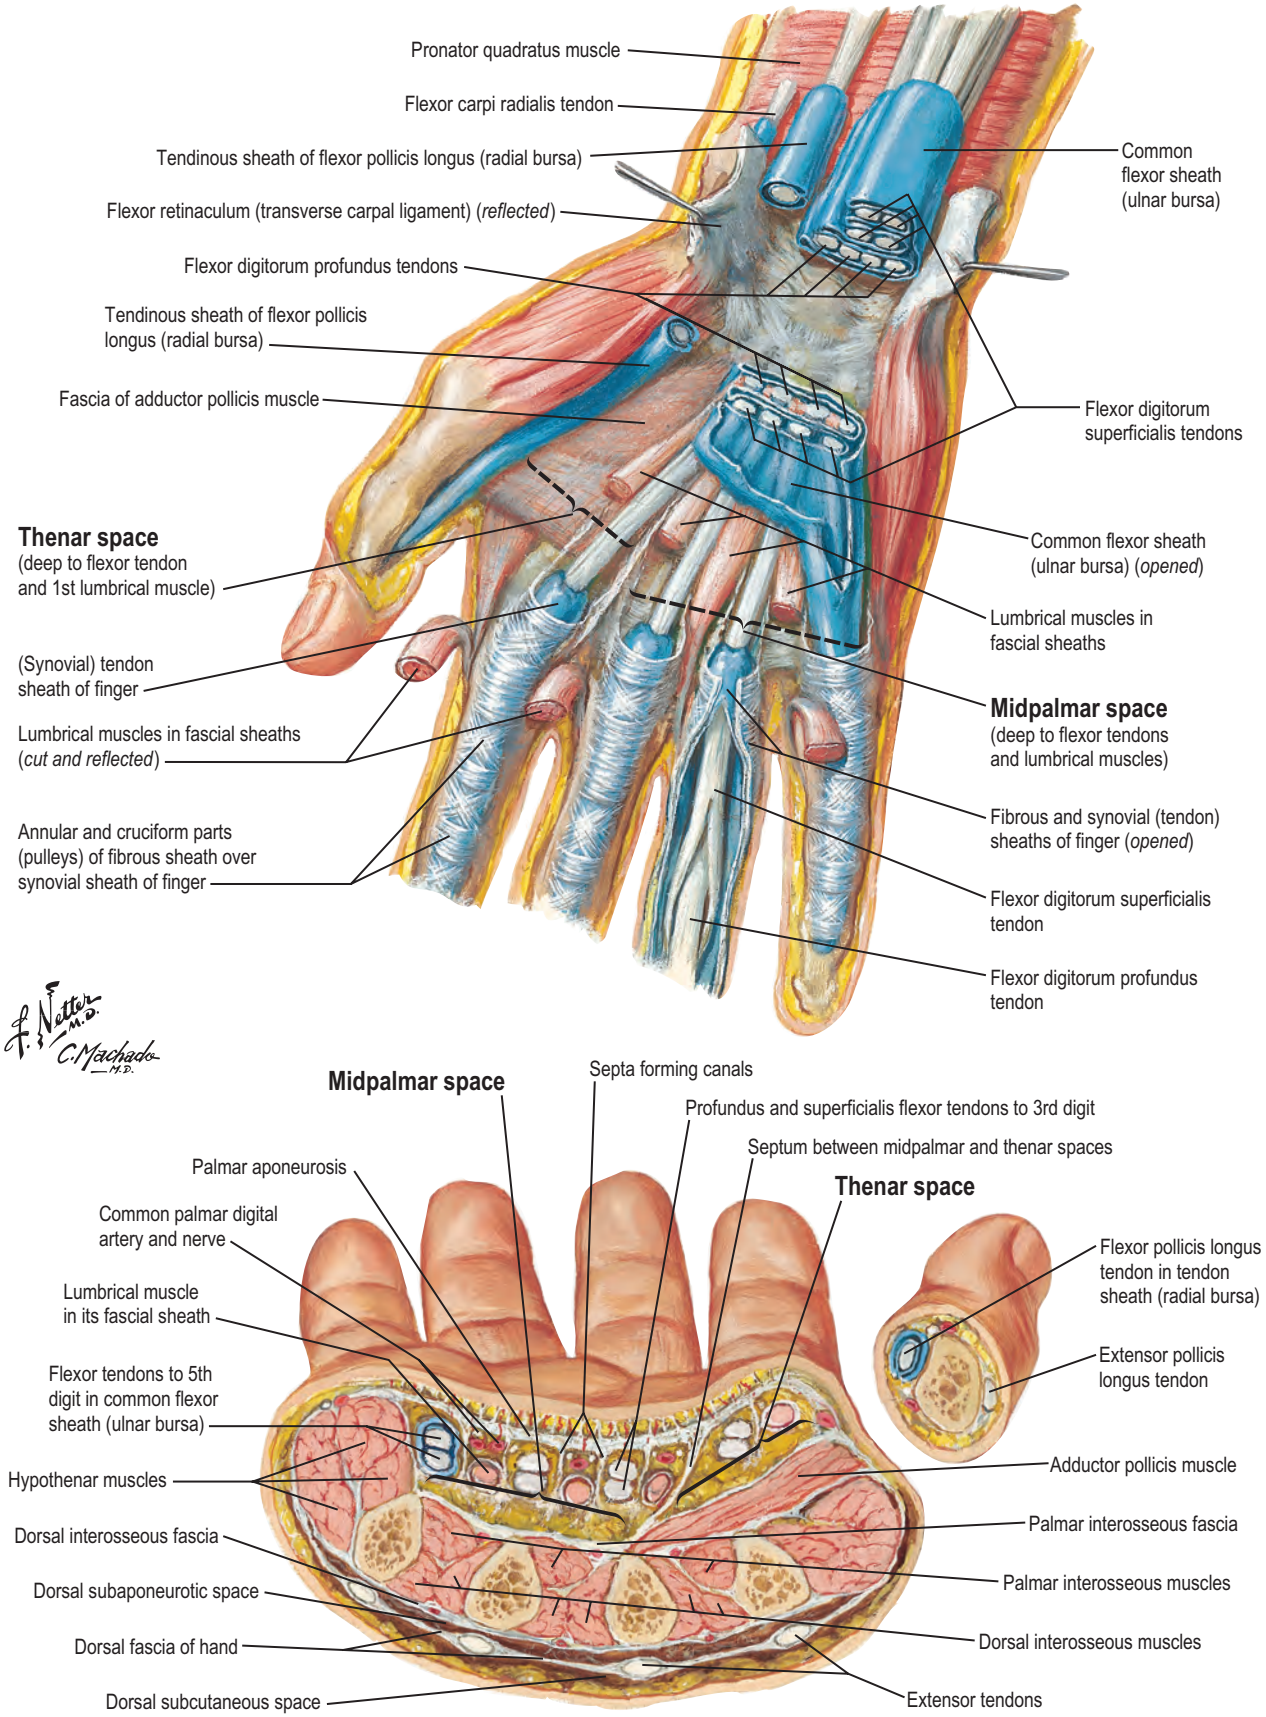

Fig. 1.5 These deep palmar and midpalmar axial views of the hand reinforce the concept of distinct anatomic compartments separated by fascia. *(Reprinted with permission from www.netterimages.com © Elsevier Inc. All Rights Reserved.)*

fourth and fifth metacarpals are palmar-abducted by the hypothenar muscles innervated by the ulnar nerve, a volar, concave, transverse metacarpal arch is created, approximating a semicircle. The mobile metacarpal heads are pulled dorsally by extrinsic extensor tendons when the thenar and hypothenar muscles relax. It is obvious that a flaccid paralysis of the intrinsic muscles of the hand in median and ulnar nerve palsy will produce a flattened or even reversed transverse metacarpal arch. The active production of a semicircular transverse arch by the thenar and hypothenar muscles creates the proper circumferential arrangement of the metacarpophalangeal joints for convergence of the fingers in flexion. In this position the fingers, flexing at the metacarpophalangeal joints only, converge, forming with the thumb a cone, the apex of which lies over the anatomic center of the hand (Fig. 1.8). A vertical line dropped from the apex of the cone to the center of its base will strike the third metacarpophalangeal joint. This point at the apex of the transverse metacarpal arch is the anatomic center of the hand. With the fingers fully abducted, the tips form radii of equal length from the anatomic center of the hand. The same radius projected proximally falls at the wrist joint.

The most important single motor operating the central hand beam at the wrist level is the extensor carpi radialis brevis, which works against gravity, positioning the pronated hand into extension. In the absence of any other motors it pulls the central third metacarpal into extension, making it the apex of the passively created transverse metacarpal arch.

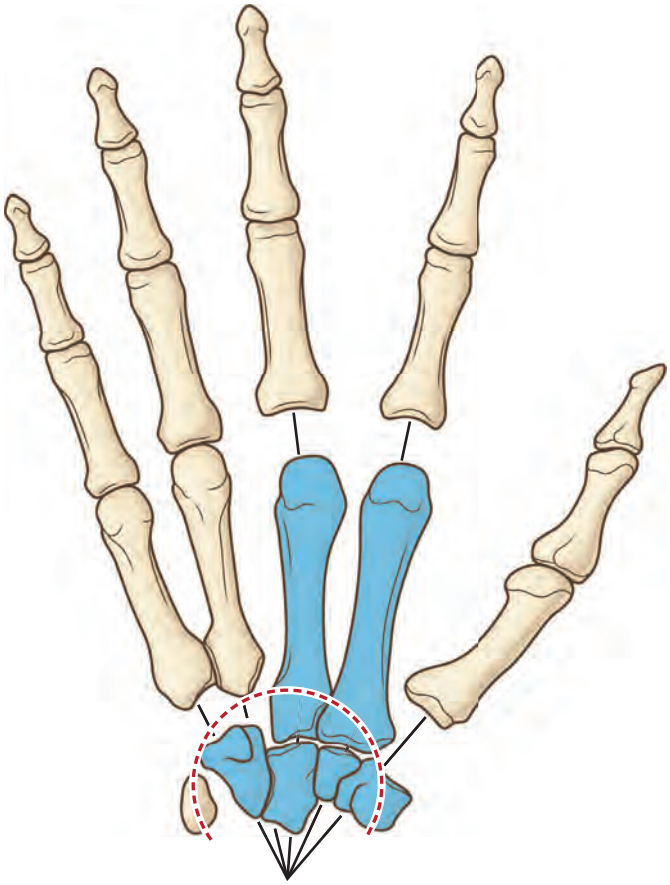

Fig. 1.7 Exploded view of the functional elements of the hand: (1) the thumb and its metacarpal with a wide range of motion at the carpometacarpal joint; (2) the index digit with independence of action in several planes; (3) the third, fourth, and fifth digits with the fourth and fifth metacarpals; and (4) the fixed unit consisting of the carpals with the fixed transverse carpal arch and the second and third metacarpals forming a fixed longitudinal arch. *(Redrawn after McCarthy JG.* Plastic Surgery. *Philadelphia: WB Saunders, 1990.)*

The wrist

The wrist joint is the site for major postural change between the arm beam and the working hand end piece (Fig. 1.9). It has a multiarticulated architecture that creates a potentially wide range of motion in flexion, extension, radial deviation, ulnar deviation, and circumduction. The distal radioulnar joint allows pronation and supination of the hand as the radius rotates around the head of the ulna. The proximal row of carpal bones (scaphoid, lunate, triquetrum, pisiform) articulates with the distal radius and ulna, providing the ability to flex and extend the hand and perform radial and ulnar deviation. The distal carpal row (trapezium, trapezoid, capitate, and hamate), along with the second and third metacarpals, forms the "fixed unit" of the hand.

The radiocarpal joint includes the carpal bones and the distal radius (Fig. 1.10). The principal articulation of the carpus is with the distal surface of the radius. The articular surface of the radius slopes in several planes. In the radial-to-ulnar plane, the radius exhibits an average slope of 22°. In the dorsal-to-palmar plane, the articular surface of the radius slopes 12° with the dorsal surface more distal than the palmar surface. Fractures of the distal radius frequently result in a loss of the normal radiocarpal configuration in one or both planes. A loss

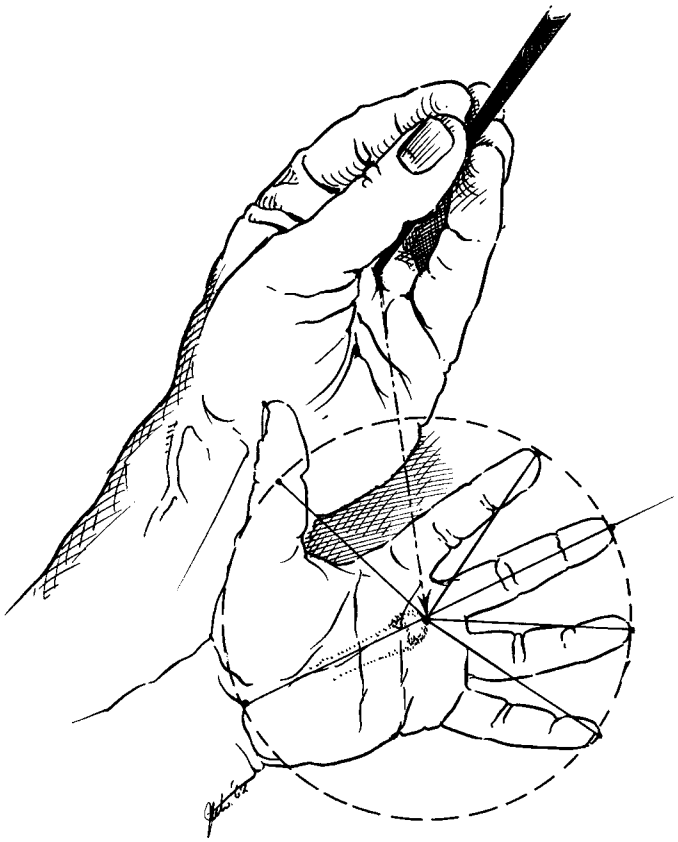

Fig. 1.8 When the adaptive arch is semicircular, the fingers converge in a cone over the anatomic center of the hand – the long-finger metacarpophalangeal joint. *(From McCarthy JG.* Plastic Surgery. *Philadelphia: WB Saunders, 1990.)*

of the normal dorsal-to-palmar tilt of the articular surface will result in a change in the biomechanical properties of the wrist joint, which may lead to degenerative arthritis.

The relationship of the length of the radius to the length of the ulna is fairly constant in individuals, and is termed ulnar variance. The distal ulna will complete the curve of the articular surface of the radius. If the end of the ulna falls short of this curvature, the condition is termed ulnar negative variance. If the ulna extends distal to this imaginary extension, the condition is termed ulnar positive variance. Either condition may lead to wrist problems. Ulnar negative variance is associated with a higher incidence of Kienböck's disease, avascular necrosis of the lunate. Ulnar positive variance greater than 2–3 mm is associated with ulnar impaction (Fig. 1.11).

Gilula and others have described several anatomic features that denote normal extracarpal and intracarpal architecture.[26] A line that follows the proximal articular contours of the proximal row of carpal bones circumscribes a smooth arc, termed the greater arc (Fig. 1.12). A disruption in the smooth appearance of this arc is one of the signs of carpal abnormality, such as abnormal rotation of one of the bones of the proximal carpal row, as would be seen with disruption of the scapholunate ligament. Similarly, the joint line between the proximal and distal row of carpal bones circumscribes another smooth arc, termed the lesser arc. The presence of abnormalities in either of these arcs may be an indication of carpal pathology, either acute or chronic.

The scaphoid and lunate bones of the proximal carpal row form the convex articular counterparts of the concave distal radius for the major wrist articulation. In fact, the articular surface of the radius is divided into scaphoid and lunate fossae (Box 1.2). The triquetrum articulates with the lunate in the proximal row, and with the hamate across the midcarpal

joint. The pisiform is essentially a floating bone, unimportant for carpal stability.

All four of the bones in the distal carpal row present articular surfaces for junction with the metacarpals. The distal carpal row forms a solid architectural arch with the central capitate as the keystone. The nature of the articulations of the distal carpals with one another, and of the carpal ligament (flexor retinaculum), is such that they make up a strong and fixed transverse carpal arch (Box 1.3).

BOX 1.2 Clinical pearl: blood supply to the scaphoid

Investigations by Gelberman and Menon have described two main vessel systems that perfuse the scaphoid via ligamentous attachments.[27] The superficial palmar branch of the radial artery contributes a volar blood supply that feeds the distal scaphoid. The dorsal carpal branch of the radial artery contributes a dorsal blood supply that also primarily feeds the distal scaphoid. Therefore, the proximal scaphoid is poorly vascularized and is susceptible to nonunion after proximal pole fracture.

The complex motions of the wrist are a product of the sums of the movements of the carpal bones in various planes and degrees of rotation relative to one another. The motion of any one carpal bone is a consequence of several factors. The first factor is the contour of the bone and the arrangements of its articular surfaces. The second is the degree of freedom afforded by intrinsic ligaments, which are ligaments originating from one carpal bone and inserting on another carpal bone, and by extrinsic ligaments, which are ligaments arising from the radius or ulna and attaching to a carpal bone or bones. This complex set of ligaments and the shape of the intercarpal and radiocarpal articulations control movement because no muscles arise or insert on any of the carpal bones except for the pisiform.

This unique adaptation of nature avoids the need for a thickly muscled wrist and hand unit. It permits great flexibility in positioning the hand in space without the need for sets of muscle agonists and antagonists to control the several degrees of freedom of movement.

The proximal row of carpal bones is anchored to the radius by a series of stout palmar ligaments arising primarily from the radius and by an additional set of stout ligaments arising from the ulna and the palmar portion of the triangular fibrocartilage complex. The triangular fibrocartilage complex separates the distal end of the ulna from the ulnar-sided carpal bones and serves to suspend the distal ulna to the radius at the distal radioulnar joint. These primary extrinsic palmar ligaments take the form of an inverted "V" with its apex pointed distally.

The three most predominant nerves innervating the triangular fibrocartilage complex are the dorsal cutaneous branch of the ulnar nerve (100%), the medial antebrachial cutaneous nerve (91%), and the volar branch of the ulnar nerve (73%). Other nerves play a minor role in the innervation of the triangular fibrocartilage complex: the anterior interosseous nerve, the posterior interosseous nerve and the palmar branch of the median nerve.[28]

BOX 1.3 Clinical pearl: checking for malrotation

The tubercle of the scaphoid is found at the distal flexion crease of the wrist joint, lateral to the tendon of the flexor carpi radialis. It is an important skeletal landmark in evaluating digital malrotations. Normally, each finger points to the scaphoid tubercle when individually flexed. A finger that points away from the tubercle may do so because of destructive flattening of the carpal arch. More commonly, it may result from malrotation following a metacarpal or phalangeal fracture (Fig. 1.13).

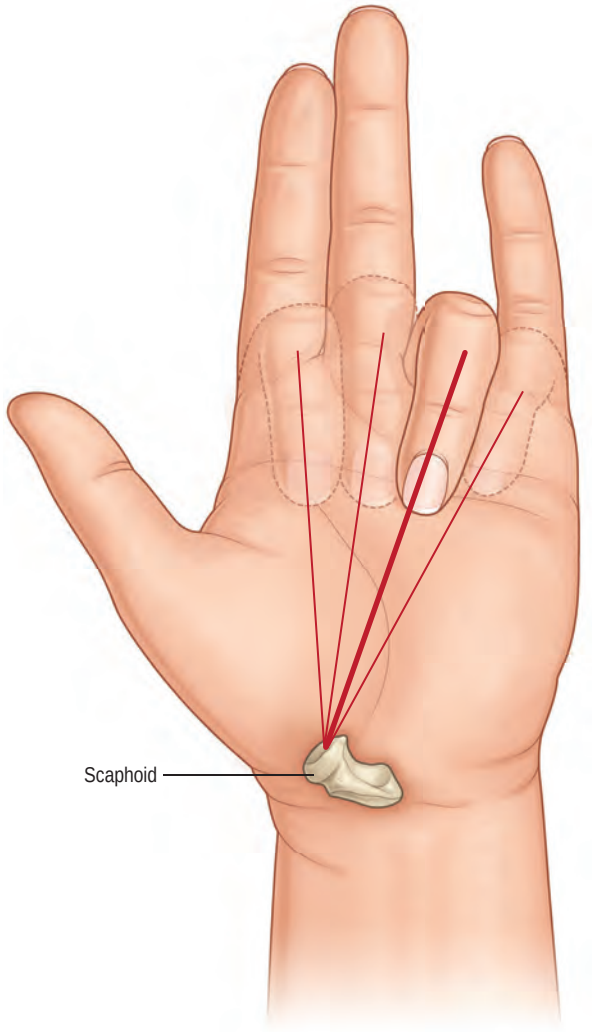

Fig. 1.13 Each finger in correct alignment points to the tubercle of the scaphoid when flexed individually. *(Redrawn after Chase RA.* Atlas of Hand Surgery, *vol. 1. Philadelphia: WB Saunders, 1973.)*

Dorsally, the extrinsic radiocarpal ligament complex is thinner and is primarily a condensation of capsular tissues, except for two stout structures, the dorsal intercarpal ligament joining the distal pole of the scaphoid and the triquetrum, and the dorsal radiocarpal ligament. According to work by Viegas, these two dorsal ligaments form a unique lateral "V" configuration that allows variation in length by changing the angle of the "V" while maintaining a stabilizing force on the scaphoid during wrist range of motion.[29]

The intrinsic ligaments are broad, stout structures that link one carpal bone to another, either within the proximal or distal row, or linking one carpal row to the other. The two most significant intrinsic ligaments are the scapholunate ligament and the lunotriquetral ligament. The scapholunate ligament anchors the scaphoid to the lunate to allow these two carpal bones to move in synchrony. Berger has subdivided this U-shaped structure into three regions: dorsal, proximal, and palmar.[30] The dorsal region is thick and controls scapholunate stability. The proximal portion, composed mainly of fibrocartilage, and the palmar region, with thin and obliquely oriented fibers, are less important for stability.[31] The lunotriquetral ligament is also composed of dorsal, proximal, and palmar portions. There is less motion between these two carpal bones. Disruption of either the scapholunate or lunotriquetral ligaments may lead to wrist instability as the normal restraints on synchronous motion are removed.

Joint motion

The bony anatomy of the hand is presented in Fig. 1.14. Normal metacarpophalangeal joint motion in the fingers ranges from 0 to 90°. Lateral activity in the metacarpophalangeal joints is limited by the rein-like collateral ligaments. These ligaments are loose and redundant when the metacarpophalangeal joints are in extension, allowing maximal medial and lateral deviation. As the metacarpophalangeal joint is flexed, the cam effect of the eccentrically placed ligaments and the epicondylar bowing of the collateral ligaments result in tightening and strict limitation of lateral mobility (Fig. 1.15). The fingers that have been fixed in extension during a period of healing have had the stage set for collateral ligament shrinkage and locking of the metacarpophalangeal joints in hyperextension.

The proximal interphalangeal joint can be pushed to 110° of flexion, but extension usually cannot be carried beyond 5° of hyperextension because of the ligamentous volar plate, which is an inseparable part of the joint capsule. The medial and lateral collateral ligaments are a part of the capsule. They are radially fixed in a manner that allows no medial or lateral deviation of the joint in any position. The shape of the articular joint surface also strongly contributes to this stability in lateral motion.

The distal interphalangeal joints of the fingers can be pushed into about 90° of flexion before they are limited by the dorsal joint capsule and extensor mechanism. The distal interphalangeal joints extend to 30° of hyperextension. There is no lateral mobility in these joints with the collateral ligaments intact. The collateral ligaments of the distal interphalangeal joints are simply thickened medial and lateral portions of the joint capsule.

Biomechanical concept: joint motion

Brand and Hollister, in their textbook, *Clinical Mechanics of the Hand*, discuss how joints move.[32] An axis of rotation of a joint refers to a line fixed to the proximal bone about which the motion of the distal bone appears to be a pure rotation. For the simple (hinge type) interphalangeal joints of the fingers, the motion occurs only in flexion and extension; the axis of rotation is perpendicular to the sagittal plane and is located in the distal head of the phalanx proximal to the joint. A related concept is that of the degrees of freedom of a joint. The degrees of freedom of a joint are the minimum number of axes of rotation that can be used to describe completely the motion of the bone distal to the joint. The wrist as a whole, for example, has two degrees of freedom (flexion–extension and radial–ulnar deviation), represented by two nearly perpendicular axes of rotation.[33] The kinematics of more complex joints such as the thumb carpometacarpal joint[34] or the intercarpal joints[35] is still the subject of research and thought to have at least two degrees of freedom with nonintersecting, nonperpendicular axes of rotation.

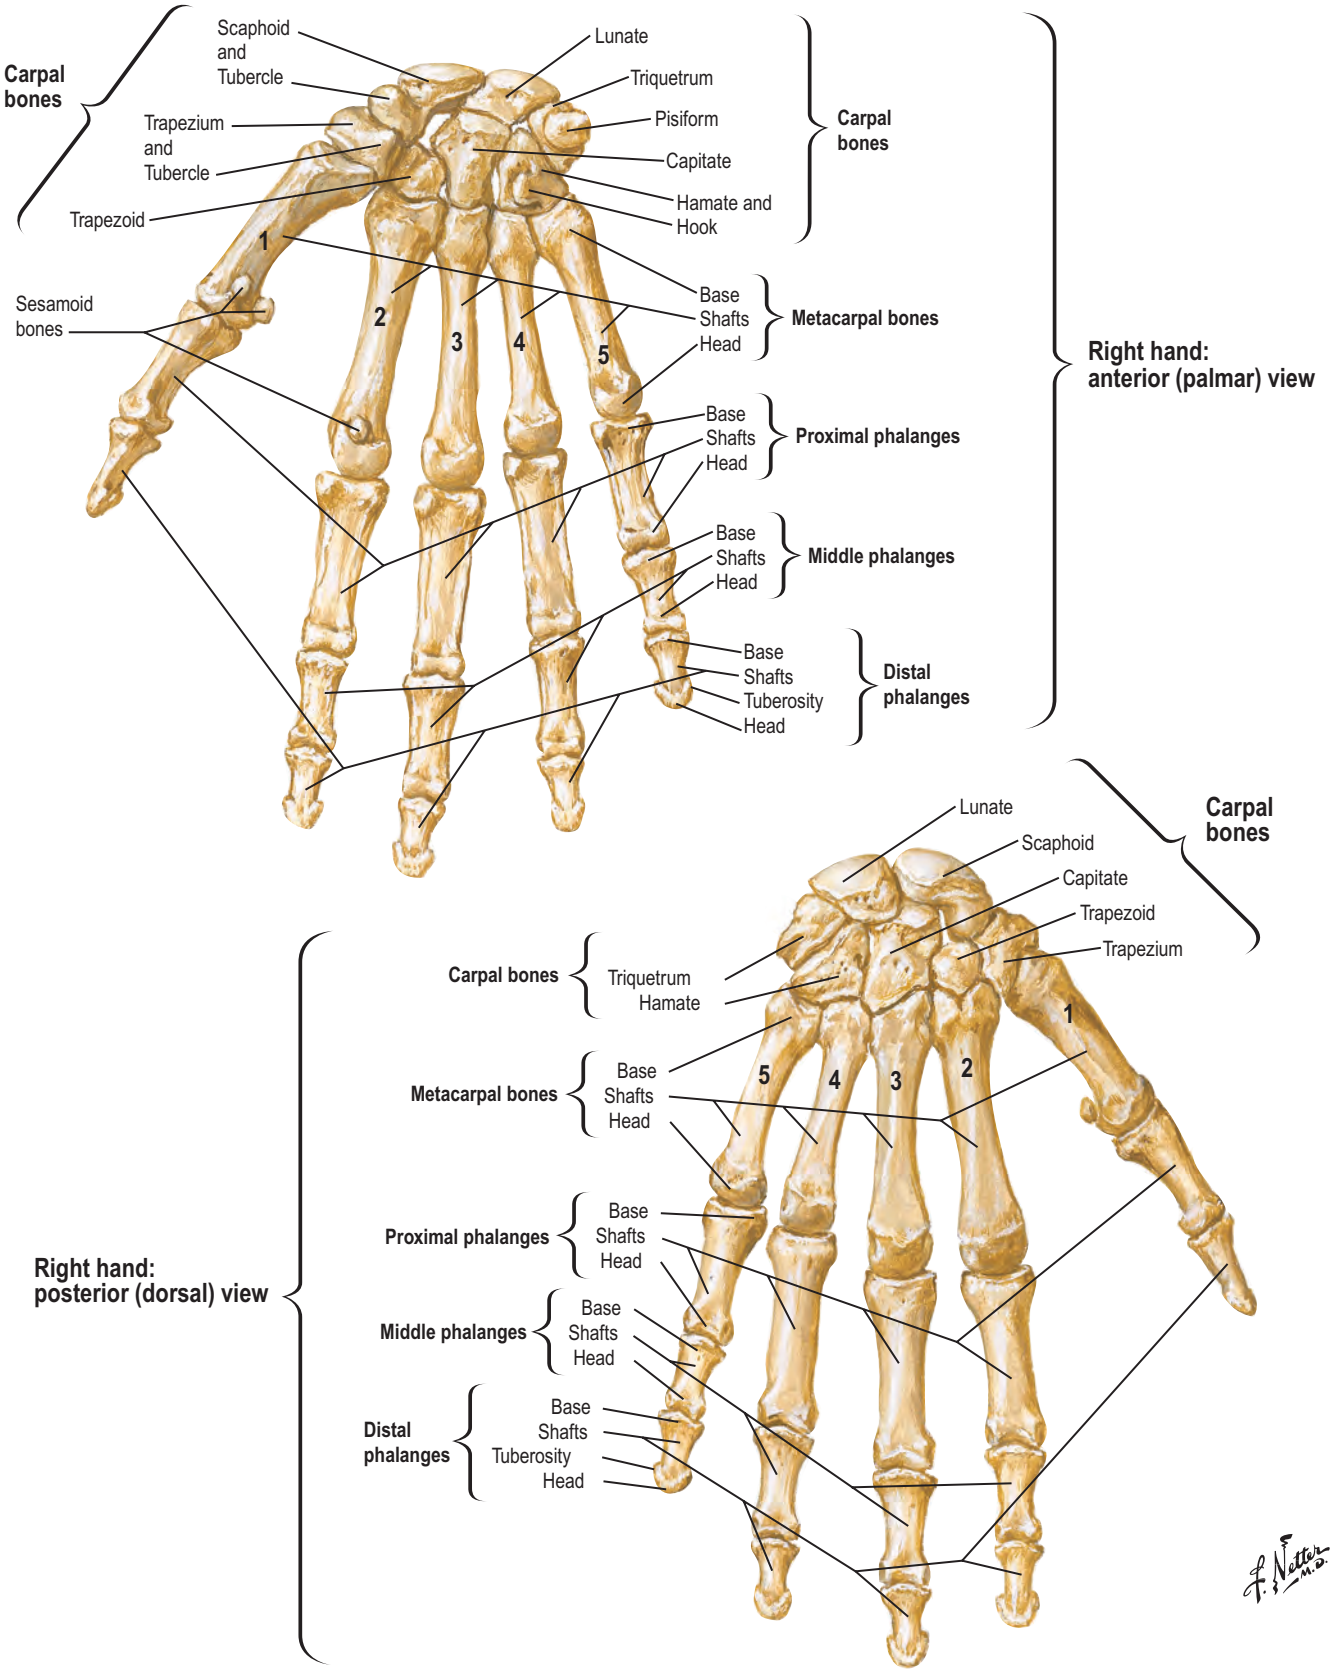

Fig. 1.14 Bony anatomy of the wrist and hand. *(Reprinted with permission from www.netterimages.com © Elsevier Inc. All Rights Reserved.)*

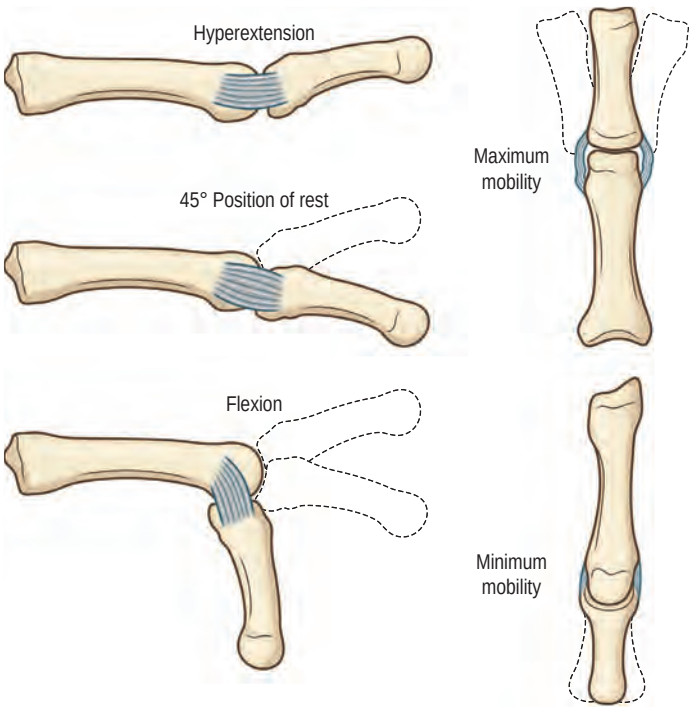

Fig. 1.15 (A–D) The true collateral ligaments of the metacarpophalangeal joint are loose in extension but tight in flexion of the joint as a result of the cam effect of the metacarpal head in relationship to the proximal phalanx. This accounts for the lack of lateral mobility of the joint when it is flexed. *(Redrawn after Chase RA.* Atlas of Hand Surgery, *vol. 1. Philadelphia: WB Saunders, 1973.)*

In each finger, there is no difference between the radii of curvature of the ulnar and radial condyles of the middle phalanx head. Conversely, the radius of curvature of the distal phalanx ulnar groove is significantly greater than that of the radial groove. This asymmetry between the distal phalanx grooves and the middle phalanx results in a translational component during the flexion of the distal interphalangeal joint that may contribute to degenerative changes and development of arthritis.[36]

The proximal and distal interphalangeal joints are hinge joints: any lateral motion is limited in all phases of flexion and extension by radially oriented collateral ligaments, which are tight at any angle. The metacarpophalangeal joints, in contrast, allow motion through several axes. The capsule, including the collateral ligaments and volar plate, is quite lax, allowing medial and lateral deviation, flexion, extension, and thereby circumduction and a small degree of distraction. In the absence of other sources of stabilization, upon cutting of the collateral ligaments the metacarpophalangeal joint becomes a flail, unstable mechanism. Nature, fortunately, has created another source of lateral stability – the interosseous muscles. By virtue of the selective variable pull, the interossei normally influence lateral motion in the metacarpophalangeal joint to the extent allowed by the unyielding collateral ligaments. If the collateral ligaments are sacrificed, the interossei remain the sole source of lateral stability. When there is intrinsic (ulnar) paralysis, if the collateral ligaments are sacrificed, all lateral stability is lost and disastrous ulnar deviation occurs. At the interphalangeal joints lateral stability is again dependent on the collateral ligaments, but at this level there is no second line of defense. The collateral ligaments of the interphalangeal joints, therefore, cannot be sacrificed without creating a lateral instability that is curable only by fusion of the interphalangeal joints.

Palmar or volar plates are found in the metacarpophalangeal and interphalangeal joints where they reinforce the joint capsules, enhance joint stability, and limit hyperextension. The plates of the MCP and IP joints are structurally and functionally similar. The volar plates of the metacarpophalangeal joints are the sites of insertion of the intermetacarpal ligaments, which limit separation or fanning of the metacarpal heads. The volar plate is fixed to that portion of the capsule that originates from the proximal phalanx, and therefore the plate moves with the proximal phalanx in flexion and extension. Dorsal to this ligament on each side of the metacarpal heads are sagittal bands that connect the volar plates to the tendon of the extensor digitorum and to the extensor expansion. The volar plates to the proximal and distal interphalangeal joints are also stout structures that may become scarred in cases of fracture/dislocation and may ultimately lead to joint flexion contractures (Box 1.4).

BOX 1.4 Clinical pearl: check rein ligaments

Check rein ligaments are, in fact, abnormal structures that are found only after fibrosis of the proximal interphalangeal joint occurs.[37] The volar lateral ridges of the proximal phalanx are termed "assembly lines" and represent a coalition of the flexor sheath and Cleland's and Grayson's ligaments. Normally, there is no connection between the volar plate and these assembly lines. However, in the proximal interphalangeal joint with a flexion contracture, fibrosis has occurred and stout check rein "ligaments" have formed from the volar plate that prevent full joint extension.

The thumb

The thumb occupies the extreme radial position in the transverse arch of the hand. The column of bones making up the thumb architectural base comprises the two phalanges, the metacarpal, and the trapezium. Its formula differs from that of the remaining digits by virtue of its two named phalanges rather than three. From a functional point of view, however, the thumb metacarpal can be compared to a proximal phalanx and the trapezium to a grossly foreshortened metacarpal. This suggests that the thumb is a digit recessed by a short metacarpal (the trapezium) with the proximal phalanx loosely syndactylized to the second metacarpal. There is no clear evidence to support this point of view phylogenetically, but it seems sensible in understanding the gross anatomy of the thumb's architecture. Like the finger metacarpophalangeal joints, the thumb's metacarpotrapezial joint has the greatest degree of freedom of any in the digital rays. The metacarpotrapezial joint is a synovial joint separated and distinct from the general intercarpal joints of the wrist. The trapezium itself articulates with the trapezoid and scaphoid with ligamentous restraints that sharply limit trapezial motion in relationship to the carpus (Fig. 1.16).

The uniquely wide range of thumb motion as compared with that of the remaining digits is attributable largely to the joint between the base of the first metacarpal and the trapezium. In simplest terms, it is described as a biconcave double saddle joint with a permissively loose capsule. That

combination allows movements best described as flexion, extension, adduction, and abduction through infinite combinations that result in circumduction. The thumb rotates as a cone with its apex at a point where the axes of flexion–extension and abduction–adduction cross within the carpometacarpal joint.[38–40]

The first carpometacarpal joint is best described as a double saddle where one saddle sits atop another, allowing three degrees of motion: (1) flexion–extension; (2) abduction–adduction; and (3) medial rotation–lateral rotation.[41] As the thumb rocks along the central ridge of the trapezial saddle in abduction and adduction, the metacarpal saddle's extensions over the trapezial saddle engage the trapezial saddle's medial or lateral condylar parts along the central axis. The axis line is curved in such a way that when the metacarpal is adducted, it locks into medial rotation, and when it is abducted, it locks into lateral rotation. This accounts for the sweep of the thumb in adduction to abduction along the transverse arch of the metacarpal heads. This mandatory rotation into medial rotation on adduction helps to position the thumb for pulp-to-pulp opposition of the thumb to the fingers. In neutral position the axis of the trapezium, represented by its central ridge, sits at about 60° from a line through the heads of the central stable second and third metacarpals. The base of the first metacarpal has a quadrilateral articular surface that is a complementary match to the articular surface of the trapezium. Its concavity is slightly exaggerated on the ulnar volar side by a protrusion or "beak" for insertion of the important anterior oblique carpometacarpal ligament, commonly referred to as the "volar beak" ligament. As in some other joints in the body (e.g., the shoulder), stability and close coaptation of the joint surfaces between the trapezium and the first metacarpal are dependent on the presence of operational muscles and tendons. As noted above, there is a lot of slack in the joint capsule, allowing a wide range of motion, including joint distraction of up to 3 mm.[42]

An important stabilizing capsular ligament for the first carpometacarpal joint is the anterior oblique carpometacarpal ligament or volar beak ligament referred to above. It extends like the leg of a person seated in the trapezial saddle extending from the "beak" of the first metacarpal to the anterior crest of the trapezium and adjacent intercarpal ligaments. It retains the fragment of bone fractured free from the base of the metacarpal as the metacarpal displaces radially in Bennett's fracture. In advanced metacarpotrapezial joint arthritis it weakens and attenuates, as also does the intermetacarpal ligament, allowing radial subluxation of the metacarpotrapezial joint.[43]

The ligament at the radial border of the joint is like a radial collateral ligament and is referred to as the dorsoradial or anteroexternal ligament. Thus, the radial side of the joint support is the right anteroexternal ligament, which inserts close to but beneath the insertion of the abductor pollicis longus on the radial base of the first metacarpal. It forms part of the joint capsule and then attaches to the anterior crest of the trapezium. Dorsally, one sees the posterior oblique ligament crossing the dorsal joint capsule from the radially positioned posteroexternal tubercle of the trapezium to attach to the ulnar base of the first metacarpal.

There is a stout intermetacarpal ligament between the base of the first metacarpal and the adjacent base of the second metacarpal, and good evidence that this ligament together with the anterior oblique ligament is a key to prevention of radial subluxation of the metacarpotrapezial joint, as seen in arthroses of the joint.[44] Function and range of motion within the limits imposed by these ligaments are influenced by the extrinsic and intrinsic muscles of the thumb and the external forces applied to the thumb. Bettinger and Berger have updated this ligamentous anatomy to include 16 different ligaments that are thought to stabilize the trapezium and trapeziometacarpal joint.[45]

The first metacarpophalangeal joint differs from other metacarpophalangeal joints in several respects in both anatomic make-up and function. Generally, the first metacarpophalangeal joint range of motion in flexion and extension, as well as abduction and adduction, is less than that in the finger metacarpophalangeal joints. The metacarpal and proximal phalanx are more stout in order to accommodate to greater forces normally borne by the thumb in pinching and grasping. The head of the first metacarpal is different because the radial articular prominence is larger than the ulnar. The articular surface of the proximal phalanx is fashioned reciprocally to match. The collateral ligaments are similar to those of finger metacarpophalangeal joints. The metacarpophalangeal portion is taut in flexion and looser in extension. In extension, the portion of the fanlike collateral ligaments to the palmar plate is taut; thus, adduction and abduction are limited in both extension and flexion.[46] Some pronation but no supination is allowed at the metacarpophalangeal joint when it is in

extension. In supination, the joint locks into a stable position for secure grasping.

The sturdy fibrocartilaginous volar plate of the metacarpophalangeal joint extends from the palmar base of the proximal phalanx to the neck of the metacarpal. It regularly incorporates two sesamoid bones, one medial and one lateral to the flexor pollicis longus.

The nature of the condyle of the proximal phalanx of the interphalangeal joint to the thumb is such that, upon flexion of the joint, pronation of the distal phalanx occurs.

Muscles and tendons

Extrinsic extensors (Video 1.1 ▶)

Extensor muscles lie on the dorsum of the forearm and hand and are innervated by the radial nerve (Figs. 1.17–1.19). The brachioradialis is a flexor of the elbow joint but is included with the extensor muscles because it is supplied by the radial nerve. The brachioradialis and the extensor carpi radialis longus originate from the lateral supracondylar ridge of the humerus. The four superficial extensors (extensor carpi radialis brevis, extensor digitorum communis, extensor digiti minimi, and extensor carpi ulnaris) originate from the common extensor tendon which is attached to the supracondylar ridge and the lateral epicondyle.

The extensors can be divided by function. The extensor carpi radialis longus and brevis and the extensor carpi ulnaris serve to extend the wrist. The extensor digitorum communis, extensor indicis proprius, and the extensor digiti minimi are finger extensors. Three extrinsic extensors assist in thumb motion: abductor pollicis longus, extensor pollicis brevis, and extensor pollicis longus.

Biomechanical concept: muscle structure

Muscles are composed of tissue that can actively contract under the influence of the brain and spinal cord to produce hand and finger motion and forces by pulling on bones via tendons.[47,48] Muscle tissue is composed of parallel arrangements of muscle fibers that can actively shorten and passively resist stretching, but cannot actively lengthen. The muscles of the hand anchor to bone at either end, typically by a short tendon at their origin (proximal end) and a long tendon at their insertion (distal end). Muscle fibers run along the length of the muscle attaching to tendon at either end. The aponeurosis is the transitional region where the contractile fibers of the muscle interdigitate with the collagen fibers that form the tendon. Tendons are stout parallel bundles of collagen fibers that often cross multiple joints of the hand before inserting into bone. Some tendons of the hand are atypical as they bifurcate or combine before inserting into bone to form the extensor mechanism (or extensor hood) of the fingers. The lumbrical muscle is atypical as it both originates from and inserts on to tendon (the flexor profundus tendon and the extensor mechanism, respectively) and has no direct bony attachment.

Striated muscle fibers are themselves parallel assemblies of similarly long cells with multiple nuclei containing sarcomeres, the fundamental contractile unit of muscle tissue. At the biochemical level, sarcomeres are interdigitated filaments of f-actin and myosin proteins. Muscle activation and contraction occur when a neural command causes the release of calcium ions inside the muscle cell to cause the free end of the myosin filaments to "ratchet" past the f-actin filaments to increase the overlap between them by metabolizing adenosine triphosphate, an important source of energy fueling cellular processes. The maximal force a muscle can produce is proportional to the number of parallel muscle fibers that compose it (physiological cross-sectional area), and the angle the fibers make with the line of action of the tendons (pennation angle). Mammalian muscle tissue is considered to produce a maximal stress of around 35 N/cm^2, which is a remarkable ratio of force per unit weight that is difficult to match artificially. In addition, the connective tissue that holds together the muscle fibers grants muscle tissue passive viscoelastic properties.

The extensor retinaculum prevents bowstringing of tendons across the wrist (Fig. 1.20). Six extensor compartments exist (Video 1.1 ▶ and Fig. 1.21): (1) abductor pollicis longus and extensor pollicis brevis; (2) extensor carpi radialis longus and extensor carpi radialis brevis; (3) extensor pollicis longus; (4) extensor digitorum communis and extensor indicis proprius; (5) extensor digiti minimi; and (6) extensor carpi ulnaris.

Extension of the phalanges of the fingers and thumb is dependent both on long extensors at the metacarpophalangeal joints and on an interplay between the long extensors and intrinsic muscles at the interphalangeal joints. The extensor digitorum is a series of tendons with a common muscle belly that enters into the central extensor of each of the fingers. There are intertendinous bridges between these separate tendons over the dorsum of the hand. Independent long extensor power is supplied to the index finger through the extensor indicis and to the little finger through the extensor digiti minimi. In each case the independent extensor lies on the ulnar side of the long extensor tendon to these two fingers from the extensor digitorum (Fig. 1.22).

Biomechanical concept: the extensor mechanism of the fingers (Fig. 1.23)

The extensor tendons are attached by dorsal expansions or dorsal hoods (Video 1.2 ▶). These expansions are divided into three structures. (1) Lateral bands pass on either side of the proximal phalanx and extend all the way to the distal phalanx. The lumbrical and dorsal and palmar interossei muscles contribute to the lateral bands. (2) A single central slip passes down the middle of the finger, ending at the base of the middle phalanx. (3) The retinacular ligament runs obliquely along the middle phalanx, and connects the fibrous digital sheath on the volar side of the phalanges to the extensor expansion.

The extensor hood of the fingers is an example of tendons bifurcating and recombining in an intricate network that results in complex muscle actions. For example, extensor muscles can flex the proximal interphalangeal joints, and intrinsic

muscles can simultaneously flex the metacarpophalangeal joint and extend the interphalangeal joints.[49] The effect of each muscle at each joint, however, may depend on finger posture and the distribution of tendon tension. Detailed cadaver studies have shown that, although the change in length of the different components of the extensor hood is relatively small,[50,51] their spatial orientation varies considerably from one finger configuration to another, and it has been suggested that the extensor mechanism may act as a floating net to amplify tendon forces[52,53] or to coordinate joint motion.[54,55] However, the anatomy of the insertion of the extrinsic and intrinsic muscles is quite complex and shows variations in the geometry of muscle bellies and insertion tendons.[56,57]

Each of the three extrinsic muscles to the thumb on its extensor surface inserts on one of the thumb bones. The abductor pollicis longus inserts on the metacarpal where it primarily radially abducts the metacarpal, but since it bridges the wrist it secondarily radially deviates the wrist. The extensor pollicis brevis inserts on the proximal phalanx, so that it primarily acts as an extensor of the metacarpophalangeal joint but acts at the other joints with the abductor pollicis longus.

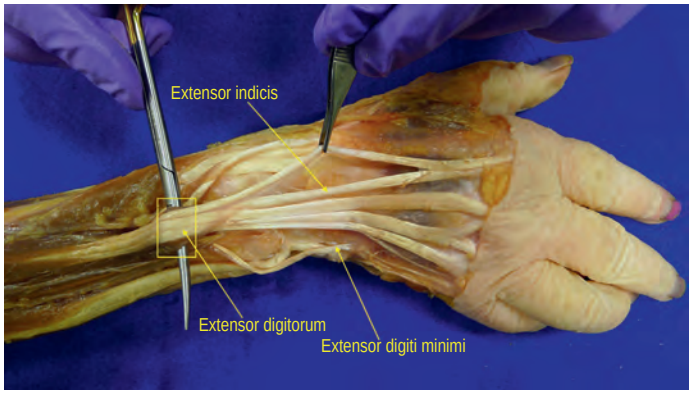

Fig. 1.22 Anatomic relations of the extensor digitorum, extensor indicis and extensor digiti minimi muscles. *(Upper limb cadaver dissection, Stanford University Division of Plastic Surgery. © 2015 James Chang, Anais Legrand. All Rights Reserved.)*

The extensor pollicis longus inserts on the distal phalanx and is the primary extensor of the interphalangeal joint. It secondarily acts to extend and dorsally abduct the other two thumb joints.

Pronators and supinators

The pronator teres originates from the common flexor origin and inserts at the midportion of the radius (Fig. 1.24). It is innervated by the median nerve and is a primary forearm pronator and a weak forearm flexor. The pronator quadratus is a short wide muscle that spans transversely across the distal radius and ulna. It is also innervated by the median nerve and is a forearm pronator. At the upper border of the pronator quadratus muscle, the anterior interosseous artery pierces the interosseous membrane and reaches the back of the forearm, where it anastomoses with the dorsal interosseous artery (Fig. 1.25). The supinator originates from the lateral epicondyle of the humerus and inserts on the proximal third of the radius. It is inn ervated by the deep branch of the radial nerve and is a primary supinator, assisted by the biceps brachii.

Extrinsic flexors (Video 1.3 ▶)

Flexion of the phalanges into the palm is a complicated motion representing the sum of actions of the long flexors (profundus and superficialis) and long extensors (extensor digitorum, extensor digiti minimi, and extensor indicis), modified and enhanced by the intrinsic muscles (interossei and lumbricals) (Figs. 1.26–1.31). The long flexors to the fingers are responsible for flexion of the interphalangeal joints and are supplements to active flexion of the metacarpophalangeal joints and the wrist joint.[58]

Biomechanical concept: muscle force production

Muscles can produce force in different ways.[59] Concentric contractions occur when muscle fibers can shorten to induce tendon stretch, tendon excursion, and/or joint motion. Eccentric contractions occur when tendon forces overpower the passive and active force the muscle can produce and the muscle fibers lengthen during muscle activation. Isometric contractions occur when the muscle is not allowed to shorten (calling this state of the muscle a "contraction", when in reality it remains the same length, is a historical artifact). The structural and biochemical properties of the sarcomere make the exact magnitude of muscle force for a given level of neural excitation a function of length of the fibers, velocity at which fibers shorten or lengthen, and its previous activation history. The force–length relationship of muscle (sometimes called the Blix curve) indicates that there is an optimal length of the fiber at which maximal force can be produced, and it drops at longer or shorter fiber lengths (Fig. 1.32). Thus, the length at which the muscle is placed in reconstructive surgeries or tendon transfers can greatly influence the force the muscle can produce postoperatively. *The force–velocity relationship of muscle indicates that muscle force drops greatly from its isometric level when muscle fibers shorten rapidly during concentric contractions, and rises to a plateau almost double its isometric level when muscle fibers lengthen rapidly during eccentric contractions* (Fig. 1.33).

The flexors are located on the volar side of the forearm and wrist and are innervated by the median nerve, except the flexor carpi ulnaris, and the flexor digitorum profundus to the ring and small fingers, which are innervated by the ulnar nerve (see Figs. 1.26–1.31). The flexor carpi radialis, flexor carpi ulnaris, and palmaris longus provide wrist flexion. The digital flexors (flexor digitorum superficialis, flexor digitorum profundus, and flexor pollicis longus) pass through the carpal tunnel to provide dual flexion to the fingers and single flexion to the thumb (Video 1.3 ▶).

The flexor digitorum superficialis tendon lies palmar (superficial) to the profundus tendon in the palm.[60] It flattens, then splits at the level of the proximal phalanx, and its two tails surround the profundus, decussating behind the profundus to insert on the middle phalanx. The flexor digitorum profundus perforates the flexor digitorum superficialis to run superficially along the length of the proximal and middle phalanges to insert at the base of the distal phalanx. The superficialis and profundus flexors contribute most of the force for digital flexion. The flexor digitorum profundus of the index finger is unique in that it has an independent muscle belly. The flexor pollicis longus inserts at the distal phalanx of the thumb (Box 1.5).

In the finger and distal palm, the flexor tendons pass through a fitted fibrous flexor sheath that has thickened areas. The tendons at this level are surrounded by synovial sheaths. The flexor pollicis longus is the interphalangeal flexor of the thumb equivalent to the finger profundi. The flexor digitorum profundus is the only muscle that flexes the distal interphalangeal joint. Testing for profundus function requires observation of active flexion of the distal interphalangeal joint. Selected flexion of one or more of the metacarpophalangeal joints, or either the proximal or distal interphalangeal joint, depends on stabilizing fixation of the remainder by flexor–extensor interplay. Elimination of any single motor element reduces the selective adaptability of a finger.

As noted above, a muscle may positively influence any joint between its site of origin and its insertion. The flexor digitorum profundus muscle originates in the forearm, and its tendon therefore bridges the wrist joint, the metacarpophalangeal joint, the proximal interphalangeal joint, and the distal interphalangeal joint before it inserts on the distal phalanx. It may flex any of these joints, depending on the dynamic fixation of the others. Fixation of the distal interphalangeal joint converts the profundus tendon into a functional superficialis tendon by recessing its prime site of action to the proximal interphalangeal joint. By combined fixation of any of the joints, the profundus tendon may primarily flex any selected one.

BOX 1.5 **Clinical pearl: independent and common flexor muscles**

The flexor profundi to the third, fourth, and fifth fingers work from a common muscle belly. Acting in unison, they fit the architectural concept of this unit as a stable vise for grasping objects. The independent function of the index profundus frees the index finger for use with the thumb to manipulate an object grasped by the viselike ulnar unit. Independence of action is well developed in the superficialis muscles and the intrinsic muscles.

Biomechanical concept: the shape of hand muscles

Many muscles of the hand depart from the simple fusiform (fish-like) shape seen in most textbooks. Many are flat, while others have multiple bellies. The interosseous muscles, for example, are bipennate. That is, a central common tendon is pulled on by fibers originating in different bones. The opposite arrangement is also found in muscles like the flexor superficialis of the fingers, which originate in a short belly that leads to a tendon that inserts in a second larger belly that then subdivides into four branches, each with a superficialis tendon to each finger. While it is possible to find muscle fibers that fire only when one finger is being flexed,[61,62] the degree to which force production in each belly is independent of the others is still unknown. Moreover, most extrinsic flexor and extensor muscles have tendons that are connected by thin strands of collagen at the level of the metacarpals that prevent independent motions of the fingers (try to extend the ring finger with all other fingers flexed). Other muscles such as the adductor pollicis have a fan-shaped origin where the resultant force at the insertion tendon depends on the distribution of force among muscle fibers. Whether or not muscle fibers fire in synchrony to produce a consistent resultant force, or if the fibers can be subdivided in functional regions to produce different resultant forces, is still unknown.

It is intriguing to realize that under certain conditions the flexor profundus may accentuate extension of the proximal interphalangeal joint. The profundus pulling primarily at the distal interphalangeal joint may flex it acutely. In flexing the distal interphalangeal joint, the insertion of the extensor mechanism is advanced distally. This advancement, combined with either a contraction or fixation of the lateral bands, results in extension of the proximal interphalangeal joint. This effect is easily aborted by the intact flexor superficialis, whose prime flexion function is exerted on the proximal interphalangeal joint. Absence of the superficialis, whether occasioned by injury or by tendon graft replacement of the profundus only, results not infrequently in flexion of the distal interphalangeal

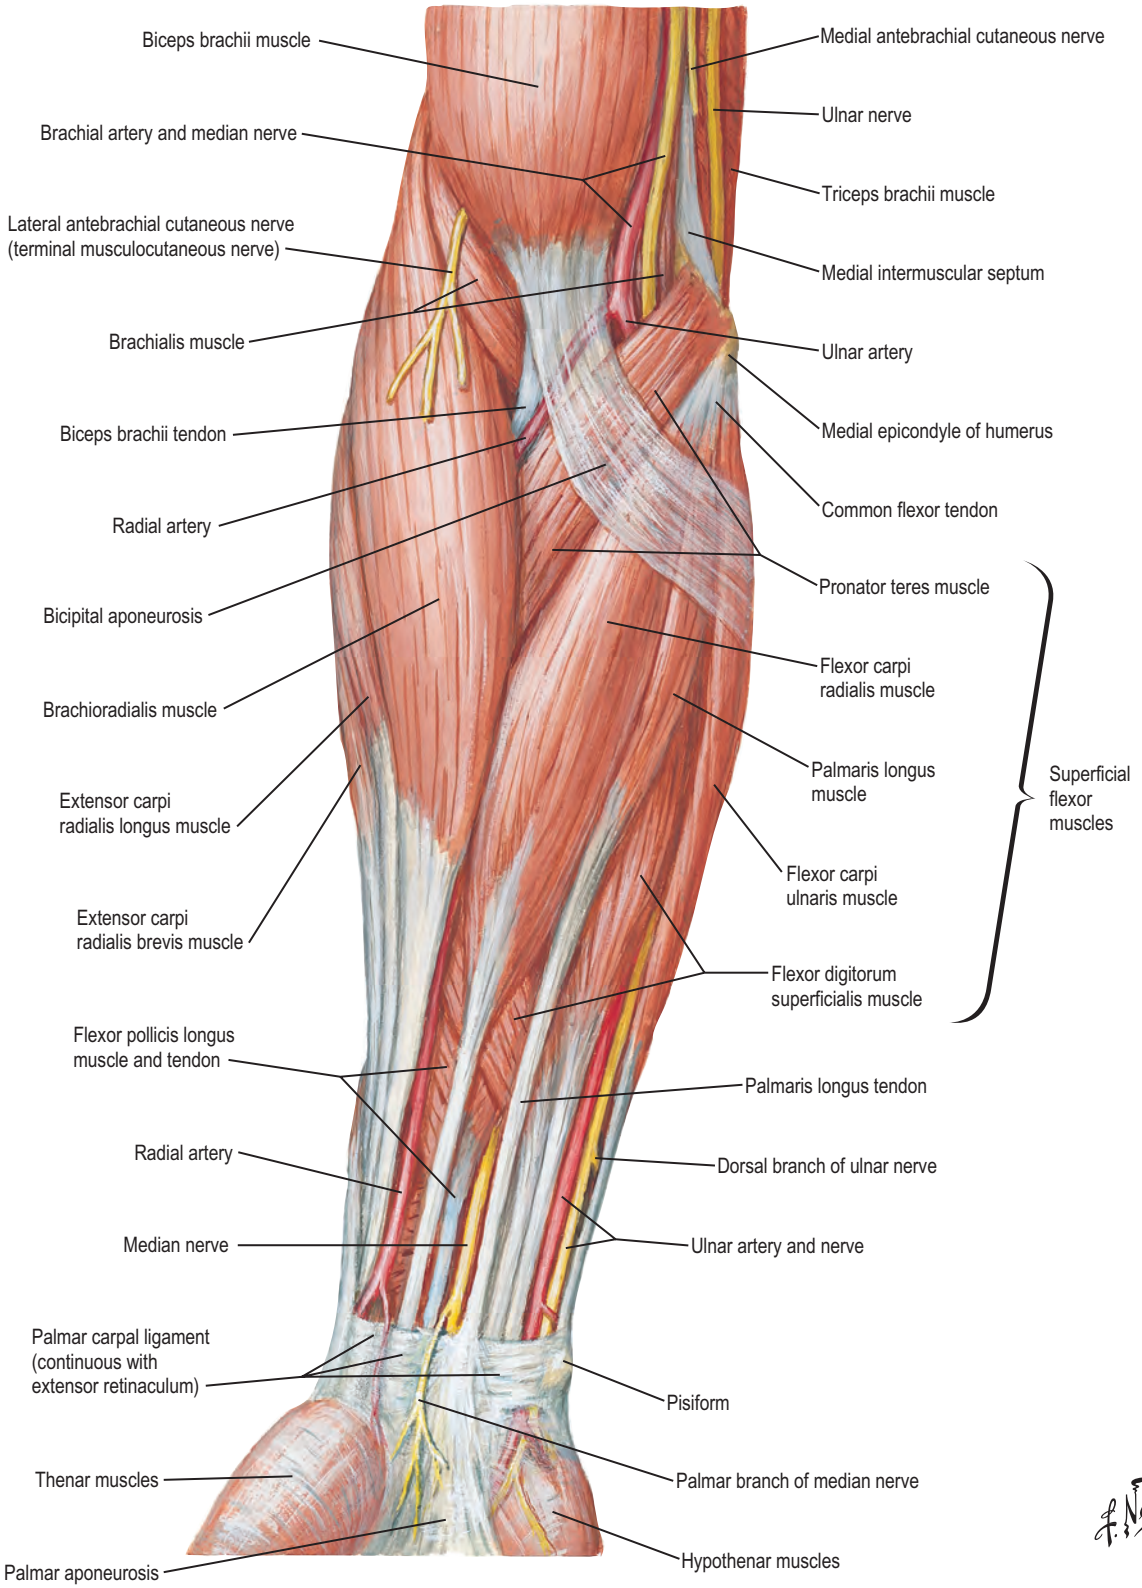

Fig. 1.26 The anatomy of the flexor muscles, from superficial to deep. *(Reprinted with permission from www.netterimages.com © Elsevier Inc. All Rights Reserved.)*

joint with recurvatum deformity at the proximal interphalangeal joint. This can be corrected by fusion of the distal interphalangeal joint, making the profundus a functional superficialis, or by tenodesis or capsulodesis of the proximal interphalangeal joint in mild flexion. It is wise to keep in mind the innumerable functional circumstances that can be created by selective interplay of multiple motor forces exerted through a series of interdependent joints.[63]

Biomechanical concept: moment arms

The moment arm of a tendon about an axis of rotation of a joint is defined as the shortest distance between the axis of rotation and the tendon as it crosses the joint (Fig. 1.34). This distance can vary with joint angle because of the suspension system of pulleys guiding flexor tendons, and/or the curved but not circular contour of the joint surfaces guiding extensor tendons.[63] The greater the moment arm, the greater the excursion of a tendon (and change in length of a muscle) that accompanies a given angle of rotation of the joint. Similarly, the moment of force (rotational action) of a tendon force about an axis of rotation increases with the magnitude of the moment arm of the tendon. These relationships between moment arm and tendon excursion/force assume hinge-type joints without sliding actions, which holds well for most finger joints. Note that a tendon that crosses a joint with multiple degrees of freedom (such as the thumb carpometacarpal joint) will have simultaneous and different actions about each axis of rotation.

The gross anatomic configuration and function of the extrinsic digital flexor tendons have been known since antiquity. The great growth in our knowledge and understanding of functional biomechanics, muscle physiology, tendon nutrition, and blood supply has influenced the management of problems involving these important flexor tendons. The long flexor tendons cross multiple joints. The tendon–muscle unit has an effect on each joint it crosses, which is altered by the positioning of the other joints in the linkage system. Thus, the influence of the long flexor tendon on one joint in the system is augmented by the function of its antagonists at each of the other joints it crosses. For example, a digital flexor tendon aids in flexing the wrist, but its flexion capability within the digit at the metacarpophalangeal joints and interphalangeal joints is increased by wrist extension using wrist extensors, which in fact are antagonists to the digital flexors at the wrist. This is the simplified definition of synergistic function – finger flexion augmented by wrist extension, and vice versa.

Synergistic and antagonistic groups of muscles in hand function must be considered when functional substitution by tendon transfers is contemplated. Obviously, certain groups of muscles have developed functional synergism, which makes readjustment natural when one group is transferred to take on the function of the other. Examples of such natural synergism are the united functions of the wrist flexors and digital flexors or the wrist extensors and digital flexors.

In its course from forearm to fingers, the digital profundus flexor crosses the palmar aspect of the wrist joint, the metacarpophalangeal joint, and the interphalangeal joints. The relationship of the tendon to the joint axes is maintained by retinacular structures, or pulleys. This prevents the bowstring effect, which would allow the tendon to move away from the joint axis, changing the moment arm and therefore the force exerted at that joint by the flexor tendon. The finely balanced relationship between the flexor muscle–tendon unit at each joint in the series may be disrupted by such a change. Such alterations can be compensated for, to some extent, by graded, proportional changes in the controlled power of antagonists, but the physiologic balance may be interfered with.

The retinacular system

The large, restraining pulley at the wrist, which serves all the long digital flexors, is the transverse carpal ligament (Fig. 1.35). It bridges the volar surface of the carpals from the pisiform and hook of the hamate medially to the scaphoid tubercle and trapezium laterally. It confines the nine extrinsic flexor tendons and the median nerve within the carpal tunnel, and prevents bowstringing of the flexor tendons at the wrist.

Three pulleys housing the flexor pollicis longus within the thumb are usually present. The proximal annular pulley is at the level of the metacarpophalangeal joint arising from the volar plate and base of the proximal phalanx. The distal annular pulley is located over the volar plate of the interphalangeal joint. Between the two is a single oblique pulley that originates proximally on the ulnar side of the middle phalanx, where it also gains fibers from the adductor pollicis before it extends to the middle one-third of the radial palmar surface of the middle phalanx. The oblique pulley must be preserved in order to prevent bowstringing of the flexor pollicis longus tendon.

Four or five discrete annular pulleys and three cruciate bands are ordinarily present in the fingers (Fig. 1.36). The most proximal pulley (A1) begins 0.5 cm proximal to the metacarpophalangeal joint. It is anchored to the volar plate and the proximal phalanx. Just distal to it is the second annular band (A2), which is the largest pulley, extending to nearly the proximal one-half of the proximal phalanx. The first cruciform band (C1) lies distal to A2 and well proximal to the proximal interphalangeal joint. The third annular pulley (A3) lies over the proximal interphalangeal joint arising from its volar plate.

The second cruciate ligament (C2) is at the base of the middle phalanx. The fourth annular pulley (A4) lies over the middle one-third of the middle phalanx, and just distal to it is the third cruciate (C3). Often it is possible to identify thickening of the sheath over the distal interphalangeal joint, which, when present, is designated the fifth annular pulley (A5). The A2 and A4 pulleys insert directly into bone over the proximal and middle phalanges, respectively. In contrast, A1, A3 and A5 are narrower, more flexible, and insert mostly into the volar plate; additionally, with the cruciate pulleys, they permit compression without impingement and expansion during finger flexion and extension, respectively.

The pulleys are strategically placed to maintain the relationship of the flexor tendons to the axis of each finger joint, thus preventing the bowstring effect. The A2 and A4 pulleys are crucial to prevent bowstringing. The gaps between pulleys allow unrestrained flexion and extension of the joints by folding and pleating of the thin sheath between pulleys.

The synovial sheaths are closed sacs around the tendons composed of a visceral layer on the tendon surface and a parietal layer on the fibrous sheath surface. The thumb synovial sheath is continuous from the wrist to the distal extreme of the flexor pollicis longus. The digital synovial sheaths for the index, long, and ring fingers usually start at the level of the distal palmar crease and extend to the distal interphalangeal joints. Often the little-finger sheath extends more proximally to communicate with a common sheath around the finger flexors and then across the wrist to the distal forearm, where tendons pass through the carpal tunnel.

During embryonic development, synovial sacs form where the flexor tendons are subject to restraint by retinacula. The tendon invaginates into the sac, creating a two-layered, closed synovial membrane around the tendon. The tendon carries its segmental nutrient vessels, and thus with invagination a mesentery-like mesotenon is formed. As time passes, and where the tendon has great excursion in relationship to adjacent bone, the mesentery refines itself to tiny, flexible bands, or vincula. At the sites of insertion, where differential motion between the bone and tendon is least, the mesenteric configuration persists, as it does for flexor tendons in the hand outside the confining tunnels. The vincula brevia form the residual mesotenon at the sites of insertion of the profundus and superficialis tendons on the phalanges (Fig. 1.37). The vincula longa are the flexible, vessel-carrying bands to each tendon

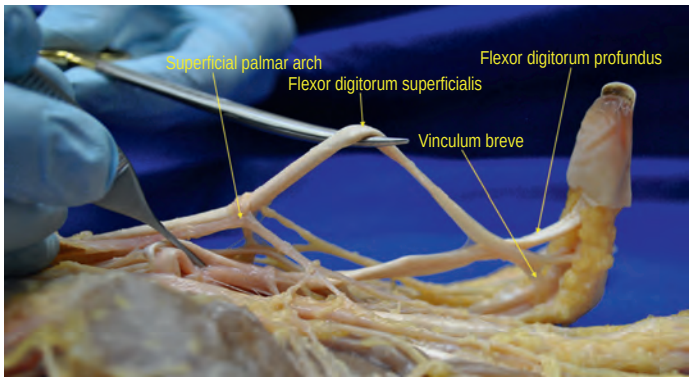

Fig. 1.37 Flexor digitorum superficialis and profundus; lateral view of the hand. *(Upper limb cadaver dissection, Stanford University Division of Plastic Surgery. © 2015 James Chang, Anais Legrand. All Rights Reserved.)*

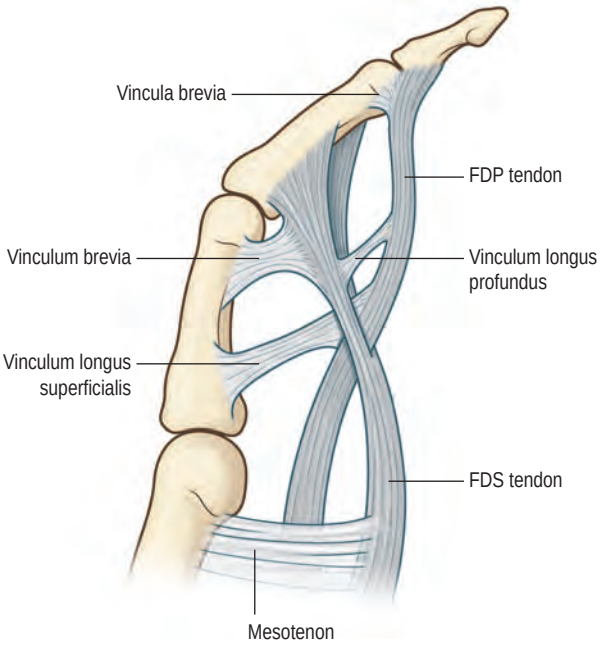

Fig. 1.38 The common configuration of the vincula. FDP, flexor digitorum profundus; FDS, flexor digitorum superficialis. *(Redrawn after Chase RA.* Atlas of Hand Surgery, *vol. II. Philadelphia: WB Saunders, 1984.)*

in the area where the complete mesotenon has disappeared (Fig. 1.38).

Because the cell population of tendons is sparse, metabolic demand is low and cells can survive with minimal nutritional support. The longitudinal blood supply to a tendon comes from its musculotendinous junction and its insertion site into bone. The segmental blood supply derives from the mesotenon where a mesotenon exists and from the vincula within the digital sheaths. It is now clear that synovial fluid within the sheath supplies nutrition to the tendon much as synovial fluid in a joint supports cartilage. This fact has altered thinking about the necessity for adhesion formation to ensure cell survival within a lacerated tendon stripped of blood supply or within tendon grafts.

On the basis of the anatomy of the flexor tendons and the associated synovial and fibrous sheaths, the area traversed by the tendons is divided into clinically important zones (Fig. 1.39).

- Zone 1 is the area traversed by the flexor digitorum profundus distal to the insertion of the flexor digitorum superficialis on the middle phalanx.
- Zone 2 extends from the proximal end of zone 1 to the proximal end of the digital fibrous sheath.
- Zone 3 is the area traversed by the flexor tendons in the palm and is free of fibrous pulleys. It extends, therefore, from the proximal end of the finger pulley system (Al) to the distal end of the wrist retinaculum, the transverse carpal ligament.
- Zone 4 is the carpal tunnel. It extends from the distal to the proximal borders of the transverse carpal ligament.
- Zone 5 extends from the proximal border of the transverse carpal ligament to the musculotendinous junctions of the flexor tendon (Box 1.6).

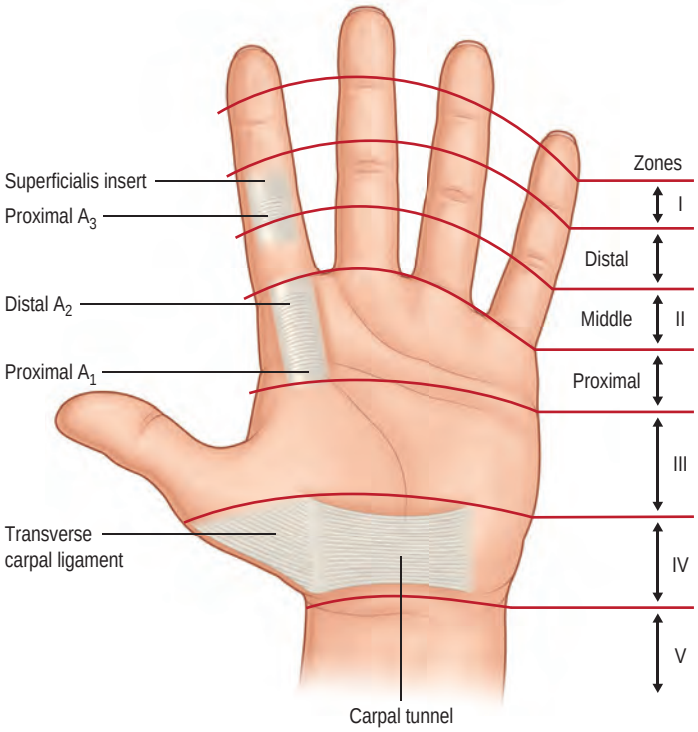

Fig. 1.39 Flexor tendon zones are classified for their relevance to flexor tendon injuries. *(Redrawn after Chase RA.* Atlas of Hand Surgery, *vol. II. Philadelphia: WB Saunders, 1984.)*

A knowledge of the classical anatomy of the synovial sheaths and potential anatomic spaces in the hand is essential for proper diagnosis and treatment of serious hand infections. The flexor tendons are shrouded in synovial sheaths, particularly where there is flexion mobility in the longitudinal arch of each ray and at the wrist. The synovial sheath of the flexor pollicis longus generally extends from the flexor insertion to a point proximal to the wrist flexor retinaculum. The same is true of the synovial sheath around the little-finger flexors, but as the little-finger sheath approaches the proximal palm just distal to the carpal tunnel, it expands to encompass the flexors of the ring, long, and index fingers. At this point it is referred to as the ulnar bursa. Each index, long, and ring finger has a flexor synovial sheath from the point of insertion of the profundus tendon to the level of the distal palmar crease in the palm. The deep space beneath the flexor tendons is divided into two compartments by the heavy vertical septum from the palmar fascia to the third metacarpal. Ulnar to the septum is the midpalmar space, and radial to it lies the thenar space. The thenar space straddles the adductor pollicis muscle like two legs extending between the adductor and deep flexors on the palmar side, and between the adductor and the first dorsal interosseous on the dorsal side. Infection starting in the digital synovial sheaths may extend proximally to the deep palmar spaces.

BOX 1.6 Clinical pearl: examination of extrinsic flexors

The function of the flexor digitorum profundus can be confined by active flexion of the distal interphalangeal joint. It is the only flexor of this joint. Since a muscle–tendon unit affects every joint between its origin and insertion, the flexor digitorum profundus may also flex the proximal interphalangeal joint. This makes the diagnosis of superficialis nonfunction more difficult. Each superficialis flexor has its own muscle belly, and each acts independently of the others. The profundus flexors are not as independent, since there is a common muscle for the long, ring, and little finger profundus tendons, and a variable degree of interconnection between these and the index finger profundus. The diagnosis of disruption of flexor digitorum superficialis function is confirmed by check-reining the profundus by holding the other fingers in extension while the patient actively attempts to flex the finger whose superficialis is being tested. Flexion of the finger at the proximal interphalangeal joint while the distal interphalangeal joint remains loosely extended confirms the functional integrity of the flexor digitorum superficialis.

Intrinsic muscles (Video 1.2 ▶)

Intrinsic muscles arise and insert within the hand (Figs. 1.40 & 1.41). They can be divided into four groups. The thenar muscles are a group of four muscles consisting of the abductor pollicis brevis, flexor pollicis brevis, opponens pollicis brevis, and the adductor pollicis brevis. The abductor pollicis brevis, opponens pollicis brevis, and superficial head of flexor pollicis brevis are median-innervated whereas the adductor pollicis brevis and the deep head of the flexor pollicis brevis are ulnar-innervated.

The hypothenar muscles are all innervated by the ulnar nerve. These four muscles include the palmaris brevis, abductor digiti minimi, flexor digiti minimi brevis, and opponens digiti minimi.

Lumbricals originate from flexor digitorum profundus tendons and insert on the radial aspect of the extensor mechanisms, distal to the metacarpophalangeal joint. They contribute to the flexion of metacarpophalangeal joints and the extension of the interphalangeal joints (Video. 1.4 ▶). The index and middle-finger lumbricals are innervated by the median nerve, whereas the ring and small-finger lumbricals are innervated by the ulnar nerve. The tiny lumbrical muscles harmonize function between the lateral band interphalangeal extensor mechanism and the flexor digitorum profundus. They have a moving site of origin from the profundus tendon. As the flexor profundus contracts, the lumbrical origin moves proximally. At the same time, the lumbrical insertion moves distally as the extensor is advanced by interphalangeal flexion. The separation of its insertion and origin makes the lumbrical more effective in flexing the metacarpophalangeal joint. Conversely, with a change in balance of power, the lumbrical tends to pull the profundus distally as it shortens the lateral bands. This combination of profundus relaxation and lateral band pull results in extension at the interphalangeal joints. Despite the fact that lumbricals have the smallest cross-sectional area in the upper extremity, they have the greatest number of muscle spindles, which are responsible for gathering proprioceptive input. They play an important role in the sensory feedback of the distal interphalangeal, proximal interphalangeal, and metacarpophalangeal joints of the fingers. Specifically, the lumbrical muscles may be important for forming a precision pinch comprised by the first three digits.[64]

All interossei are ulnar-innervated. There are three volar muscles and four dorsal muscles. The interossei originate from the metacarpals and form the lateral bands with the lumbricals. The interosseous muscles function as ulnar and

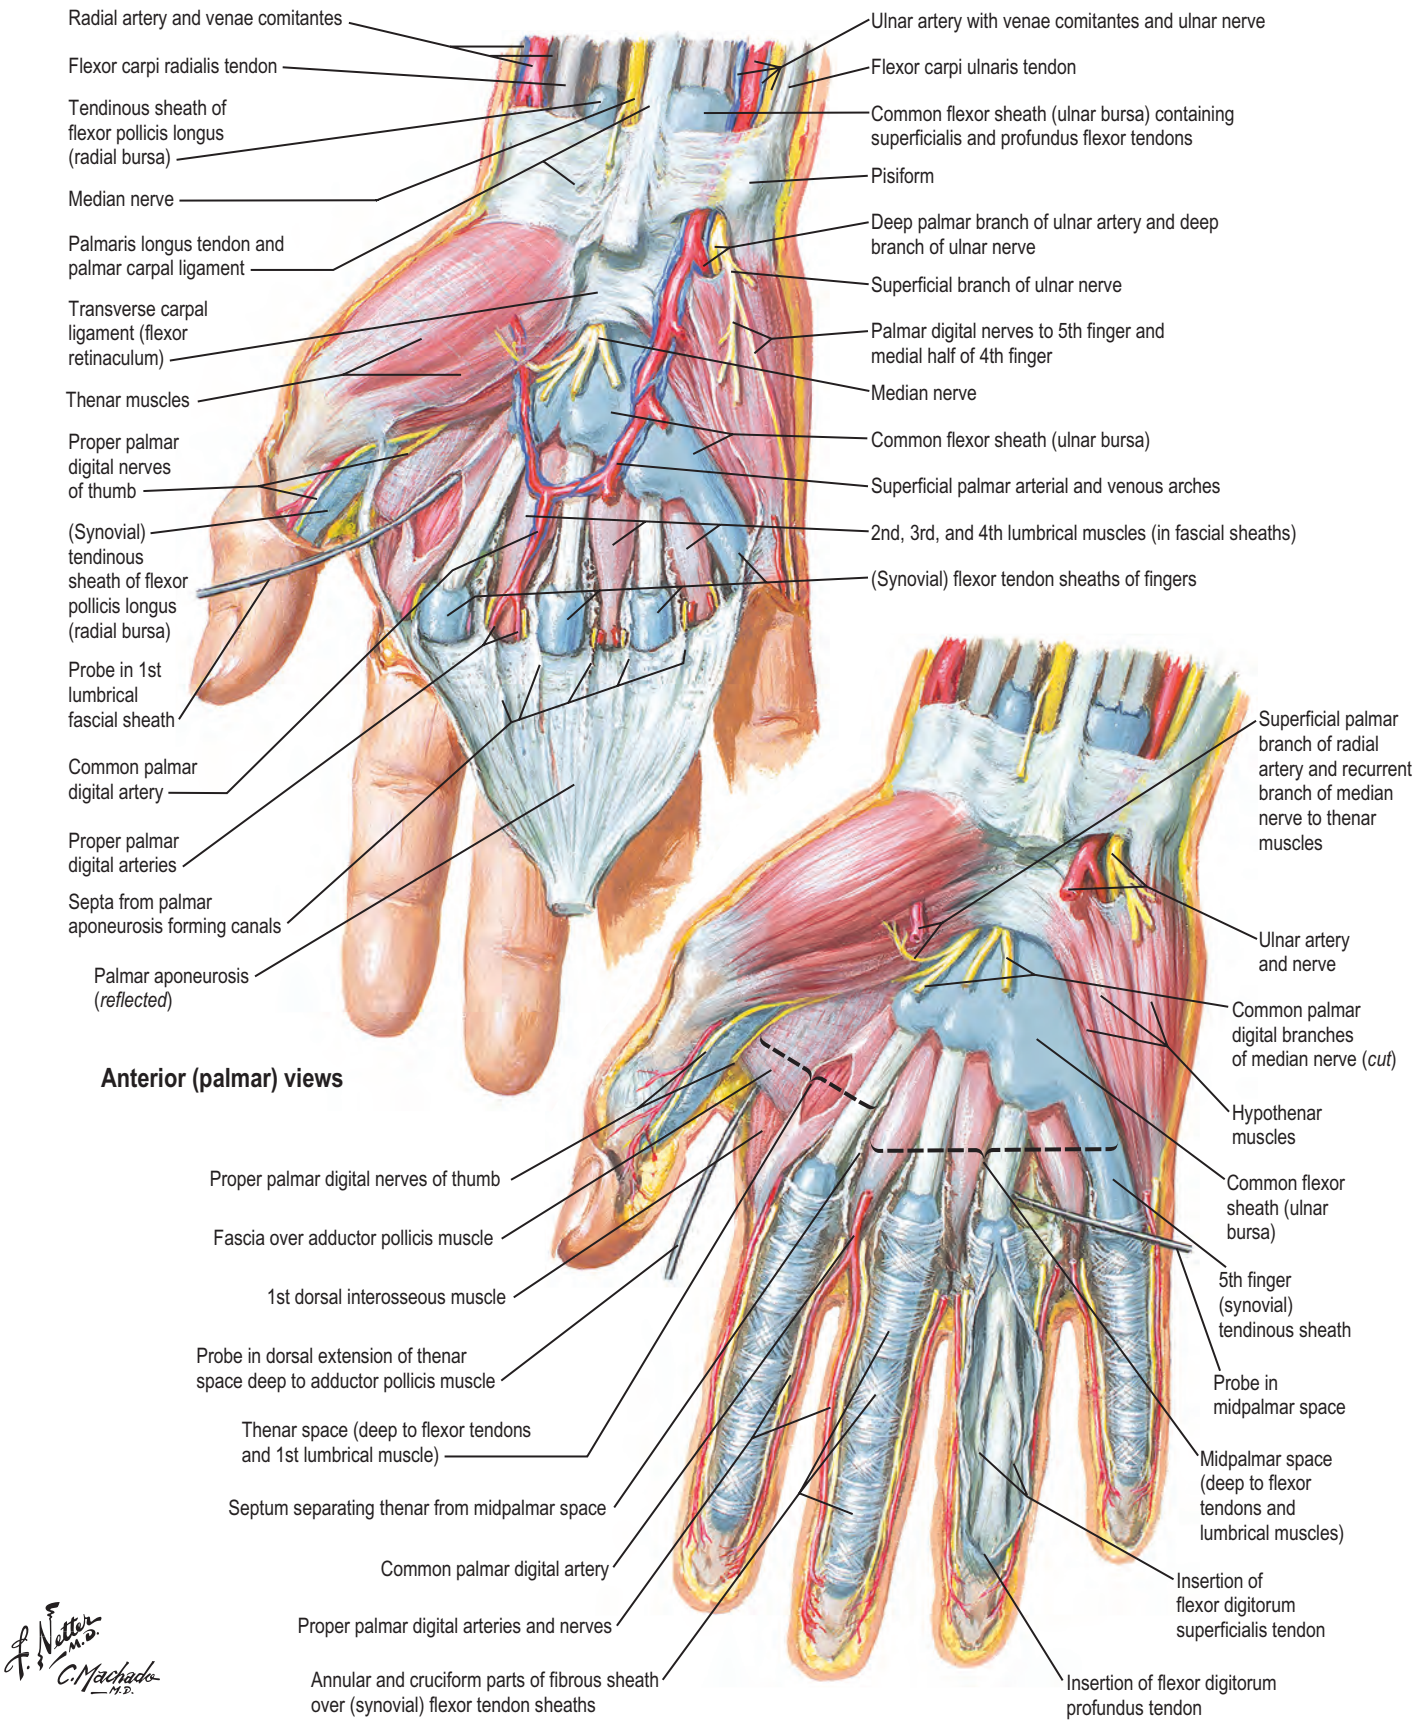

Fig. 1.40 Superficial and deep intrinsic muscles in the hand. *(Reprinted with permission from www.netterimages.com © Elsevier Inc. All Rights Reserved.)*

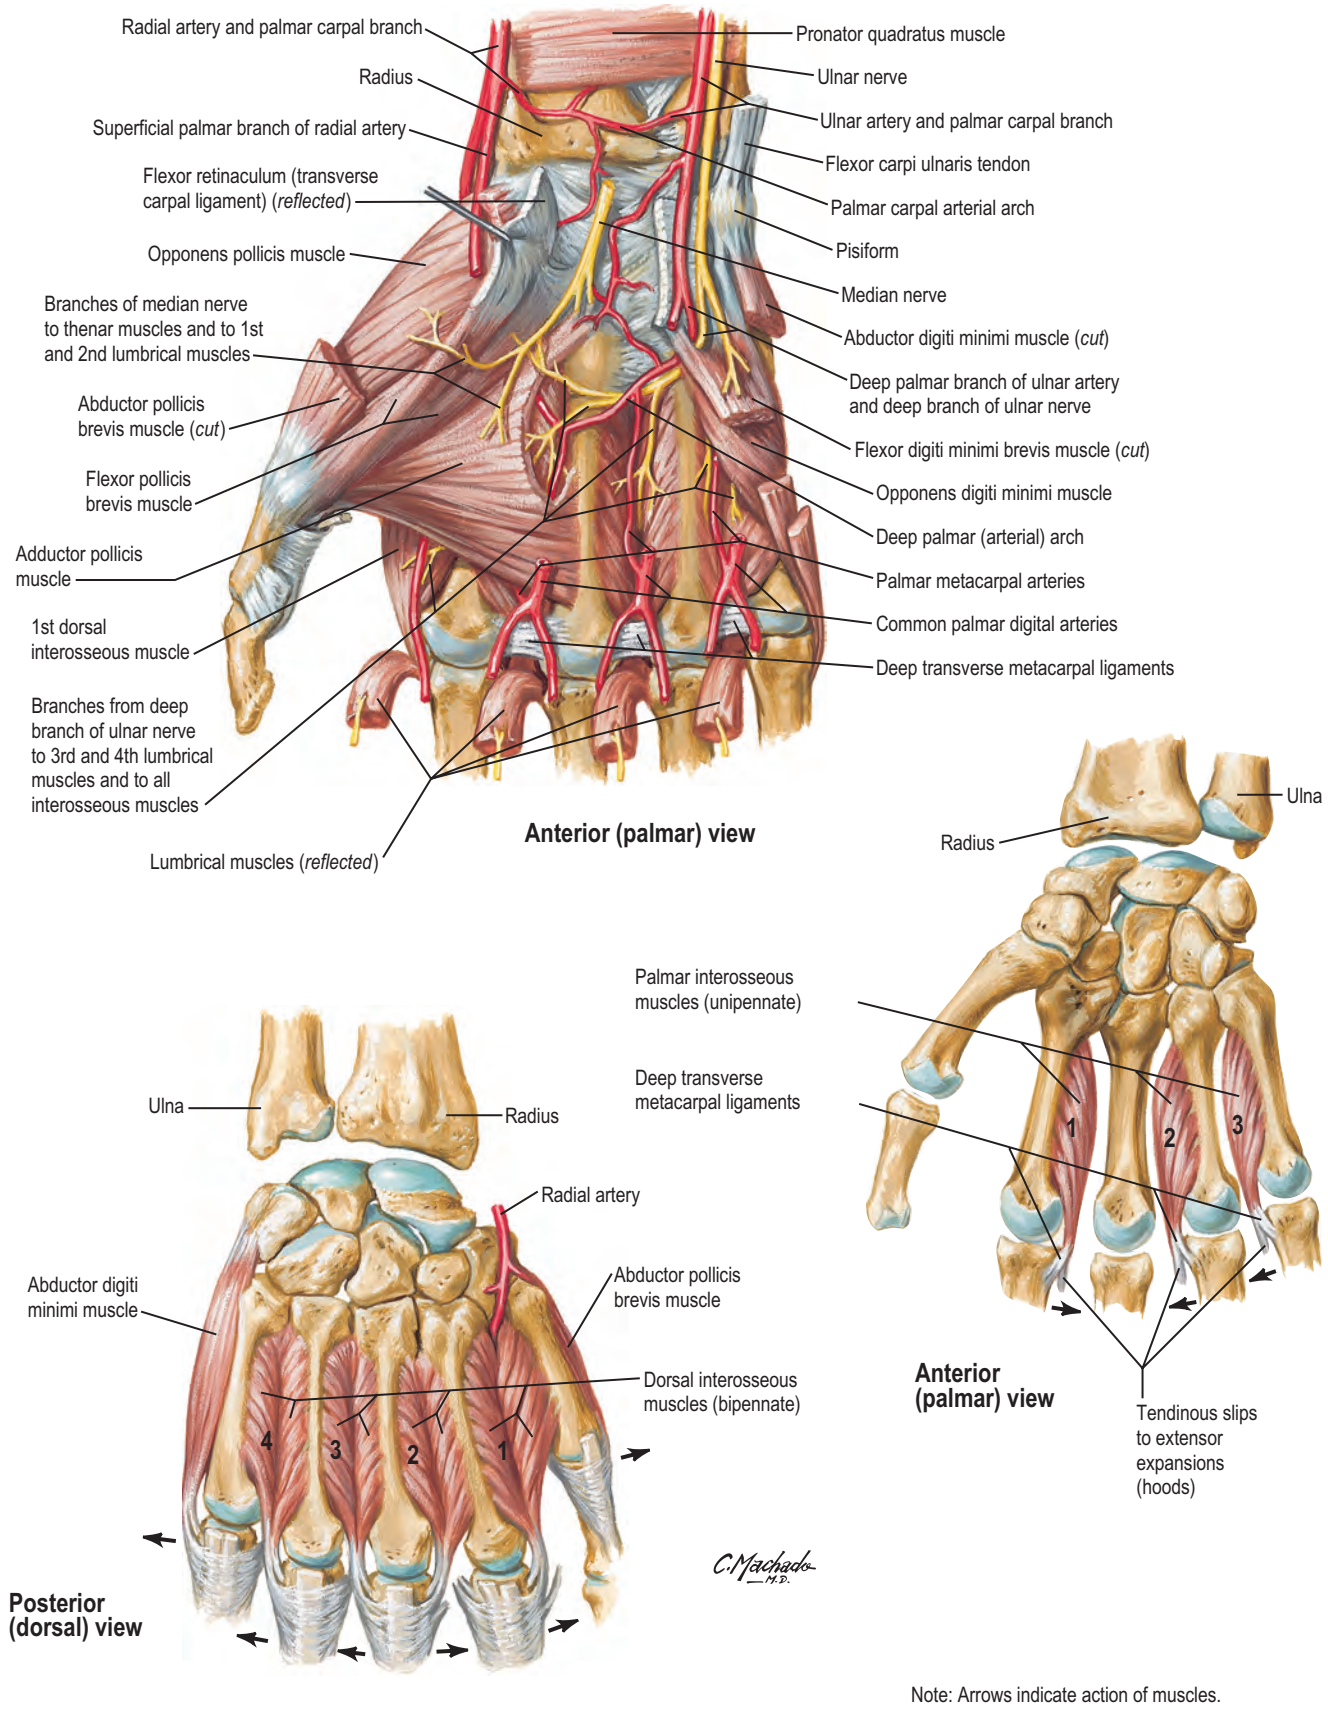

Note: Arrows indicate action of muscles.

Fig. 1.41 Superficial and deep intrinsic muscles in the hand. *(Reprinted with permission from www.netterimages.com © Elsevier Inc. All Rights Reserved.)*

radial deviators of the fingers as well as flexors of the metacarpophalangeal joints and extensors of the interphalangeal joints. The dorsal interossei act as abductors from the axis of the hand, which falls in the middle of the long finger. The long finger moves both radially and ulnarly under the influence of the second and third dorsal interossei. The abductor digiti minimi is the dorsal interosseous equivalent of the little finger. The palmar interossei adduct the fingers to the hand axis.

The pull of all the interossei palmar to the axis of the metacarpophalangeal joints and dorsal to the interphalangeal joint axis acts to flex the metacarpophalangeal joints and extend the interphalangeal joints. The position assumed is called the "intrinsic plus" posture (Fig. 1.42 & Box 1.7).

With the hand axis or fixed unit in position, the metacarpal arch is adjusted primarily by the thenar and the hypothenar muscle groups. The median nerve generally innervates all the thenar muscles on the radial side of the flexor pollicis longus. These two and one-half muscles (the abductor pollicis brevis, opponens pollicis, and superficial head of the flexor pollicis brevis) are positioning muscles that act to bring the first metacarpal into palmar abduction, thus increasing the concavity of the transverse metacarpal arch. This in turn prepares the thumb for proper pulp-to-pulp opposition with the fingers.

The thumb is steadied in position by contraction of the antagonist muscles to the abductors and the thumb adductor.

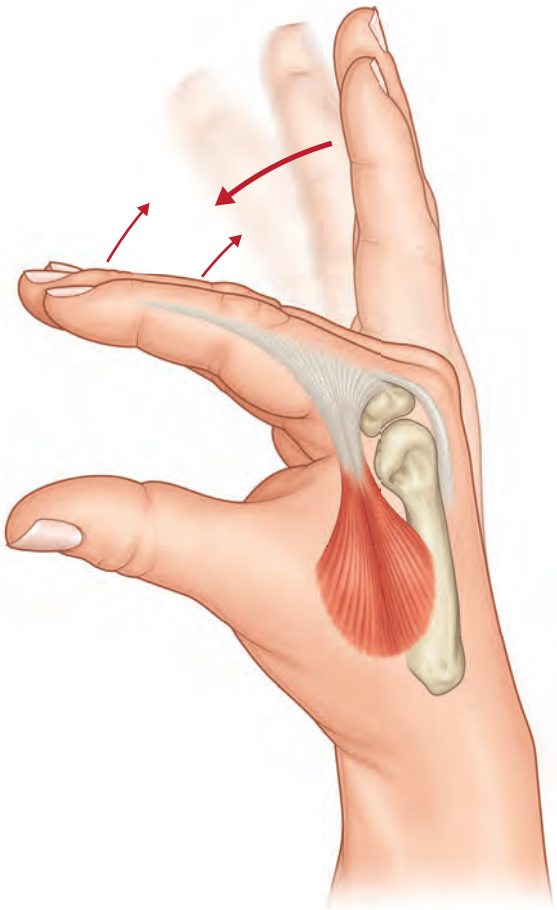

Fig. 1.42 All interossei act as prime flexors of the metacarpophalangeal joints since they pass palmar to the joint axis. Extensions into the lateral bands result in extension of the interphalangeal joints. *(Redrawn after Chase RA.* Atlas of Hand Surgery, *vol. 1. Philadelphia: WB Saunders, 1973.)*

BOX 1.7 Clinical pearl: examination of intrinsic muscles

Examination of the hand for finger intrinsic function requires little more than an understanding of the anatomy described above and its related function. Function of the interossei may be assessed by asking the patient to adduct and abduct the fingers from the hand axis in the middle of the long finger. The ability to flex the metacarpophalangeal joints with the interphalangeal joints extended ("intrinsic plus" posture) confirms interosseous function. Paralysis is reflected by clawing of the fingers with hyperextension of the metacarpophalangeal joints and flexion of the interphalangeal joints on attempts actively to extend the fingers ("intrinsic minus").

Lumbrical function is best reflected by having the patient fully flex the finger (extrinsic flexor function), then move the finger smoothly into extension at the interphalangeal joints while holding active flexion at the metacarpophalangeal joint.

Tightness or contracture of the interossei results in inability actively or passively to flex the interphalangeal joints while the metacarpophalangeal joint is extended. Inability to flex the interphalangeal joints may be a result of fixation of the extrinsic extensor tendons proximal to the metacarpophalangeal joint. Testing to differentiate these two possible etiologies is done by passively extending, then passively flexing, the metacarpophalangeal joint while assessing the degree of passive extension of the interphalangeal joints. If the interphalangeal joints passively extend when the metacarpophalangeal joint is extended, the interosseous muscle and tendon are short. If, by contrast, the interphalangeal joints extend when the metacarpophalangeal joint is passively flexed, the extrinsic extensor is adherent proximal to the metacarpophalangeal joint (Fig. 1.43).

Both the adductors and the abductors support flexion of the metacarpophalangeal joint to prevent recurvatum at this joint on pinching, which may occur with paralysis of either or both (Froment's sign). With graded relaxation of the abductors, the adductor will dominate and pull the thumb against the side of the hand.

The carpometacarpal joint is a saddle joint with a lax capsule. This allows a wide range of circumduction motion and even a small degree of distraction of the joint on traction. Stability of the thumb root is heavily dependent on the muscles affecting it. The radial-innervated extensor pollicis longus and brevis and abductor pollicis longus secure the metacarpal dorsally. Opposing this to achieve stability are two groups of intrinsic muscles that, together with the extensor and dorsal abductor, triangulate the metacarpal. These two intrinsic groups are the median-innervated palmar abductors (the abductor pollicis brevis, opponens pollicis, and superficial head of the flexor pollicis brevis) and the ulnar-innervated adductors (the adductor pollicis, first dorsal interosseus, and deep head of the flexor pollicis brevis).

When there is paralysis of any of the three major motor nerves, thumb stability is compromised. In median nerve palsy, the positioning muscles of the thenar eminence are lost, resulting in inability to oppose the thumb for pulp-to-pulp opposition with other digits. Ulnar nerve palsy results in adduction weakness and imbalance of the structures influencing the metacarpophalangeal joint. Radial nerve palsy destroys extension and dorsal abduction function, with resultant adduction contracture that becomes fixed after an extended period of unopposed adduction. The ulnar nerve innervates the hypothenar muscle group, which serves further to develop the concavity of the transverse metacarpal arch (Box 1.8).

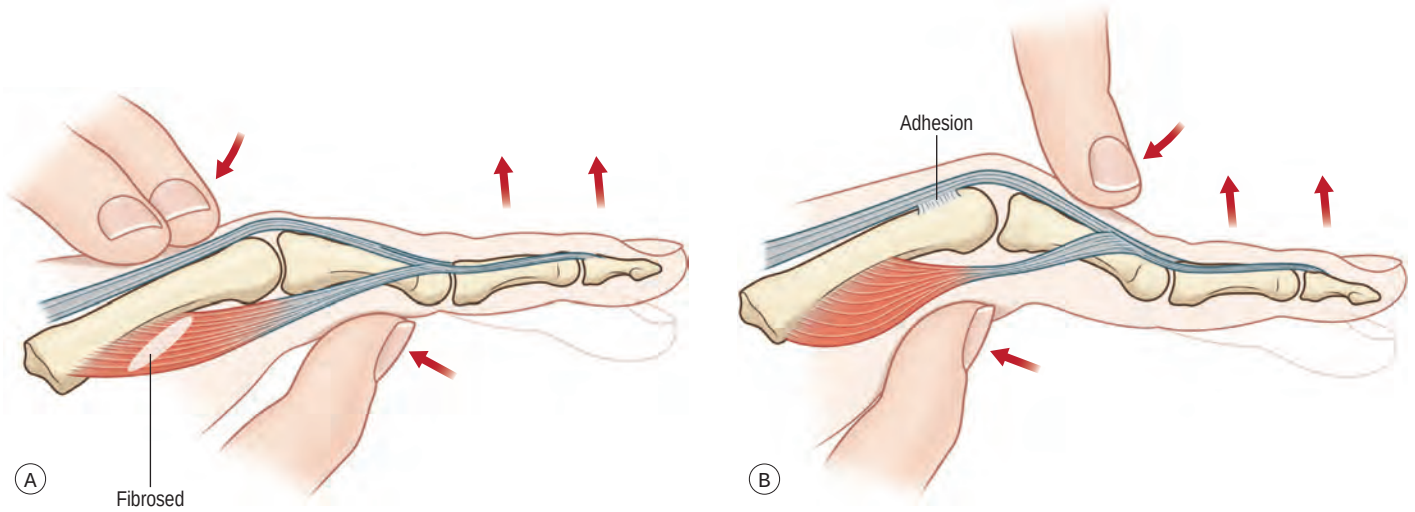

Fig. 1.43 (A,B) Testing for tightness or shortening of the interosseous muscles as a cause of passive extension contracture of the interphalangeal joint. The metacarpophalangeal joint is passively extended and the interphalangeal joints passively extend. If the cause of extensor tightness at the interphalangeal joint is a result of long extensor adhesions to the metacarpal, the interphalangeal joints will passively extend on passive flexion of the metacarpophalangeal joint. *(Redrawn after Chase RA.* Atlas of Hand Surgery, *vol. II. Philadelphia: WB Saunders, 1984.)*

Blood supply

The vascular inflow to the upper arm and hand is a continuation of the axillary artery to the brachial artery. The brachial artery is palpable just medial to the biceps tendon at the level of the elbow. The brachial artery branches into the radial and ulnar arteries at the bicipital aponeurosis of the elbow (Fig. 1.44). Supplementary arteries in the forearm include the anterior interosseous artery, the posterior interosseous artery, and the median artery.

The radial artery continues distally in the forearm between the brachioradialis and flexor carpi radialis muscles. At the wrist, the radial artery is located near the styloid process of the radius, and then travels dorsally, crossing the "anatomic snuffbox" deep to the tendons of the abductor pollicis longus, extensor pollicis brevis, and extensor pollicis longus (Fig. 1.45). In the hand, it penetrates between the first and second metacarpal bones, through an arcade in the first dorsal interosseous muscle, to enter the palm and form the deep palmar arch. A superficial branch of the radial artery arises at the level of the distal radius before the artery enters the "snuffbox" and courses over or through the abductor pollicis brevis to contribute to the superficial palmar arch. This branch contributes blood supply to the skin over the thenar area and the underlying intrinsic muscles of the thumb.

The ulnar artery is the other major branch of the brachial artery. Soon after the takeoff of the ulnar artery, the common interosseous artery originates and itself branches into the anterior and posterior interosseous arteries. The ulnar artery continues in the forearm under the flexor carpi ulnaris muscle. At the wrist, it lies radial to the pisiform and ulnar to the hook of the hamate and travels into the hand through Guyon's canal, deep to the palmaris brevis and the hypothenar fascia. Here it divides into a deep palmar branch and a superficial palmar branch. The superficial branch becomes the dominant contributor to the superficial palmar arch. The superficial arch crosses the palm at the level of the fully abducted thumb. The deep branch contributes to the deep palmar arch.

In general, the blood supply of the hand is conveniently divided into palmar vessels, which are subdivided into a superficial and a deep layer, and a single dorsal layer (Fig. 1.46).[65] For example, the superficial vascular arch and its branches constitute the superficial group, the deep arch and the palmar metacarpal branches make up the deep layer, and the dorsal arch with its dorsal metacarpal branches forms the dorsal distribution (Box 1.9).

The superficial palmar arch gives rise to three common digital arteries and multiple branches to intrinsic muscles and skin. The deep vascular arch lies at the proximal ends of the metacarpals deep to all the flexor tendons. It arises chiefly from the radial artery and becomes an arch by anastomosis with the deep branch of the ulnar artery. The deep arch is the major source of blood supply to the thumb and to the radial

BOX 1.8 **Clinical pearl: dynamics of hand function**

The central backbone of the hand is positioned in extension by the very important extensor carpi radialis brevis and longus. Flexion is affected by the flexor carpi radialis. All three muscles insert on the central two metacarpals (the second and third). These key motors are responsible for positioning the hand axis in preparation for operation of the adaptive hand elements around it. There are numerous other modifying motors to adjust the hand axis in the exact position desired, such as the flexor carpi ulnaris and extensor carpi ulnaris, which produce ulnar deviation. The fixed unit of the hand is extended from the radius at the radiocarpal joint. The entire complex is a beam attached to the ulna by the distal radioulnar joint, the interosseous membrane, and the proximal radioulnar articulation. Rotation around the fixed ulna in supination and pronation is largely under the influence of the median-innervated pronator teres and pronator quadratus and the radial-innervated supinator. The biceps and brachioradialis augment supination.

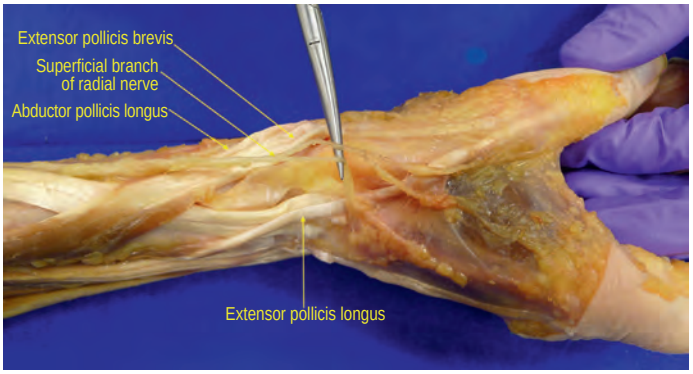

Fig. 1.45 The anatomic snuffbox. The superficial branch of the radial nerve can be palpated by stroking along the extensor pollicis longus. *(Upper limb cadaver dissection, Stanford University Division of Plastic Surgery. © 2015 James Chang, Anais Legrand. All Rights Reserved.)*

side of the index finger. This blood supply comes from the first of the four palmar metacarpal arteries. The first metacarpal artery is the prime source of blood supply to the radial and ulnar proper digital arteries of the thumb and the radial proper digital artery of the index finger. These digital arteries generally receive collateral branches from the superficial palmar arch as well. After giving its branch to the index finger, the first metacarpal artery becomes the primary source of blood supply to the thumb and is frequently called the princeps pollicis (Box 1.10).

The dorsal arteries originate proximally from the posterior interosseous artery and a dorsal perforating branch of the anterior interosseous artery. These arteries are joined by branches from the radial and ulnar arteries to form a dorsal carpal arch. Dorsal metacarpal arteries arise from this arch and extend distally to the margins of the fingers.[66–70] These dorsal arteries are joined by a varying number of vessels perforating from the deep palmar metacarpal arteries. In fact, the dominant supply to the dorsal metacarpal arteries may come from these perforators. Dorsal arteries to the thumb come from branches of the radial artery before it plunges through the first dorsal interosseous arcade. Thus, the dorsal arterial blood supply of the thumb is similar to that of the fingers (Box 1.11).

Veins generally follow the arterial pattern in the deep system as venae comitantes. An abundant superficial system of venous drainage also exists (Fig. 1.47). Ultimately, these

BOX 1.9 Clinical pearl: the Allen's test

This test may be used to assess the competence of the major arterial contributors to blood supply in the hand and the functional efficiency of the vascular arches in the hand. Palpate the radial and ulnar pulses at the wrist and prepare to compress these arteries. Have the patient make a very tight fist. Compress the arteries and ask the patient to extend the digits. The hand will be blanched white. Release pressure on one of the arteries and observe the return of a red flush on the hand. Normally, the flush is immediate and progresses across the whole hand without delay. This confirms the patency of the artery and the competence of circulatory collaterals through the vascular arches. The test may be performed to confirm the competence of each of the two major arteries before surgery or to check their competence after repair, thrombectomy, manipulation, or injury.

The Allen's test principle may be used in clinically assessing the competence of the two proper digital arteries in the fingers. It may be done by observing return of color after compression of both arteries and release of one to the digit. Compress one artery, then the other, and then both to note the individual proper artery contribution to cutaneous blood supply. The technique may be useful when one is planning an island pedicle flap from a donor finger whose digital artery may have been damaged by an injury proximal to the finger.

BOX 1.10 Clinical pearl: the relative size of digital vessels

Although two digital arteries (radial and ulnar) usually perfuse each finger, there are differences in the diameter of the radial versus ulnar digital arteries.[66] In the thumb, the ulnar digital artery is usually much larger. The index finger is similarly ulnar-dominant whereas the small finger is radial-dominant. The arteries to the middle and ring fingers do not have appreciable size differences between radial and ulnar sides. This anatomic variation may be important in finding adequate vessels for microanastomosis during replantation or revascularization.

BOX 1.11 Clinical pearl: dorsal metacarpal artery flaps

The dorsal arterial circulation of the hand is the source of multiple intrinsic hand flaps. The radial artery and the dorsal carpal arch give off the first and second metacarpal arteries which run in the intermetacarpal spaces between the thumb and index finger, and the index finger and middle finger, respectively. The third metacarpal artery is much smaller and is less reliable for flap transfer. Although multiple uses and variations have been described, the simplest method to catalogue these flaps is by artery and by direction of flow. Therefore, both the first and second dorsal metacarpal arteries may be used in an anterograde or retrograde fashion.

The first dorsal metacarpal artery (FDMA) has been found to originate from the dorsal radial artery, just distal to the extensor pollicis longus tendon. In a series of 30 hand dissections, 90% of hands had superficial or fascial FDMAs, 40% of hands had a deep intramuscular branch, and 30% had both vessels present.[67] The external diameter averaged 1.0–1.5 mm at the largest part. This vessel can be used to harvest a pedicled island flap of skin from the dorsum of the index proximal phalanx innervated by a branch of the radial sensory nerve.[68] In the anterograde fashion, this flap may reach about the dorsum of the radial two-thirds of the hand, and even to a portion of the volar hand. The reach of the FDMA flap can be extended distally if designed in a retrograde fashion.[69]

The second dorsal metacarpal artery (SDMA) was found in 29 of 30 (97%) hands dissected. The origin of this vessel varied, including from the dorsal carpal arch, radial artery, FDMA, and the posterior interosseus artery. Once the SDMA reached the index finger extensor tendons, the vessel passed deep to the tendons and within the fascia of the second dorsal interosseous muscle. The SDMA branched and became superficial at the level of the metacarpophalangeal joints. The pedicle, being more central than the FDMA, can nearly reach the entire dorsum of the hand and can also be extended in a retrograde fashion, to reach the level of the proximal interphalangeal joints of the index and middle fingers.[70]

superficial veins contribute to the cephalic and basilic veins of the upper extremities. Lymphatic drainage terminates in the axillary, supraclavicular, and subclavicular nodes.

Peripheral nerves

The peripheral nerves to the upper extremity have anatomic relationships of great importance to the surgeon. For example, one needs to know the anatomic availability for nerve block and sites where nerves are subject to compression or injury. Sites of particular susceptibility to injury coincide quite accurately with the sites chosen for anesthesia.

With the ability to perform fascicular and group fascicular repair of nerves in addition to epineurial repair, it is important for surgeons to understand the generic internal structure of peripheral nerves. The epineurium is the tubular fibrous support structure surrounding the entire nerve; it also courses between the fascicles. Subdivisions consisting of multiple fascicles within the nerve are covered by epineurium. Each fascicle is covered by perineurium. Within each fascicle are separate axons, some myelinated and some unmyelinated. Motor, sensory, and sympathetic fibers are present within each peripheral nerve. Blood vessels are found on the epineurial surface and in the internal supporting structure of the nerve. The internal topography is plexus-like, as described in detail in the classic monograph by Sunderland.[70]

The radial nerve arises from the posterior cord of the brachial plexus (C6–8). As the nerve passes the distal humerus, muscular branches innervate the brachioradialis and extensor carpi radialis longus muscles (Fig. 1.48). The radial nerve divides into terminal deep and superficial branches at the proximal forearm (Fig. 1.49). The deep posterior interosseous nerve supplies the supinator as well as muscles in all the extensor compartments: extensor carpi radialis brevis, extensor digitorum communis, extensor digiti minimi, extensor carpi ulnaris, extensor indicis proprius, extensor pollicis longus, extensor pollicis brevis, and abductor pollicus longus muscles. Finally, the deep posterior interosseous nerve terminates to supply carpal joint sensation.

The dorsal or superficial branch of the radial nerve courses through the forearm in relationship to the brachioradialis muscle on the radial side of the arm. The superficial branch of the radial nerve crosses the "anatomic snuffbox" between the extensor pollicis brevis and the extensor pollicis longus in the loose subcutaneous tissue. Here it exchanges fibers with terminal branches of the lateral antebrachial cutaneous nerve. The area the superficial branch of the radial nerve supplies is the skin of the dorsum of the hand over the radial two-thirds, the dorsum of the thumb, and the index, long, and half of the ring finger proximal to the distal interphalangeal joint.

The median nerve arises from the lateral and medial cords of brachial plexus (C5–T1) (Fig. 1.50). In the forearm, muscular branches supply the pronator teres, flexor carpi radialis, palmaris longus, and flexor digitorum superificialis muscles. The anterior interosseous branch of the median nerve innervates the flexor pollicis longus, flexor digitorum profundus (index and middle finger), and pronator quadratus muscles, and provides wrist sensation. Proximal to the wrist and running between the flexor carpi radialis and palmaris longus tendons, the palmar cutaneous branch provides lateral palmar sensation (Fig. 1.51). As the median nerve passes through the carpal tunnel, the recurrent motor branch innervates the thenar muscles (abductor pollicis brevis, opponens pollicis, and flexor pollicis brevis (superficial head). Sensory branches supply digital nerves to the thumb, index, and middle fingers, as well as the radial aspect of the ring finger (Video 1.5 ▶).

Lastly, the ulnar nerve enters the upper extremity as a branch of the medial cord of the brachial plexus (C8–T1) (Fig. 1.52). Muscular branches innervate the flexor carpi ulnaris and flexor digitorum profundus muscles to the ring and small fingers. The palmar cutaneous branch of the ulnar nerve provides sensation to hypothenar eminence and medial portion of the palm. The dorsal branch of the ulnar nerve courses around the ulnar aspect of the forearm in its distal one-fourth after branching from the main trunk at a variable site in the distal one-third of the forearm. It passes from its position deep to the flexor carpi ulnaris out through the dorsal fascia to become subcutaneous (Fig. 1.53). This sensory nerve branches to innervate the ulnar portion of the dorsum of the hand, the dorsum of the little finger, and at least part of the dorsum of the ring finger. In contrast, the main sensory branch forms the ulnar digital nerve to the small finger and the common digital nerve which divides into the small-finger radial digital nerve and the ring-finger ulnar digital nerve. The deep motor branch of the ulnar nerve passes through the pisohamate and opponens tunnel in company with the deep branch of the ulnar artery. It courses with the deep vascular arch across the depths of the palm, giving off motor branches to the four hypothenar muscles (abductor digiti minimi, opponens digiti minimi, flexor digiti minimi brevis, and palmaris brevis), all the interossei, the two ulnar lumbricals, and the thumb intrinsics ulnar to the flexor pollicis longus – the adductor pollicis brevis and the flexor pollicis brevis (deep head).

Essentially the flexor pollicis longus divides the hand into a median and ulnar-innervated portion from the motor standpoint. The ulnar nerve is far less important from the standpoint of hand sensation but is very important for its motor innervation of all the hypothenar muscles and interossei. In addition, it innervates the thumb adductor, the deep head of the flexor pollicis brevis, and the two ulnar lumbricals. Classically, all the intrinsic muscles on the radial side of the flexor pollicis longus are median nerve-innervated (the abductor pollicis brevis, opponens, and superficial head of the flexor pollicis brevis). All other intrinsic muscles in the hand receive their innervation from the ulnar nerve. The two tiny radial lumbricals (median nerve innervated) are the only exceptions to this axiom (Boxes 1.12 & 1.13).

Conclusion

In the human hand, the complicated motor balance at each joint resulting from contraction, fixation, or relaxation of opposing muscle groups is worthless in the absence of the precisely fitted elements in the skeletal architecture. The skeletal framework with its restraining ligaments is beautifully designed but is useless without proper dynamic motor tension. The anatomic presence of both architecture and functioning muscles is only serviceable when there is integrity

BOX 1.12 **Clinical pearl: median and ulnar nerve lacerations**

The ulnar and median nerves are frequently injured just proximal to the wrist. The nerves are quite superficial and it is a region where injuries to all structures are frequent. Median palsy alone results in anesthesia over the important exploring and manipulating digits (the thumb, index, and long fingers, and part of the ring finger) on the palmar surface. The median positioning muscles of the thumb become paralyzed, resulting in an inability to position the thumb for pulp-to-pulp opposition with other digits. In addition, the two radial lumbricals are paralyzed, but this may be barely perceptible functionally. There is a constant midvolar blood vessel on the median nerve that helps in its identity and in achieving very accurate axial rotation to perfect end-to-end opposition.

The ulnar nerve divides into a deep motor branch and a superficial sensory branch just beyond the pisiform. Occasionally, stab wounds of the hand result in transection of the motor branch with no sensory loss. A guide to proper fascicular orientation in the ulnar nerve is the fact that one can identify that portion destined to be the deep or superficial branches well above the wrist.

BOX 1.13 **Clinical pearl: crowded areas with unyielding boundaries**

Flexion and extension motions in the hand occur at two levels, the wrist and the finger joints. Flexion at these joints would surely create volar bowstringing at the long flexor tendons unless it were prevented by fixed retinacular conduits at these points. At the wrist the flexor retinaculum is the fixed roof of the carpal tunnel. The fibrous flexor sheath in the digits forms a fitted pulley system with condensed thickening in the areas of greatest fulcrum responsibility. At the wrist and in the digital fibrosynovial sheaths, anatomic structures create full occupancy. Any addition, whether it be more structures, postinjury or inflammatory swelling of the contents, or inflammatory tightening of the sheath, sets the stage for an inflammatory reaction and adhesion formation.

At the wrist, the median nerve passes beneath the flexor retinaculum and the transverse carpal ligament as the most superficial structure in this crowded space. It is subject to compression injury when swelling occurs within the carpal tunnel.

Just proximal to the wrist, the ulnar nerve passes from beneath the flexor carpi ulnaris along the radial side of the easily palpable pisiform. At this point the nerve enters a fibromusculofascial space that is tubular in configuration, crossing the entire length of the carpus. This is Guyon's tunnel, which is quite separate from the carpal tunnel, through which the median nerve and longitudinal structures to the digits pass. Guyon's tunnel starts at a hiatus formed by the distal edge of the volar carpal ligament superficially and the proximal edge of the transverse carpal ligament deeply. The pisiform forms the ulnar side of the tunnel, and fibers from the volar carpal ligament that plunge down to join the underlying transverse carpal ligament form the radial wall. There is no fibrous roof on the proximal part of the tunnel until the pisohamate arcade fibers are encountered distally. The roof of the tunnel, therefore, consists of a thick layer of fascia continuous with the hypothenar fascia and generally a part of the palmaris brevis muscle. Through this rather soft hiatus, the superficial branch of the ulnar artery and the arterial branches to the palmaris brevis and overlying skin pass, together with the superficial branches of the ulnar nerve. Within Guyon's tunnel the ulnar nerve lies ulnar to the artery, and the division of the ulnar nerve into its deep motor branch and two superficial branches is evident. After the superficial branches of the artery and nerve emerge through the roof of the tunnel, the deep artery and deep branch of the ulnar nerve enter the pisohamate tunnel beneath the pisohamate arcade. Although the tunnel of Guyon is devoid of a thick, fibrous roof, it is nonetheless covered by palmaris brevis fascia, creating an unyielding space, and its contents are therefore subject to compression from a variety of causes. Repeated trauma, as when one uses the heel of the hand to pound objects, may result in swelling of the tissues and resultant hypertrophy and fibrosis or hemorrhage in the tunnel, which may squeeze the nerve or artery, or both. Ganglia, tumors, or displaced bone may cause compression in the ulnar tunnel, just as occurs with the median nerve in the carpal tunnel.

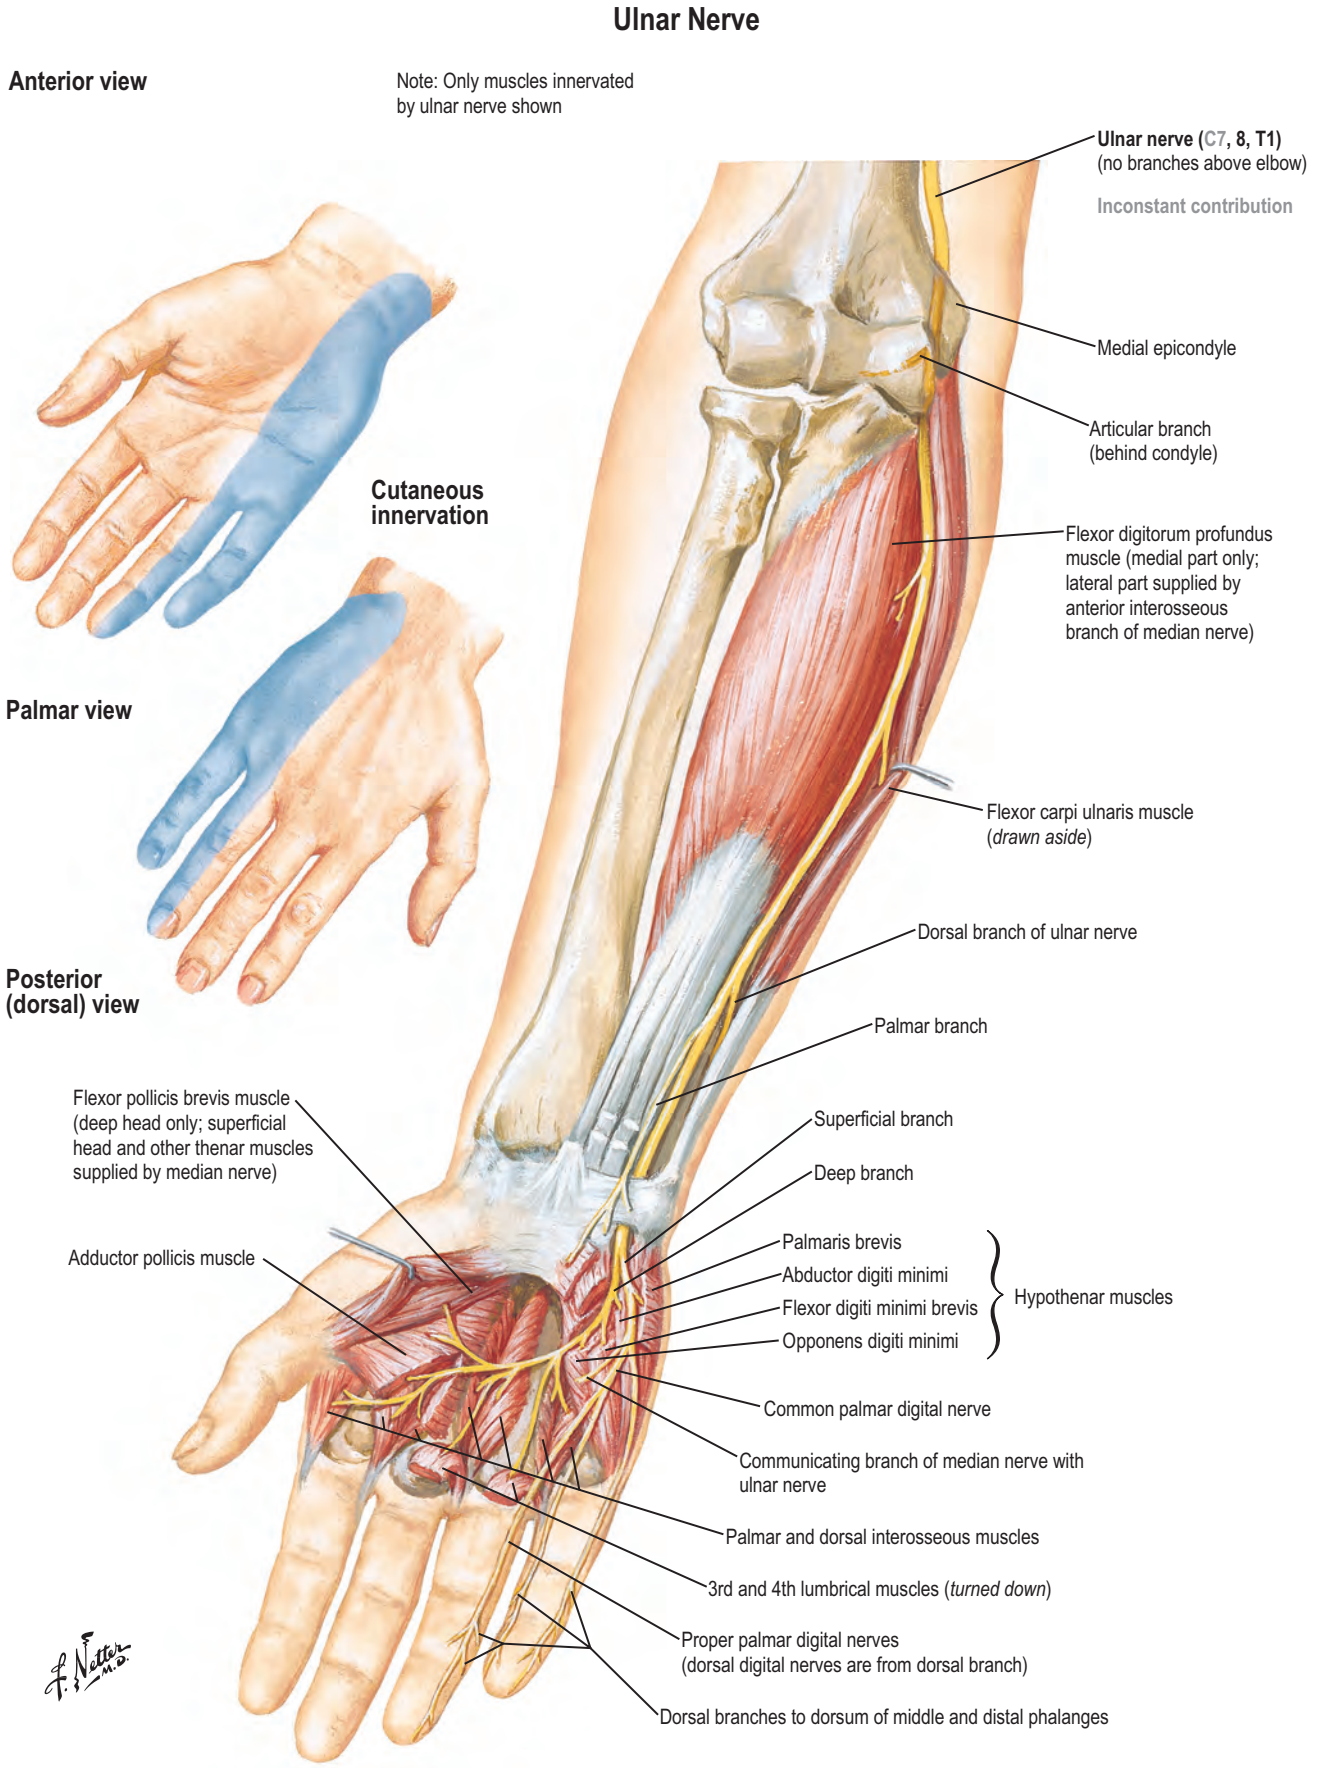

Fig. 1.52 The ulnar nerve classically gives sensory innervation to the little finger and the ulnar half of the ring finger. All hypothenar muscles, all interossei, the two ulnar lumbricals, the adductor pollicis, and the ulnar half of the flexor pollicis brevis are usually innervated by the ulnar nerve. *(Reprinted with permission from www.netterimages.com © Elsevier Inc. of the central nervous control mechanisms. As a unified interrelated melding of these elements emerges, hand function becomes the marvelous adaptable fact that it is in humans. Its function is modified and further refined by sensory integrity. Sensation is protective and influential on central motor function. Moreover, special sensation as it resides in the hand makes the hand a special sense organ with which human beings explore their environment. From a practical standpoint, surgeons need repeatedly to remind themselves of the anatomic basis for diagnosis and management of surgical problems in the hand.

Examination of the upper extremity

Ryosuke Kakinoki

Access video content for this chapter online at expertconsult.com

SYNOPSIS

- Physical examination of the upper extremity starts with a detailed and accurate patient history.
- Physical examination of the upper extremity consists of inspection, palpation, measurement of length, girth, and ranges of motion, assessment of stability, and detailed assessment of the associated nerve and vascular systems.
- Thorough understanding of the anatomy, physiology, and biomechanics of the upper extremity is essential to perform a physical examination correctly and to make a correct diagnosis of pathologic conditions of the upper extremity.
- Examiners must master correct physical examination techniques based on the anatomy, physiology, and biomechanics.
- The entire upper extremity should be examined, even if the patient's complaint focuses only on the hand.
- It is essential to master correct techniques of physical examination to identify the pathologic conditions of patients.
- Examiners should have their own routine protocol of examination of the upper extremity so as not to leave a part unexamined.
- Comparison of the affected upper extremity with the contralateral unaffected one helps examiners identify pathologic conditions.
- Imaging modalities such as X-rays, CT or MRI should be used to confirm the diagnosis drawn from the physical examinations.

Obtaining a patient history

The patient history can be the most important tool in developing an accurate diagnosis. The history should not only detail the patient's current complaint, but should also document other elements of the patient's history which may be of great significance for interpreting the patient's current problem and choosing between treatment options. A patient history should include information on the patient's demographics, current complaint, medical history, allergies, medications, and socioeconomic status. The time course of the patient history interview should also be documented.

Patient demographics

The patient's name, age, occupation, hand dominance, and hobbies should be documented. Information about previous injuries or diseases should be obtained regardless of whether they seem to be related to the patient's current complaint.

Current complaint

All information on the patient's current problem, including symptoms of pain, numbness, tingling (paresthesia), weakness, dislocation, coldness, clumsiness, or poor coordination and clicking or snapping should be documented. Each symptom should be characterized according to its location, intensity, duration, frequency, radiation and associated symptoms. The patient history should include information on activities or treatments that aggravate or ameliorate the symptoms. It is also important to record the time and place at which the initial injury occurred and the mechanism.

In trauma cases, the following data are especially important:

1. The time of the injury and the interval between the injury and the patient's presentation should be determined. The interval between an injury and revascularization of amputated fingers has a great effect on the outcome of replantation surgery.
2. The environment in which the injury occurred is important. Whether an injury occurred in a dirty or a clean environment may determine whether infection is likely to be present.
3. The mechanism of injury is also important. For example, information on the posture of the fingers and hand at the time of a tendon laceration is helpful for locating a transected tendon stump.
4. Any previous treatment associated with the injury is documented.

In non-trauma cases, the following data are especially significant:

1. The time at which symptoms such as pain, abnormal sensation, swelling or stiffness began and the subsequent progression of the symptoms is critical.
2. The effects of the symptoms on the patient's daily life, hobby or job are unique to that patient.
3. One must also ascertain whether or not the symptoms are limited to one part of the body.
4. Activities or postures that aggravate or ameliorate the symptoms are also discussed.
5. The association between time and the intensity of symptoms must be carefully documented (e.g., whether pain increases just after waking up in the morning or during the night).

Medical history

The patient's health status may influence diagnosis and treatment. Before starting treatment, it is essential to determine whether the patient has diabetes, or cardiac, pulmonary, and/or renal disease and whether the patient has a history of rheumatologic disease. Documentation of the family's medical history may be helpful for making an accurate diagnosis and for choosing an appropriate treatment if the disease is hereditary. Patients and their families should be questioned about previous problems associated with bleeding and anesthesia. It is also important to determine the course of any prior surgery.

Allergies and medications

The patient history should include data on any medications that the patient is taking. Previous allergic reactions to foods or medications should be noted. People who are allergic to shellfish are often allergic to contrast media that contain iodine.

Social history

The social history includes the patient's use of tobacco and alcohol. The amount of tobacco and alcohol used should be documented. Substance abuse and infection with hepatitis virus or HIV should also be noted. The patient's hobbies or sports should be documented because these activities often determine the most appropriate treatment.

Physical examination specific to the hand

Accurate diagnosis of hand problems depends on a systematic, careful physical examination. Physical examination should be performed routinely following a specific protocol. Even if the patient complains of a problem limited to the hand, the physical examination should start at the neck and shoulder region because the hand is suspended by the bones of the forearm, which connect proximally to the elbow joint, which in turn is stabilized by the humerus and the shoulder joint. In addition, numbness of the hand may be associated with cervical problems. These elements (inspection, palpation, measurement of range of motion, musculotendinous assessment, stability assessment, nerve assessment, and vascular assessment) should be included in the examination procedure for patients with problems of the upper extremities. An understanding of the interrelationships among these elements is helpful for drawing accurate diagnostic conclusions. Repeated physical examinations reveal how symptoms change over time, which is important for assessing the effectiveness of the treatment.

Inspection

When inspecting the upper extremities, it is essential to compare the affected extremity with the contralateral extremity because the latter can be used as a normal reference if the injury is unilateral.

Discoloration

An abnormal skin color or a change in the color of the skin of the upper extremity is indicative of a wide variety of problems. Infections often cause swelling and patches of redness with proximal streaking. Vascular problems caused by arterial inflow insufficiency often present as pale colored and the distal part of the upper limb appears to have shrunk, whereas those caused by venous outflow insufficiency present as a purple or dark red discoloration and a swollen limb. The color of a hematoma can be used to estimate the interval since the trauma occurred. A fresh hematoma has purple or blue patches, which then become green and finally yellow.

Deformity

Fractures, tumors, arthritis, and some infectious conditions can cause deformities of the upper extremity. Fractures of the phalanges of the fingers frequently result in angular rotation or malrotation of the fingers. When the fingers are held up, the point at which the long axes of the fingers converge corresponds with the position of the scaphoid tubercle. However, the long axis of a malrotated finger deviates from the position of the scaphoid.

Muscular atrophy

It is important to determine whether atrophied muscles are innervated by specific peripheral nerves. If the atrophic muscles are innervated by a specific nerve, the atrophy may have been caused by a peripheral nerve disorder. Muscular atrophy may occur under systemic neural or muscular pathological conditions; in most of these cases, the atrophy is symmetrical in the bilateral extremities. Generally, neurogenic diseases involve muscles in the distal part of the extremity and muscular diseases involve the proximal part of the extremity. The girths of the arm (a portion measured should be noted, like the arm girth 20 cm distal to the acromion) and forearm (a portion with the maximum diameter of the forearm) of both upper extremities should be measured routinely because this often reveals a loss of muscle mass, which may not be obvious to the eye.

Trophic changes

Trophic changes are associated with an abnormality of the sympathetic nervous system. Increased hair growth or

abnormal perspiration of the hands is often observed in chronic regional pain syndrome.

Swelling

Swelling can be identified by comparison with the uninvolved extremity. Localized swelling indicates recent trauma or inflammation. Diffuse swelling is often caused by infection. General swelling may originate from a lymphatic or venous obstruction. Swelling of the dorsum of the hand is also common.

Skin creases

Disappearance of skin creases is indicative of loss of motion of the joint under the creases and can be helpful in determining the validity of a complaint of an inability to move the fingers or upper extremities. Clear finger creases over joints that a patient claims he or she is unable to flex or extend indicate that the patient moves the joint. In such cases, the patient may be malingering or may have a psychiatric condition in which he or she cannot recognize motion of the joint.

Palpation

Palpation is a powerful maneuver for identifying masses, abnormal skin temperature, areas of tenderness, crepitance, clicking or snapping and effusion. Masses in the deep layer can be detected by palpation before they emerge as masses under the skin. When performing palpation, special attention should be paid to differences in hardness or mobility relative to that of the surrounding tissue. For example, subtle palpation can identify a palmar bowstring of a flexor tendon in a patient who complains of lack of finger flexion after an injury of the flexor pulleys.

Assessment of musculotendinous function

The integrity of the tendon and the strength of the muscle should be considered when conducting a musculotendinous assessment.

Posture

When musculotendinous units are examined, it should be kept in mind that the muscle strength and ranges of motion of the hand and digits change depending on the posture of the wrist, forearm or digits. For example, the range of motion of the distal interphalangeal (DIP) joint of a finger is less when the proximal interphalangeal (PIP) joint is passively extended than when the PIP joint is flexed.

Motion

Both passive and active ranges of motion should be documented. The range of motion of both the contralateral healthy limb and the affected limb should be measured and compared. The range of motion may be affected by the posture of the adjacent joints. For example, active and passive distal interphalangeal (DIP) joint flexion is limited when the proximal interphalangeal (PIP) joint of the same finger is extended. When the wrist joint is flexed, the active range of finger flexion decreases. The range of motion of a joint should be measured in a posture that permits maximum motion.

The passive range of motion is measured by holding proximal and distal to the joint in question and then moving the joint from one limit of motion to the other in the absence of any muscular contraction by the patient. A limited range of passive motion is associated with joint stiffness and/or soft tissue contracture.

The active range of motion of a joint is that which occurs when the patient contracts his or her muscles. The active range of motion is affected by tendon excursion, the posture of the hand and fingers, nerve function, and muscular strength.

Power

Muscle power is classed according to the Medical Research Council scale, which ranges from zero to five (0–5) (Table 2.1).[1] Grip strength is a good indicator of the global muscle strength of the upper extremity. Grip strength is measured using a dynamometer with the shoulder and elbow joints stabilized. The patient grips the dynamometer with the elbow straightened beside the trunk in the standing position or flexed 90° in the sitting position. Measurement of pinch grip strengths includes the average of three grip strength trials on the affected and unaffected hands using a Jamar pinch gauge in two different postures. These include a lateral pinch grip measured between the thumb pulp and the radial aspect of the second digit, and a thumb–forefinger pinch grip measured between the tips of the thumb and forefinger. For both grips, the shoulder is adducted and neutrally rotated, and the forearm and wrist are in a closely neutral and comfortable position (Fig. 2.1).

Examination of the muscles of the hand

There are many muscles and tendons in the hand. Muscles, the origin and insertion of which are both distal to the wrist joint, are called intrinsic muscles. Muscles extending across the wrist joint are called extrinsic muscles. Other muscles often compensate for a nonfunctioning muscle, in which case the nonfunctioning muscle appears to function. To evaluate muscle function, each muscle should be evaluated in a posture or situation in which the cooperative muscles do not function. For example, the extensor pollicis longus (EPL) can compensate for impaired thumb adduction. Even when the thumb adductors do not function because of ulnar nerve palsy, patients may be able to adduct the thumb using a functional EPL.

Table 2.1 Medical research council scale

Grade	Physical examination findings
0	No contraction
1	Flicker or trace contraction
2	Active movement with gravity eliminated
3	Active movement against gravity
4	Active movement against gravity and resistance
5	Normal power

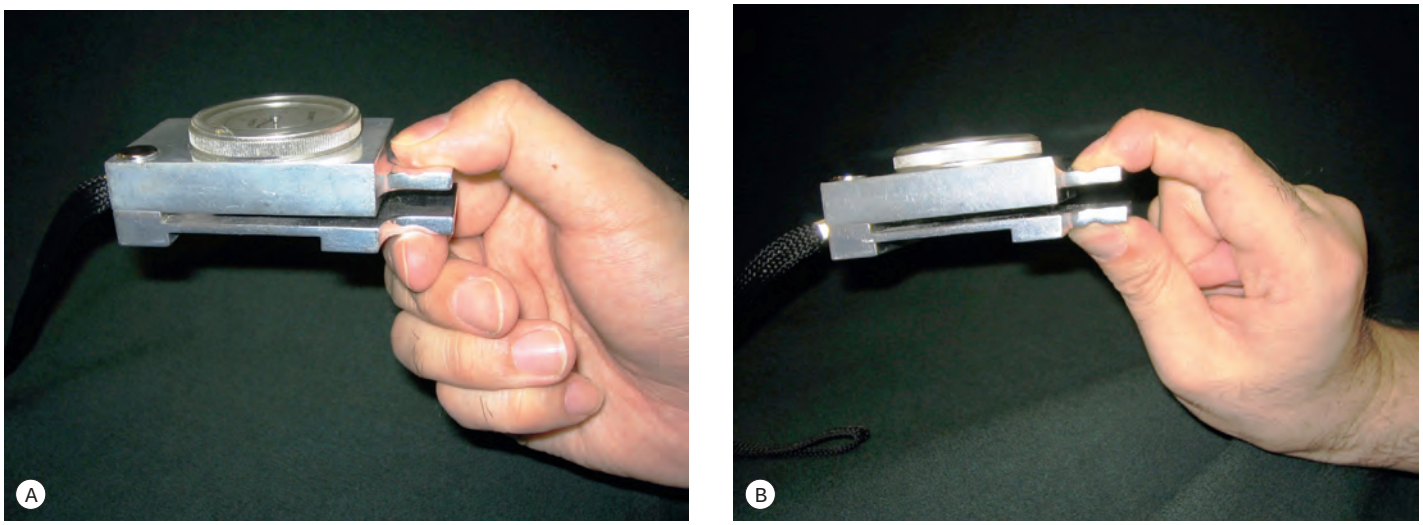

Fig. 2.1 Lateral pinch **(A)** and thumb–forefinger tip pinch **(B)** grips.

The presence of abnormal muscles or an abnormal linkage of tendons should sometimes be considered. The flexion function of the PIP joint of a finger is generally accepted to be independent of that of the other fingers because the flexor digitorum superficialis (FDS) tendon of each finger has its own muscle belly. The motion of the FDS tendon of the small finger is often linked to that of the ring and/or the long finger and the PIP joint flexion of the small finger often coordinates with that of the ring and/or long fingers.[2] The extensor digitorum manus brevis is sometimes present in the middle finger and causes dorsal wrist pain.[3]

Examination of the extrinsic muscles

Flexor digitorum profundus muscle

The flexor digitorum profundus (FDP) tendons insert on the palmar surface of the distal phalanx of the fingers. Because the FDP muscles share a common origin, holding the DIP joint of a finger in full extension may prevent motion of all FDPs.

Flexor profundus test (Video 2.1 ▶)

Purpose: This test is used to assess the continuity, excursion, and muscle power of each of the FDP tendons.
Maneuver: The patient's hand is placed palm up on a table. The examiner presses down on the proximal and middle phalanges of the target finger to keep the metacarpophalangeal (MP) and PIP joints in extension and asks the patient to flex the DIP joint. The test should be performed on each finger.

Flexor digitorum superficialis muscle

The flexor digitorum superficialis (FDS) tendons insert on the proximal half of the palmar surface of the middle phalanx of the fingers. Because each FDS tendon has its own muscle belly, its function is independent of the FDS of the adjacent fingers.

Flexor sublimis test (Video 2.2 ▶)

Purpose: This test is used to assess the continuity, excursion, and muscle power of each of the flexor digitorum superficialis tendons.
Maneuver: The patient's hand is placed palm up on a table. The examiner presses down on the distal phalanges of all fingers except that of the finger to be tested to keep the MP, PIP, and DIP joints of the other fingers in full extension. The patient is then asked to flex the finger to be tested. Each finger is tested individually. The FDS moves when the other fingers are kept fully extended.

Flexor pollicis longus muscle

The flexor pollicis longus (FPL) inserts on the palmar surface of the distal phalanx of the thumb and can be tested by asking the patient to flex the interphalangeal (IP) joint of the thumb.

Milking test of the finger and thumb flexor tendons (Video 2.14 ▶)

Purpose: To evaluate the continuity and excursion of the extrinsic flexors of the thumb and fingers. This test and the dynamic tenodesis test (Video 2.13 ▶) are useful for distinguishing nerve palsy from tendon rupture.
Maneuver: The patient is asked to place the dorsum of the forearm and the hand on a table and to relax. The examiner pushes down on the musculotendinous junctions of the flexor tendons around the palmar aspect of the mid-forearm. If the tendons have normal excursion and no adhesions, the fingers and thumb flex as the forearm is pushed down.

Extensor pollicis brevis and abductor pollicis longus muscles

The extensor pollicis brevis (EPB) inserts at the dorsal base of the proximal phalanx of the thumb. It is sometimes connected to the EPL. The abductor pollicis longus (APL) has several tendon slips and inserts at the dorsolateral base of the thumb metacarpal and trapezium. Both tendons pass through the first dorsal compartment at the wrist (the APL tendon lies radial to the EPB in the compartment). When the patient abducts the thumb maximally, the EPB and APL tendons as well as the EPL tendon merge under the skin over the radiodorsal side of the wrist and create the snuffbox. The EPB and APL tendons are palpable as taut tendons in the radiopalmar border of the snuffbox. The tendinitis of the EPB and APL at the radial wrist level is known as de Quervain's tenosynovitis. There are two provocative tests for diagnosing de Quervain's tenosynovitis.

Finkelstein test

Purpose: To detect de Quervain's tenosynovitis.
Maneuver: The patient places the hand on a table with the thumb up. The examiner pushes down on the proximal phalanx of the thumb. A patient with de Quervain's tendinitis will experience pain or discomfort in the first extensor compartment of the wrist.

Eichoff test (Video 2.15)

Purpose: To detect de Quervain's tenosynovitis.
Maneuver: The patient is asked to hold the thumb with the four flexed fingers of the affected hand. The hand is deviated ulnarly by the examiner. A patient with de Quervain's tenosynovitis will experience pain or discomfort in the first extensor compartment of the wrist.

Extensor carpi radialis longus and brevis muscles

The extensor carpi radialis longus (ECRL) and brevis (ECRB) tendons insert at the dorsal bases of the second and third metacarpal bones, respectively. The function of these muscles is to extend the wrist joint. Because the functional axis of the ECRL deviates radially, the ECRL extends the wrist dorsoradially. When the ECRB does not function, extension of the wrist deviates radially because of the intact ECRL tendon. The extensor digitorum communis (EDC) tendon also may function as a wrist extensor. To remove the EDC contribution to wrist extension, the patient is asked to make a fist and then extend the wrist. Making a fist eliminates EDC function.

Extensor pollicis longus muscle (Video 2.3)

The extensor pollicis longus (EPL) passes through the third dorsal compartment, turns radially at the Lister's tubercle and inserts at the dorsal base of the distal phalanx of the thumb. The EPL extends the IP joint of the thumb. The hand is placed palm down on a table with the thumb adducted. The patient is asked to lift only the thumb off the surface of the table, keeping the thumb adducted. The taut EPL tendon is palpable in the radiodorsal aspect of the wrist.

Clinical tip

The EPL tendon is often connected to the extensor pollicis brevis (EPB) tendon. Although the EPL tendon is not functioning, the thumb IP joint can be extended by means of the force of the EPB tendon. When examining EPL function, one must eliminate EPB function by stabilizing the thumb MCP joint.

Extensor digitorum communis muscles (Video 2.4)

The extensor digitorum communis (EDC) tendons pass through the fourth extensor compartment and insert at the dorsal base of the middle phalanges of the fingers. They mainly extend the MP joint, while the intrinsic extensors extend the PIP and DIP joints. EDC function is examined by asking the patient to lift the MP joints of four fingers (the index to the small finger) keeping the PIP and DIP joints flexed.

Extrinsic tightness test

The PIP joint is more easily flexed when the MP joint is kept extended than when it is flexed, signifying that tightness of the extrinsic muscles is present.[4]

Extensor indicis proprius muscle

The extensor indicis proprius (EIP) tendon passes through the fourth extensor compartment at the wrist deep to the EDC tendon and merges with the ulnar side of the index finger EDC tendon over the MP joint. The function of the EIP is to extend the MP joint of the index finger, which is isolated from the extension of the MP joints of the other fingers. The EIP is functional if the patient can straighten the index finger completely when the other fingers are flexed in a fist.

Extensor digiti minimi muscle

The extensor digiti minimi (EDM) tendon passes the fifth extensor compartment and merges with the ulnar side of the small finger EDC tendon at the MP joint level. Because the EDM tendon is usually divided into two tails distally, both tails of the tendon must be transected when the tendon is transferred. This tendon is evaluated by asking the patient to straighten the small finger when the other fingers are flexed into a fist.

Extensor carpi ulnaris muscle

The extensor carpi ulnaris (ECU) tendon passes through the sixth extensor compartment and inserts on the dorsal base of the fifth metacarpal bone. The function of this tendon is ulnar deviation of a wrist that is held extended. The wrist cannot be extended dorsally only by the ECU. This tendon is evaluated by asking the patient to make a fist and to lift and deviate the wrist ulnarly. The tendon is palpable radial to the ulnar styloid process.

Examination of the intrinsic muscles

Thenar muscles (Video 2.5)

The thenar muscles cover the thumb metacarpal and consist of three muscles: the abductor pollicis brevis, the flexor pollicis brevis and the opponens pollicis. The muscles move the thumb into opposition, enabling the thumb to touch the fingertips when the nails are parallel. These muscles are evaluated by asking the patient to place the dorsum of the hand flat on a table and to raise the thumb until it is perpendicular to the palm. The patient is then asked to resist a downward force by the examiner on the thumb.

Adductor pollicis muscle

The adductor pollicis (ADP) muscle arises from the third metacarpal and inserts to the ulnar base of the proximal phalanx of the thumb. Some fibers of the ADP extend dorsally to form an extensor apparatus for the thumb. Together with the first dorsal interosseous muscle, the ADP approximates the thumb to the second metacarpal.

Interosseous and lumbrical muscles (Video 2.6)

The interosseous and lumbrical muscles flex the MP joints and extend the PIP and DIP joints of the fingers. In addition, four dorsal interosseous muscles abduct the thumb and the radial three fingers and three palmar interosseous muscles adduct the fingers. The second and third dorsal interosseous muscles are evaluated by asking the patient to place the hand flat on a table and then to stretch the long finger upward (i.e., to hyperextend it) and to deviate it radially and ulnarly. Patients with ulnar nerve palsy cannot do this because of loss of power

in the interosseous muscles (the *Pitres–Testut sign*). The first palmar interosseous and the second dorsal interosseous muscles are tested by crossing the index and middle fingers (*crossing fingers sign)*. The patient is asked to cross a flexed long finger over the index finger or to cross a flexed index finger over the long finger when the palm and the ring and little fingers are placed flat on a table. (Finger abduction refers to movement away from the long finger; finger adduction refers to movement toward the long finger.)

Intrinsic tightness test (Bunnell)

Purpose: This test assesses the contracture of the interosseous muscles.
Maneuver: The PIP joint is more easily flexed when the MP joint is flexed than when it is extended (0 degree extended position) if tightness of the interosseous muscles is present (Fig. 2.2).[5] The test can be performed using radial and ulnar deviation of the finger to distinguish between tightness of the radial and ulnar lateral bands.

Lumbrical-plus test

The lumbrical muscle connects the flexor digitorum profundus tendon and the radial lateral band of each extensor tendon. The PIP and DIP joints are apt to be extended when a patient with lumbrical muscle tightness intends to flex a finger.[6] The finger flexion is thus blocked (paradoxical movement of the finger) (Fig. 2.3). This movement is often seen in the situation of FDP tendon repair using a tendon graft, which is longer than the appropriate length.

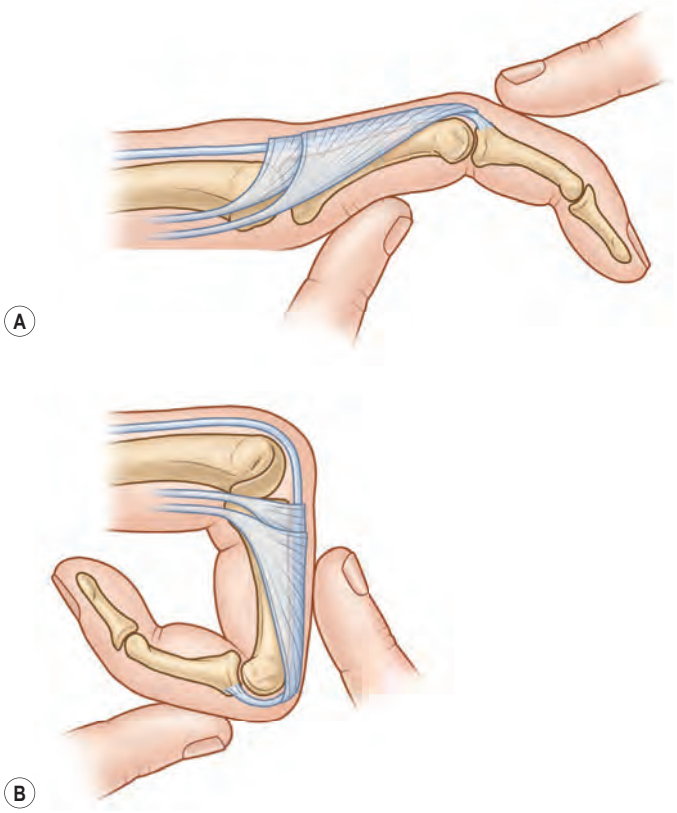

Fig. 2.2 Intrinsic tightness test. If there is a tightness of the interosseous muscles, the PIP joint can be more easily flexed when the MP joint is held flexed than when the MP joint is extended. **(A)** The MP joint is extended. **(B)** The MP joint is flexed.

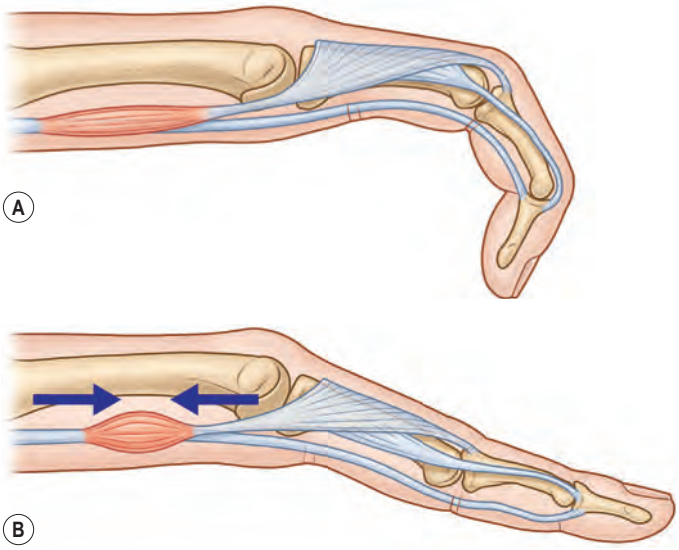

Fig. 2.3 Lumbrical muscle tightness test. Because the lumbrical muscle connects the flexor digitorum profundus tendon and the radial lateral band of the extensor tendon, the PIP and DIP joint are apt to be extended when the patient intends to flex the finger (paradoxical movement). **(A)** Normal, **(B)** Abnormal, with lumbrical tightness causing extension of the finger.

Hypothenar muscles

The hypothenar muscles (the abductor digiti minimi, the flexor digiti minimi, the opponens digiti minimi, and the palmaris brevis muscle) abduct the small finger, moving it away from the other fingers.

Assessment of stability

The tightness of the ligaments around a joint, morphology of the surface of a joint, and musculotendinous balance around a joint are useful indices of joint stability. The stability of ligaments is tested by holding the portions distal and proximal to the joint and gently moving the joint passively to stress the ligaments that stabilize the joint. When assessing joint stability, the biomechanical and physiological properties of the ligaments should be taken into consideration and the stress forces applied should be appropriate for the ligament in question. For example, the bilateral collateral ligaments of the finger metacarpal (MP) joints tighten when the joint is in the flexed position (Fig. 2.4), whereas those of the PIP joints tighten when the joints are in an extended position. The lateral instability of the MP joints is assessed at the fully flexed position, and the PIP joints should be checked at the neutral position. It is useful to measure the opening angle of the affected joint under stress using X-rays and to compare the opening angle of the affected joint with that of the corresponding healthy joint of the opposite hand (Fig. 2.5).

Assessment of the stability of wrist joints is complex and difficult. The stability of the wrist joint is determined by the stability of the radiocarpal, ulnocarpal, distal radioulnar, and midcarpal joints. Special tests for assessing the stability of specific ligaments or imaging tools such as X-rays, CT or MRI may be helpful in making a diagnosis.

Clinical tip

Assessment of the lateral instability of the MP and PIP joints of fingers.

The straight portions of the bilateral collateral ligaments of the finger metacarpal (MP) joints tighten when the joint is in the flexed position, whereas those of the PIP joints tighten when the joints are in an extended position. The lateral instability of the MP joints is assessed with the joint in full flexion, and the PIP joints should be checked with joint in the neutral position.

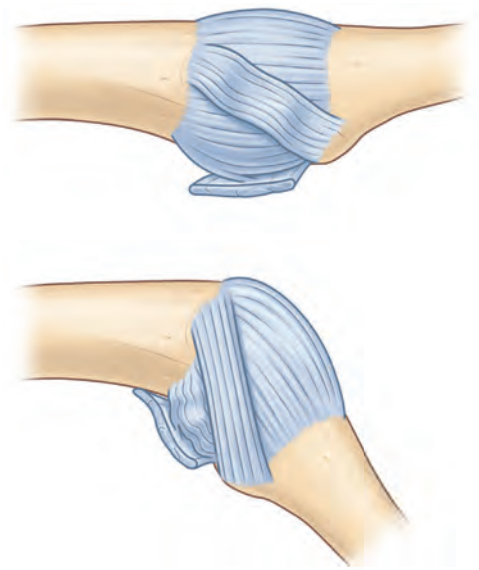

Fig. 2.4 The collateral ligament of the MP joint. The proper portion of the collateral ligament is relaxed when the joint is extended (top) and is tight when the MP joint is flexed (bottom). The smaller accessory portion has the opposite effect.

Scaphoid shift test (Watson) (Video 2.12)

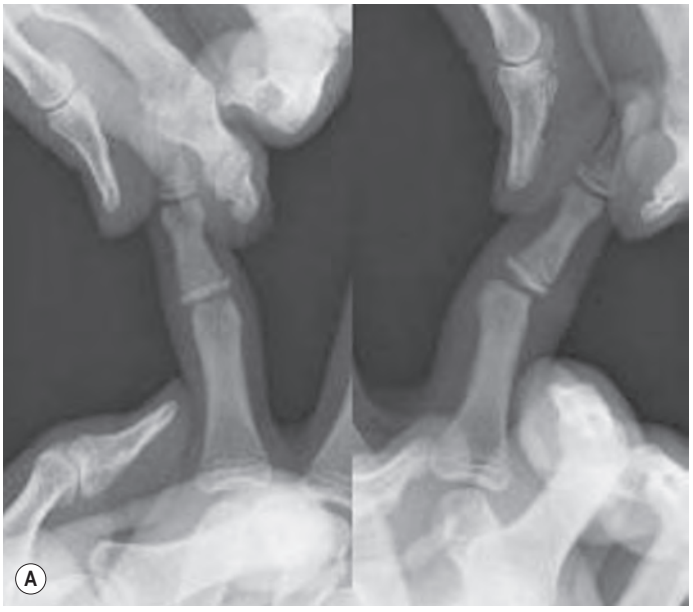
Purpose: This test was originally developed to detect loosening or disruption of the scapholunate interosseous ligament. This test can also be used to detect a scaphoid fracture or scapholunate advanced collapse (SLAC) arthritis.
Maneuver: When the wrist deviates radially, the scaphoid rotates palmarly, and the palmar prominence of the tubercle of the scaphoid thus becomes evident. However, when the wrist deviates ulnarly, the scaphoid rotates dorsally and the bony prominence is less evident. The examiner holds the dorsum of the patient's hand with his or her fingers and places his or her thumb onto the radial palmar wrist to palpate the bony prominence of the scaphoid tubercle. When the examiner holds the patient's hand and deviates the wrist radially and ulnarly, he or she will feel the motion of the bony prominence under his or her thumb. When the examiner feels the palmar movement of the bony prominence of the scaphoid tubercle when moving the patient's wrist from the ulnar to the radial deviation, he or she pushes dorsally up on the tubercle against the force of the palmar movement. If scapholunate ligament insufficiency is present, the examiner will feel a clunk on the thumb over the distal tubercle.[7]

Finger extension test

Purpose: To detect the pre-dynamic rotary subluxation of the scaphoid (dorsal wrist syndrome).[8]
Maneuver: When being asked to extend the DIP and PIP joints of all fingers fully, keeping the wrist and the MP joints of all fingers in a full-flexed position, patients with overloaded scapholunate ligaments (pre-dynamic rotary subluxation of the scaphoid) experience pain around the scapholunate joint in the dorsal wrist.

Triquetrolunate ballottement test and the lunotriquetral shuck test

Purpose: To evaluate the stability of the lunotriquetral ligament.



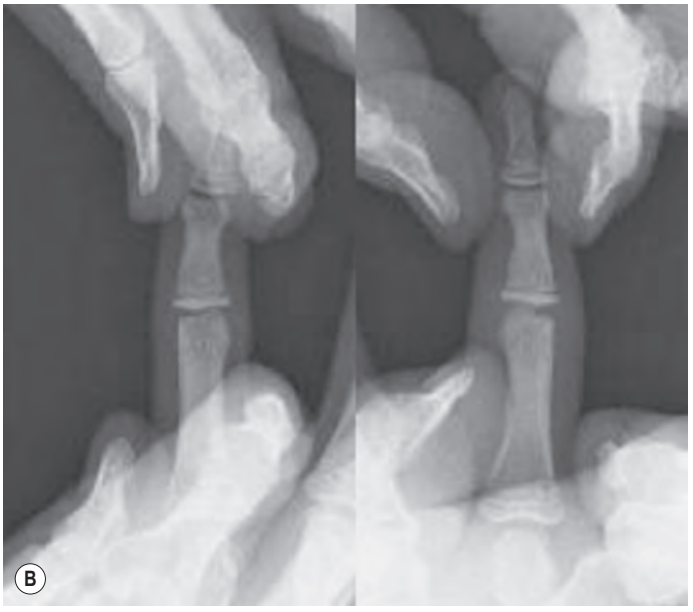


Fig. 2.5 Rupture of the radial collateral ligament of the index finger PIP joint. Measure the opening angle of the affected joint under the radial and ulnar stress forces on X-ray films and compare the angle with that of the corresponding normal joint of the opposite hand. **(A)** Affected finger. **(B)** Normal opposite finger.

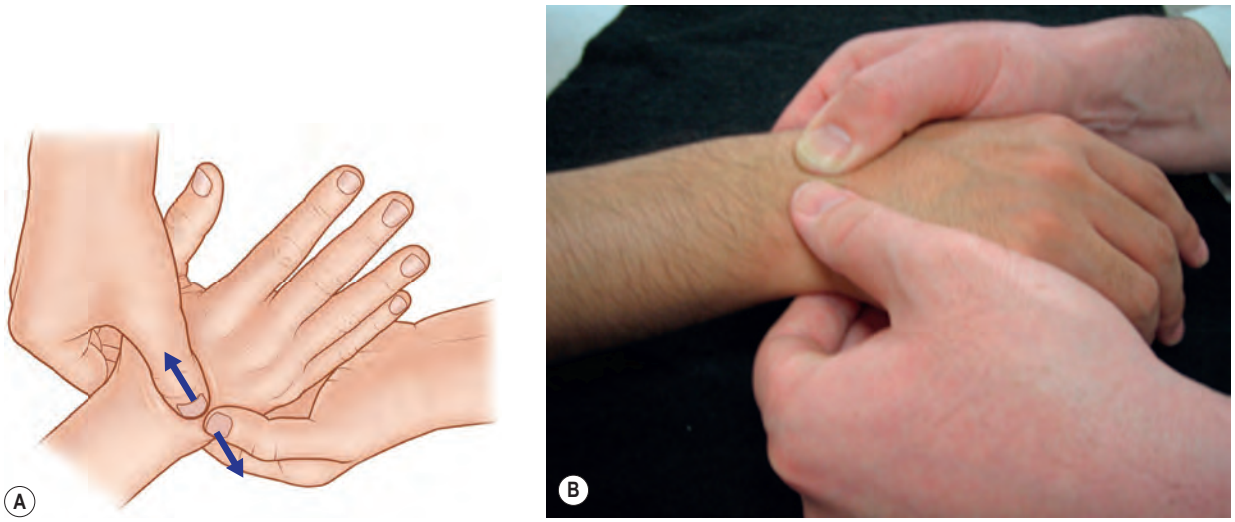

Fig. 2.6 (A,B) Triquetrolunate ballottement test.

Maneuver: The examiner places his or her thumb dorsally over the triquetrum and the index finger palmarly over the pisiform bone to keep the triquetrum–pisiform unit between the thumb and index finger. The examiner then places his or her opposite thumb on the dorsum of the lunate and pushes it palmarly down. If there is triquetrolunate ligament incompetence, the examiner will feel palmar movement of the lunate and the patient will complain of pain in the wrist (Fig. 2.6).[9] The lunotriquetral shuck test is similar to the triquetrolunate ballottement test. The patient is asked to place the elbow on a table with the forearm in neutral rotation. The examiner's thumb is placed over the dorsal side of the lunate just beyond the radiolunate joint. The examiner's opposite thumb pushes the palmar side of the pisiform dorsally to load the pisotriquetral joint. In lunotriquetral ligament incompetence, the triquetrum–pisiform unit is moved dorsally and the patient will complain of pain in the lunotriquetral joint (Fig. 2.7).[10]

Distal radioulnar joint instability test

Purpose: To evaluate the integrity of the deep layer of the dorsal or palmar distal radioulnar ligaments.

Fig. 2.7 Lunotriquetral shuck test.

Maneuver: The deep layers of the dorsal and palmar ligaments of the distal radioulnar joint (DRUJ) comprise the triangular ligament of the triangular fibrocartilage complex (TFCC) and play a primary role to stabilize the DRUJ. The deep dorsal ligament becomes taut when the forearm is supinated and the deep palmar ligament is taut when the forearm is pronated. The deep layers of the palmar and dorsal ligaments thus restrict dorsal and palmar shift of the ulnar head, respectively. The examiner sits opposite the patient at a table. The patient's elbow is flexed 90° and placed on the table. The patient's forearm is fully pronated and the examiner places his or her thumb on the palmar aspect of the ulnar head and pushes dorsally upward. This maneuver should be repeated on the healthy wrist. If abnormal dorsal movement of the distal ulna is felt with the thumb, insufficiency of the deep layer of the palmar distal radioulnar ligament (palmar portion of the triangular ligament of the TFCC) is present. Next, the patient's forearm is fully supinated and the examiner places his or her thumb on the dorsum of the distal ulna and pushes palmarly down. If abnormal palmar movement of the distal ulna compared with that of the opposite wrist is felt with the thumb, insufficiency of the deep layer of the dorsal distal radioulnar ligament (dorsal portion of the triangular ligament of the TFCC) is present (Fig. 2.8).[11]

Clinical tip

Dorsal instability of the ulna is assessed with the forearm fully pronated and palmar instability of the ulna is assessed with the forearm fully supinated.

Ulnocarpal abutment test

Purpose: To evaluate TFCC injuries and ulnar impaction syndrome.

Maneuver: The examiner places a thumb on the patient's distal ulna and holds the patient's hand with the remaining four fingers. The patient's forearm is stabilized by the examiner's opposite hand. The patient's wrist is fully deviated ulnarly and the forearm is pronated and supinated. A patient with a TFCC injury or ulnar impaction syndrome may complain of

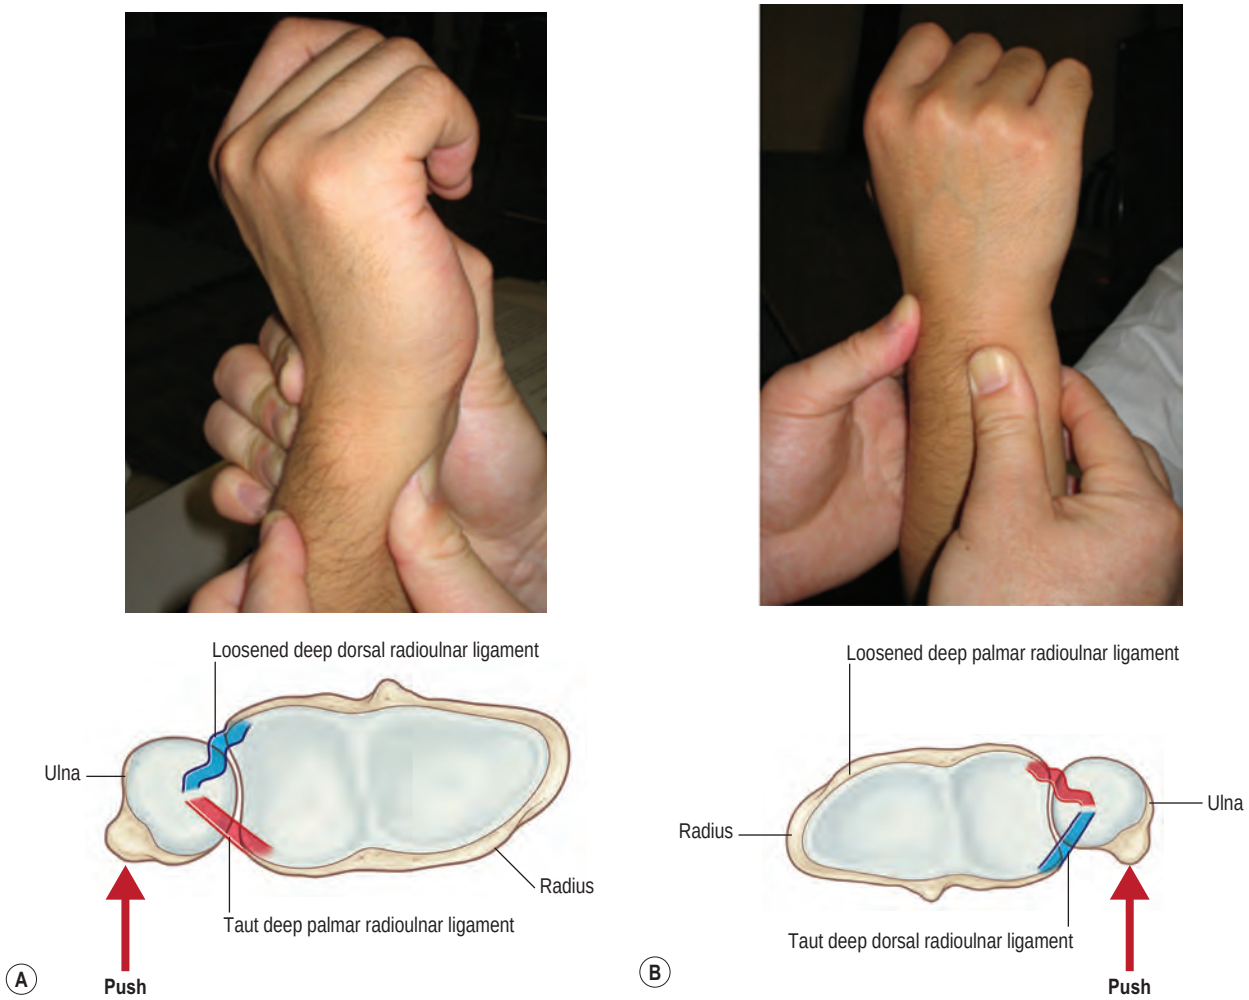

Fig. 2.8 Distal radioulnar joint (DRUJ) instability test. **(A)** Examination for the palmar instability of the DRUJ. The examiner pushes the ulna head from the palmar side when the forearm is pronated to examine the deep palmar distal RU ligament. The deep palmar ligament is taut in the forearm pronated. **(B)** Examination for the dorsal instability of the DRUJ. The examiner pushes the ulna head from the dorsal side when the forearm is supinated to examine the deep dorsal distal RU ligament. The deep dorsal ligament is taut in the forearm supinated.

ulnar wrist pain and a click or pop may be felt when the examiner's thumb is placed on the ulnocarpal joint (Fig. 2.9).[12]

The ulnar fovea sign

Purpose: To evaluate the foveal disruption of the distal radioulnar ligaments and ulnotriquetral ligament injuries.
Maneuver: The ulnar fovea is a dynamic nucleus of the ulnar wrist. The ulnar collateral ligament complex composed of the deep layer of the radioulnar ligament, the ulnotriquetral ligament, the ulnolunate ligament, and the ulnocapitate ligament attaches to the ulnar fovea. The patient sits opposite the examiner with the patient's elbow on the table. The examiner supports the patient's hand to keep the elbow in 90° to 110° of flexion, forearm in neutral rotation, and wrist in neutral position with the patient's upper limb relaxed. The examiner's thumb tip is then pressed distally and deep into the interval "soft spot" between the ulnar styloid process, flexor carpi ulnaris tendon, volar surface of the ulnar head, and the pisiform. The ulnar fovea sign is positive when there is exquisite tenderness compared with the contralateral side. The positive ulnar fovea sign supports the foveal disruption of the distal radioulnar ligaments and ulnotriquetral ligament injuries (Fig. 2.10).[13]

Pisiform gliding test

Purpose: To evaluate arthritis in the pisotriquetral joint.
Maneuver: The examiner palpates the pisiform and pushes it down against the triquetrum and applies shear force between the two bones. If there is arthritis in the pisotriquetral joint, the patient will feel pain in the joint during this maneuver (Fig. 2.11).

Midcarpal instability test

Purpose: To evaluate midcarpal stability.
Maneuver: The examiner places a thumb on the dorsal midcarpal joint and holds the patient's affected hand with the remaining four fingers. The patient's forearm is stabilized by the examiner's opposite hand. A patient with midcarpal instability will complain of pain in the midcarpal joint when the wrist is deviated ulnarly or radially. Patients with dorsal intercalary segmental instability (DISI) often complain of pain

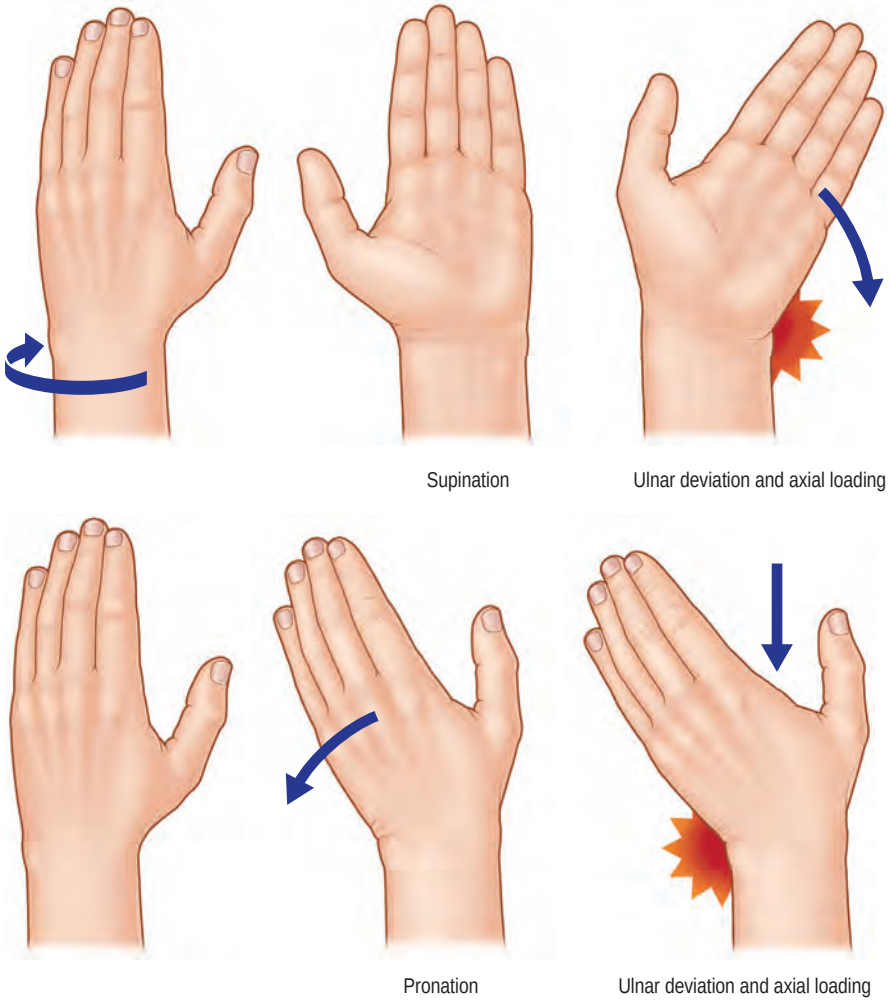

Fig. 2.9 Ulnocarpal abutment test. The wrist is subjected to ulnar deviation and axial forces with the forearm fully supinated or pronated.

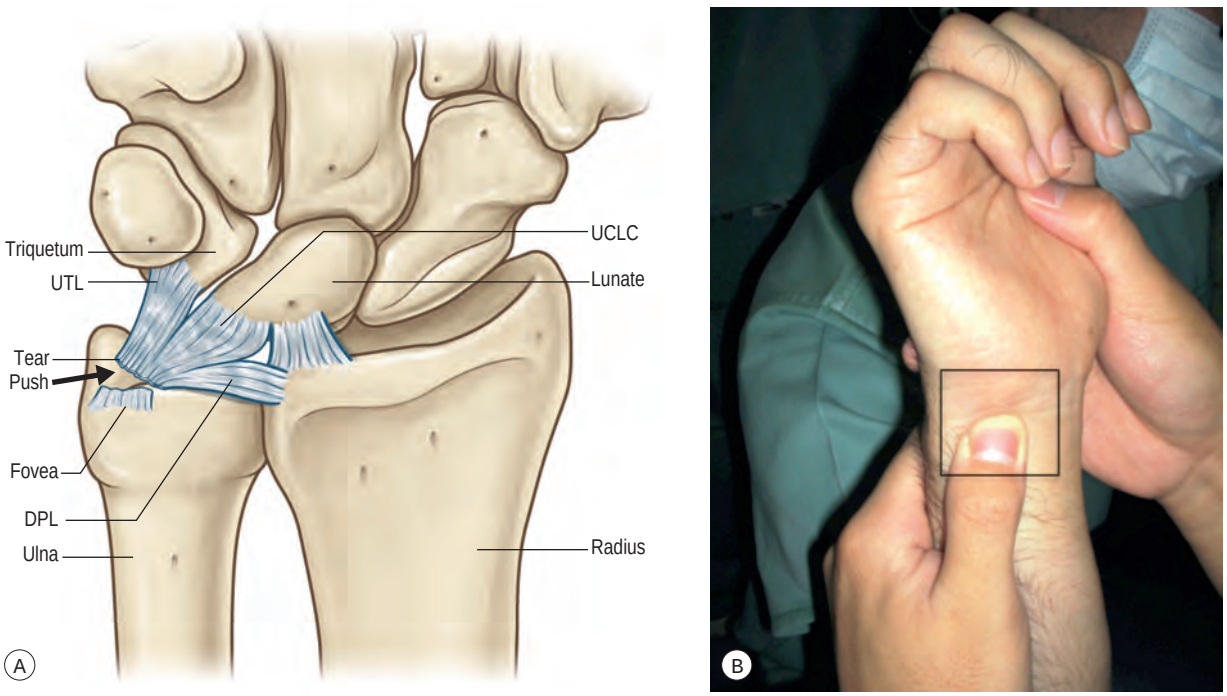

Fig. 2.10 The ulnar fovea sign. The tenderness over the ulnar fovea (positive ulnar fovea sign) strongly supports the foveal disruption of the TFCC. DPL, deep palmar ligament; UCLC, Ulnocarpal ligamentous complex; UT, ulnotriquetral ligament.

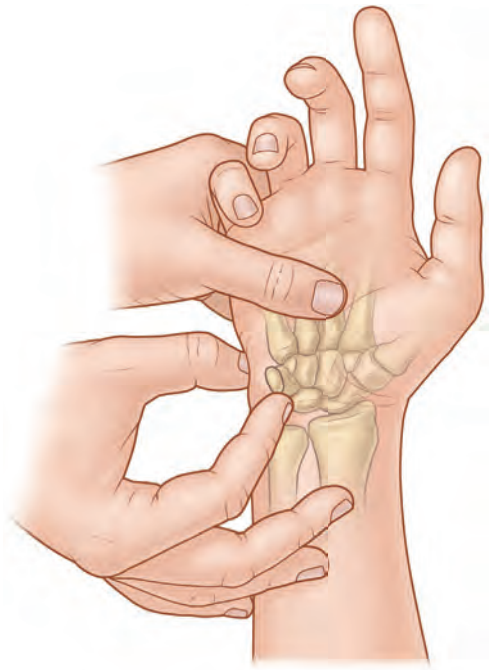

Fig. 2.11 Pisiform gliding test.

in the ulnodorsal portion of the midcarpal joint, and a click or pop may be felt when the wrist is deviated ulnarly.

Extensor carpi ulnaris synergy test

Extensor carpi ulnaris (ECU) tendinitis is a cause of ulnar-sided wrist pain. The ECU synergy test is a provocative test, indicating ECU tendinitis, which is often hard to distinguish from TFCC injuries.

Purpose: To detect ECU tendinitis.

Maneuver: The patient's forearm is held fully supinated. The examiner asks the patient to abduct all fingers and applies a counterforce to the index and small fingers sufficient to prevent abduction of the index and small fingers. A patient with ECU tendinitis will experience pain in the sixth extensor compartment (Fig. 2.12).[14]

Assessment of peripheral nerves

Evaluation of peripheral nerves should include both motor and sensory function.

To evaluate the motor function of the hand, it is necessary to understand not only the anatomy and biomechanics of the muscles of the upper extremity but also the peripheral innervation of the muscles. An understanding of the order in which branches of the nerves innervate muscles is important for assessing nerve recovery after a nerve injury or a compression neuropathy.

Sensibility testing also relies on knowledge of peripheral nerve anatomy. It is essential to understand which parts of the hand are innervated by which peripheral nerves. Peripheral nerve palsy should be diagnosed using motor and sensory evaluation. When the outcome of a motor assessment does not coincide with that of a sensory assessment, abnormal innervation of muscles or an unusual connection between peripheral nerves should be considered. The Martin–Gruber connection is an abnormal innervation of the median nerve to the motor branch of the ulnar nerve. Patients with cubital tunnel syndrome and this nerve connection may have a sensory palsy of the ulnar nerve without motor palsy.

Comprehensive sensibility evaluation includes static and dynamic two-point discrimination (2PD) testing, Semmes–Weinstein monofilament testing, vibrotactile threshold testing, and cold-heat testing. The 2PD test evaluates the tactile sensation of the skin and assesses density of the perception receptors in the skin. Stimuli generated by the static 2PD test are mainly sensed by Merkel cells (slow-adapting mechanoreceptors), while the main receptors of stimuli generated by the moving 2PD test are Meissner corpuscles (quick-adapting receptors). In the static 2PD test, a caliper is applied longitudinally to the digit and the smallest distance between the tips of the caliper that the patient can distinguish is measured. The moving 2PD test is the smallest perceived distance between the tips of a caliper that is moved longitudinally along the ulnar or radial aspect of the finger.[15] The normal distance is 3 mm for the moving 2PD test and 6 mm for the static 2PD test of the fingertips. The Semmes–Weinstein test evaluates the pressure perception of the skin of the fingers and assesses the threshold of the perception receptors in the skin. This test is conducted by touching the fingers with filaments of various diameters.[15] The vibrotactile test also assesses the threshold of the perception receptors and is performed using two types of tuning forks with 30 cycles per second (cps) and 250 cps. The vibrating forks are touched on the area examined and whether patients can recognize the vibration is examined. Main receptors of stimuli generated by the tuning forks with 250 cps are Pacinian corpuscles, while those by the forks with 30 cps are Meissner corpuscles. In the cold–heat test, the perception of heat is evaluated by touching the skin with a test tube containing water at 40–45°C and the perception of cold is tested using a test tube containing water at 10°C. Stimuli of the cold–heat test are mainly sensed by free nerve endings of the skin (Table 2.2).

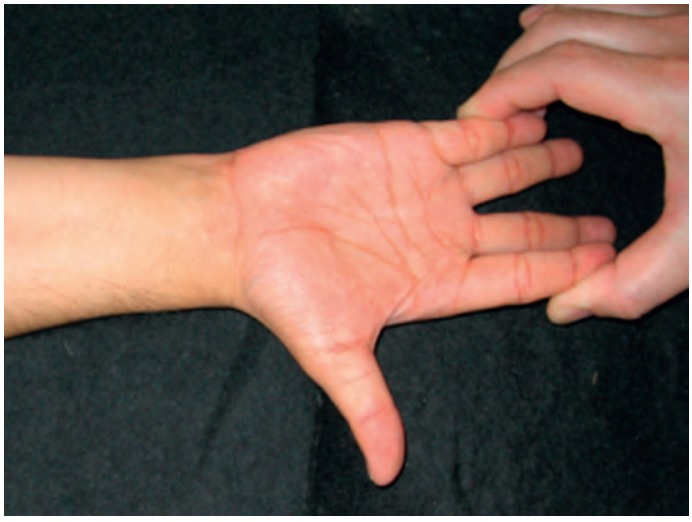

Fig. 2.12 Extensor carpi ulnaris synergy test. The patient is asked to abduct the fingers with the forearm fully supinated. The examiner applies counterforce to the index and little fingers.

Table 2.2 Specific sensory testing and main receptors

Test	Perception	Main receptor	Type of adaptation	Evaluation of innervation
Static 2PD	Tactile	Merkel cell	Slowly	Density
Moving 2PD	Tactile	Meissner corpuscle	Quickly	Density
Tune fork (250 cps)	Vibration	Pacinian corpuscle	Quickly	Threshold
Tune fork (30 cps)	Vibration	Meissner corpuscle	Quickly	Threshold
S–W test	Pressure	Merkel cell	Slowly	Threshold

cps, Cycles per second.
(Reproduced with permission from Bell-Krotosoki J, Tomancik E. The repeatability of testing with Semmes-Weinstein monofilaments. *J Hand Surg*. 1987;12A:155–161.)

Clinical tip

Ulnar nerve palsy occurring distal to the FDP muscle branches demonstrates more severe claw deformity than that occurring proximal to the branches. This is because the FDP tendons continue to flex the ring and little fingers, which accentuates the hyperextension of the MP joints and flexion of the PIP and DIP joints.

Signs and tests for peripheral nerves

Tinel's sign

Purpose: To detect nerve regeneration.
Maneuver: When the examiner taps on a peripheral nerve distal to a nerve injury such as a compression neuropathy or a laceration, the patient will experience tingling that radiates distally along the course of the nerve. This phenomenon is called a *Tinel's sign*. The most distal point of the pain indicates the site at which axon sprouting has occurred. Peripheral nerve recovery after a nerve injury can be assessed by observing the advancement of *Tinel's sign* along the nerve (approximately 1 mm/day of advancement).

Phalen's test

Purpose: This test is used as a provocative test specific to carpal tunnel syndrome.
Maneuver: With the elbow in neutral position, the patient's wrist is held in maximum palmar flexion for up to 2 min. This increases pressure on the carpal tunnel and provokes paresthesia in the area innervated by the median nerve in patients with carpal tunnel syndrome (Fig. 2.13). Maximum extension of the wrist also increases pressure on the carpal tunnel. This is called the reverse Phalen's test.

Froment's test

Purpose: To assess motor function of the ulnar nerve.
Maneuver: The patient is asked to hold a piece of paper between the ulnar tip of the thumb and the radial tip of the index fingers. The examiner slowly pulls the paper away from the patient while encouraging the patient to hold on to it. Patients with normal strength of the first dorsal interosseous and adductor pollicis muscles keep the IP joint of the thumb extended. If the patient has weakness of thumb adduction caused by ulnar nerve palsy, the patient attempts to hold the paper by flexing the thumb IP joint using the flexor pollicis longus and (hyper)extends the thumb MP joint to stabilize it (*Jeanne's sign*). Such patients also flex the PIP joint and hyperextend the DIP joint of the index finger to compensate for weakness of MP joint flexion of the index finger (Fig. 2.14).

Jeanne's sign

Purpose: To assess motor function of the ulnar nerve.
Maneuver: When patients with ulnar nerve dysfunction attempt a lateral or key pinch of the thumb, they hyperextend the thumb MP joint, which locks it to compensate for the lateral instability of the joint secondary to weakness of the thumb adductors.

Fig. 2.13 Phalen's test.

Fig. 2.14 Froment's sign. A patient with left ulnar nerve palsy attempts to hold the paper by flexing the thumb IP joint using the flexor pollicis longus and hyperextending the thumb MP joint to stabilize it. He also demonstrates flexion of the PIP joint and hyperextension of the DIP joint of the index finger to compensate for weakness of MP joint flexion of the finger (Jeanne's sign).

Fig. 2.15 Wartenberg's sign. A patient with left ulnar nerve palsy demonstrates inability to perform adduction of the left little finger when he attempts to adduct all fingers.

Wartenberg's sign

Purpose: To assess the motor function of the ulnar nerve.
Maneuver: The patient is asked to keep the fingers adducted with the MP, PIP, and DIP joints fully extended. If the patient has motor dysfunction of the ulnar nerve, the small finger deviates away from the ring finger because the third palmar interosseous muscle does not function and the extensor digiti minimi muscle abducts the small finger (Fig. 2.15).

Other signs associated with ulnar nerve palsy

Duchenne's sign: If the FDP muscles are functioning and the intrinsic muscles are paralyzed (low-level ulnar nerve palsy), the ring and little fingers show hyperextension of the MP joint and flexion of the PIP and DIP joints (claw finger deformity).
***André–Thomas sign*:** A conscious effort to extend the fingers by tenodesing the extensor tendons with palmar flexion of the wrist only increases the claw deformity.
Bouvier maneuver: When hyperextension of the MP joint of the ring and little fingers is corrected, the flexion of the PIP and DIP joints of the fingers is reduced.

The Pitres–Testut sign: This maneuver reveals the function of the second and third interosseous muscles. The patient is asked to place the hand flat on a table and then to stretch the long finger upward (i.e., to hyperextend it) and to deviate it radially and ulnarly.
The "crossed fingers" sign (Video 2.6 ▶): The function of the first palmar interosseous and the second dorsal interosseous muscles is evaluated by this sign. The patient is asked to cross a flexed long finger over the index finger or to cross a flexed index finger over the long finger when the palm and the ring and little fingers are placed flat on a table.

Tests for evaluating sensory nerve function

Two-point discrimination (2PD) test (Video 2.7 ▶)

Purpose: To evaluate the tactile sensation of the skin and assess density of the perception receptors of the skin.
Maneuver: In the static 2PD test, a caliper is applied longitudinally to the digit and the smallest distance between the tips of the caliper that the patient is able to distinguish is measured. In the dynamic 2PD test, the distance between the tips of a caliper that is moved longitudinally along the ulnar or radial aspect of the finger is measured.[14] The normal distance is 3 mm for the moving 2PD test and 6 mm for the static 2PD test. Although it is known that the main receptors for the static 2PD test are Merkel cells (slow-adapting mechanoreceptors) and those for the moving 2PD test are Meissner corpuscles (quick-adapting mechanoreceptors), the results of the 2PD test reflect the functions of multiple sensory receptors in the skin. This test is best for evaluation of nerve lacerations.

Semmes–Weinstein monofilament test (Video 2.9 ▶)

Purpose: To evaluate the pressure perception threshold of the skin. Stimuli generated by this test are mainly sensed by Merkel cells (slow-adapting mechanoreceptors).
Maneuver: Filaments of various diameters are used. The patient places a finger on a table with the palm up and closes his or her eyes. The tip of a filament is held vertically against the skin of the finger and sufficient force is applied to bend the filament before allowing it to return to the vertical position. The filament should remain in contact with the skin surface after the force is released. If the patient senses the pressure applied by the filament, other filaments of decreasing diameter are used until the patient no longer senses the pressure. The size of the smallest-diameter filament that can be sensed by the patient is recorded (Table 2.3).[16]

Table 2.3 Semmes–Weinstein test

Evaluator size	Pressure force (*g*)	Color	Interpretation
1.65–2.83	0.008–0.07	Green	Normal
3.32–3.61	0.16–0.4	Blue	Normal
3.84–4.31	0.6–2	Purple	Diminished light touch sensation
4.56–4.93	4–8	Red	Diminished protective sensation
5.07–6.45	10–180	Red	Loss of protective sensation
6.65	300	Red	Deep pressure sensation only

(Reproduced with permission from: Bell-Krotosoki J, Tomancik E. The repeatability of testing with Semmes–Weinstein monofilaments. *J Hand Surg*. 1987; 12A:155–161.)

Clinical tip

Touching the tip of the filament on the skin should be so gentle that patients cannot recognize the touch of the filament tip on the skin. Patients have to recognize the bending pressure produced by the filaments. Some patients misunderstand that the test is whether they recognize the initial touch sensation of the filaments or not.

Moberg's pick-up test

Purpose: To generally evaluate the motor and sensory function of the hand. This test is applied to patients with median nerve injuries or injuries of both the ulnar and median nerves.
Maneuver: Small items such as a button, a key, and a paperclip are placed on a cloth mat. The patient is asked to pick up each item and put it into a small box as quickly as possible with their eyes open and again with their eyes closed. The times required to finish these tasks are measured (Fig. 2.16).[17]

Assessment of the vascular system

There are two types of vascular problems: arterial and venous insufficiency. Vascular problems are assessed according to the color, capillary refill, pressure (turgor) and temperature of the affected part.

Arterial interruption causes a pale white or grayish discoloration of the affected area. Venous blockage results in blood congestion, which causes a purple–blue discoloration.

Capillary refill is indicative of the circulation status of the digits. When the fingertip or nail bed is depressed, the area under pressure turns white. When the pressure is released, the area should turn pink within 2 seconds. A delay in refill is indicative of an arterial inflow problem. Prompt refilling may indicate venous congestion. A decrease in skin pressure or temperature may also indicate vascular problems.

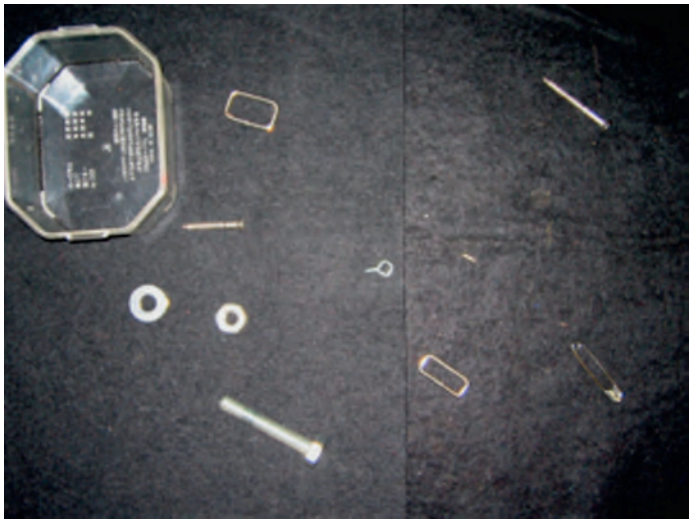

Fig. 2.16 Moberg pick-up test. A patient with eyes open or closed picks up small items on a cloth mat and puts them into the box. The time required to finish the task is recorded.

The Allen's test (Videos 2.7–2.10 ▶) is helpful for determining if there is an intact circulatory connection between the radial and ulnar arteries in the hand. If there is an intact circulatory path between the two arteries, the hand may be nourished by either of the arteries.[17] This test is essential for assessing the vascularity of the hand before harvesting radial or ulnar forearm flaps. If both arteries are not patent, pedicled forearm flap elevation may compromise the vascularity of the hand.

To assess the circulatory connection between the radial and ulnar palmar digital arteries, the same maneuver is performed at the base of the fingers and thumb (digital Allen's test [Video 2.11 ▶]). If there is no circulatory connection between the palmar digital arteries, pedicled island flap harvest should be avoided.

Allen's test (Video 2.10 ▶)

Purpose: To assess the blood supply of the radial and ulnar arteries to the hand.
Maneuver: The patient places the dorsum of the hand on a table. The examiner compresses the patient's radial and ulnar arteries at the wrist to occlude both arteries. The patient is then asked to make and release a tight fist repeatedly to exsanguinate the hand, after which the fingers are held in a relaxed position. The examiner releases the pressure on the radial artery while keeping pressure on the ulnar artery. The time taken for blood to return to the hand and fingers is noted. A normal interval for this process is 2–5 seconds. The procedure is repeated for the ulnar artery.[18]

Digital Allen's test (Video 2.11 ▶)

Purpose: To assess the blood supply of the radial and ulnar palmar digital arteries to the finger.
Maneuver: The patient is asked to place the dorsum of the finger to be tested flat on a table. The examiner compresses the ulnar and radial side of the patient's fingertip with his or her two fingers and moves them proximally to exsanguinate the finger to be tested. The examiner then releases the pressure on the radial palmar digital artery while maintaining pressure on the ulnar digital artery.

The time taken for blood to return to the finger is noted. A normal interval for this process is ≤3 seconds. The procedure is repeated for the palmar ulnar digital artery of the finger. A delay in the return of blood to the finger indicates that the blood flow of the radial or ulnar palmar digital arteries is impaired.

Physical examination specific to the forearm

The main functions of the forearm are to transmit force between the elbow and hand and to enable pronation and supination. According to a cadaveric study, 80% of an axial load applied to the wrist is transmitted to the radius and 20% is transmitted to the ulna. The axial force is distributed to the radiocapitellar and ulnohumeral joints in a 60:40 ratio, respectively. Some 20% of an axial force applied to the radius is therefore transferred to the ulna through the interosseous membrane (IOM).[19] After resection of the radial head, 90% of an axial load applied to the forearm is transferred through the IOM.[20]

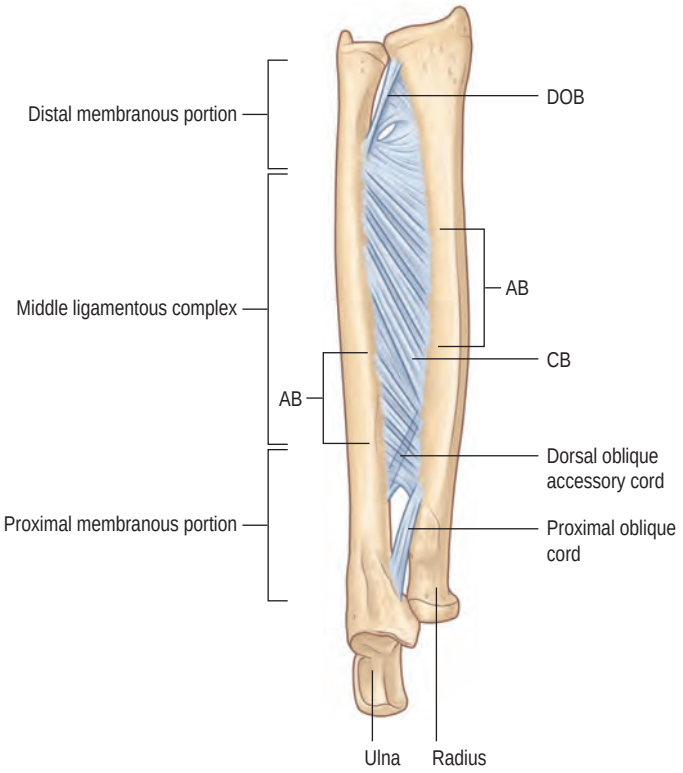

Fig. 2.17 Interosseous membrane of the forearm. CB, Central band; (DL)AB, distal ligament of accessory band; DOB, dorsal oblique band; (PL)AB, proximal ligament of accessory band.

The interosseous membrane of the forearm (IOM)

The IOM is divided into three portions. Each portion contains several fibers that connect the radius and the ulna (Fig. 2.17).[21]

Distal membranous portion

Dorsal oblique band (DOB): This band functions as a stabilizer of the DRUJ, in particular by restricting a palmar shift of the ulna in the supination position.[22]

Middle ligamentous portion

a. Central band (CB): This is the strongest fiber of the IOM and extends from the proximal radius to the distal ulna. When the radial head removed, the CB carries 71% of the overall mechanical stiffness of the forearm.[20]
b. Distal ligament of accessory band (DLAB)
c. Proximal ligament of accessory band (PLAB)

Proximal membranous portion

a. Distal oblique accessory cord (DOAC)
b. Proximal oblique cord (POC): a stabilizer of the proximal radioulnar joint

Among these fibers, the DOB and CB are isometric components and their lengths do not change during forearm rotation.[23] By contrast, the POC is shorter when the forearm is in a neutral or supination position than when it is in a pronation position. The length of the DOAC shortens as the forearm is rotated from pronation to supination.

Measurement of forearm rotation

The patient should be seated on a chair with the elbow joints tucked in lateral to the abdomen. The patient is asked to grasp a pen in each hand and to rotate the forearm. The angle between the pen and a line perpendicular to the floor should be measured.

Measurement of the muscle strength of the forearm

Supination

The main supinators of the forearm are the supinator muscle and the biceps brachii muscle. The extensor carpi radialis longus (ECRL) and brachioradialis (BR) muscles act as the forearm supinators when the forearm is pronated.

Pronation

The main pronators are the pronator teres and pronator quadratus (PQ) muscles. The flexor carpi radialis and palmaris longus muscles also act as forearm pronators. The BR muscle is a forearm pronator when the forearm is in the supinated position. A recent study revealed that the PQ is responsible for 20% of forearm pronation, except when in the fully pronated position.[24] The muscle power of the PQ should be measured when the elbow joint is fully flexed to eliminate the effects of the other pronators.

Pronation or supination strength is evaluated with the elbow joint at 90° of flexion. Pronation strength is measured by grasping the wrist with the forearm in a neutral or supination position. To test supination strength, the forearm should be in a neutral or pronation position.

Physical examinations specific to the elbow

Bony landmarks of the elbow

The medial epicondyle, lateral epicondyle and the tip of the olecranon are located along a straight line (Hüter's line) when the elbow is extended and form an equilateral triangle (Hüter's triangle) when the elbow is flexed (Fig. 2.18). This feature is helpful for identifying a deformity of the distal humerus and elbow joint caused by fracture, malunion, dislocation or growth disturbances.

On the lateral aspect, the capitellum of the humerus and the radial head are easily palpable. The extensor muscles originate from the lateral epicondyle. The radial nerve is palpable in the interface between the BR muscle and the brachialis muscle.

On the anterior aspect, the cubital fossa is bordered by the BR muscle laterally and the pronator teres muscle medially. The musculocutaneous nerve is located deep to the brachioradialis muscle and medial to the biceps brachii tendon. The pulsation of the brachial artery is palpable, as it lies medial to the biceps brachii tendon and deep to the lacertus fibrosus.

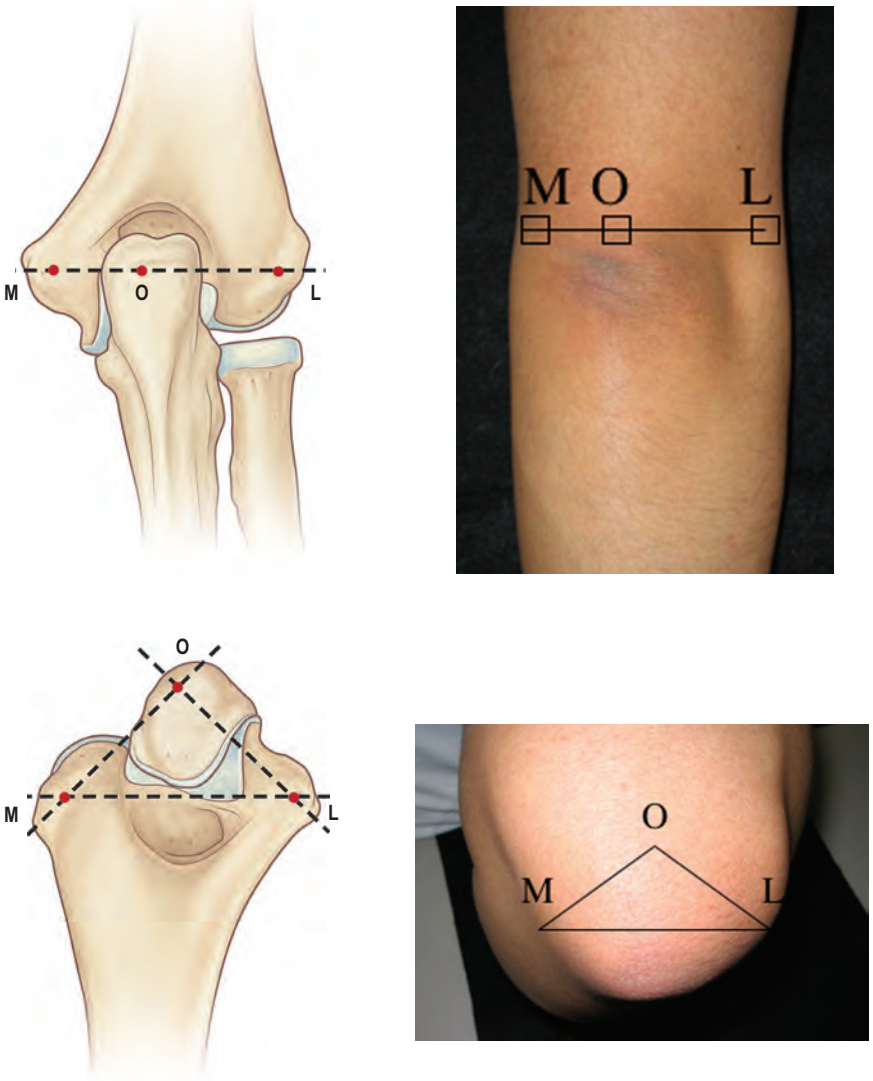

Fig. 2.18 Bony landmarks of the elbow. The medial (M) epicondyle, (L) lateral epicondyle and the tip of the (O) olecranon locate on a straight line when the elbow is extended and form an equilateral triangle when the elbow is flexed.

The median nerve is located just medial to the brachial artery under the lacertus fibrosus, which can cause median nerve palsy (pronator teres syndrome).

In the medial aspect, the ulnar nerve groove is palpable between the medial epicondyle and the ulna. The ulnar nerve is sometimes palpated as a strand in the posterior aspect of the groove. In some patients with ulnar nerve palsy, a dislocated ulnar nerve is palpable over the epicondyle when the elbow is flexed.

On the posterior aspect, the olecranon and olecranon fossa of the humerus are easily palpated. The triceps brachii tendon is attached to the olecranon.

Ligaments of the elbow

Lateral ligament complex

The lateral ligament complex consists of the following four ligaments (Fig. 2.19).

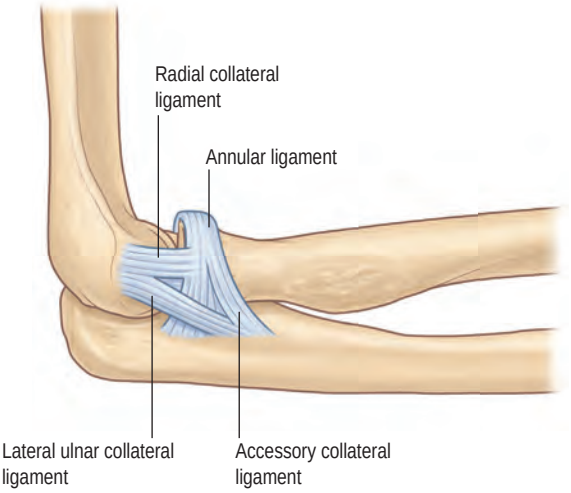

Fig. 2.19 Lateral complex of the elbow.

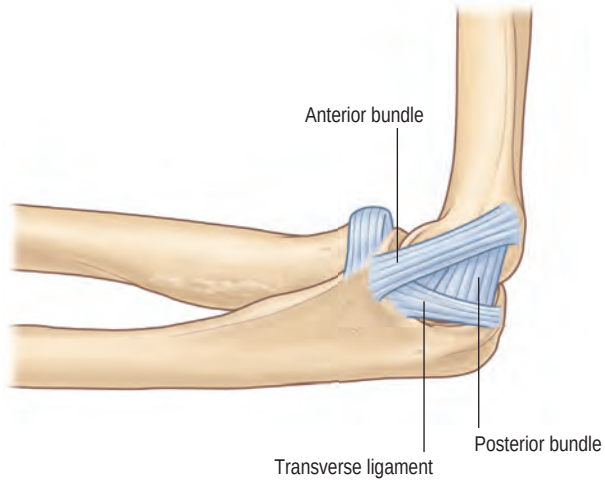

Fig. 2.20 Medial complex of the elbow.

Lateral ulnar collateral ligament

The lateral ulnar collateral ligament originates from the lateral epicondyle, blends with the fibers of the annular ligament and terminates at the tubercle of the crest of the supinator. It functions as a primary stabilizer of the joint when a varus stress is applied.

Radial collateral ligament

This structure originates from the lateral epicondyle and terminates in the annular ligament. The ligament is located near the axis of the elbow joint and is uniformly taut during elbow motion.

Annular ligament

This ligament originates from the anterior margin of the sigmoid notch and inserts on the posterior notch of the sigmoid of the ulna to connect the radial head to the ulna.

Accessory collateral ligament

The ligament blends with the inferior margin of the annular ligament to support the annular ligament during varus stress.

Medial collateral ligament complex

The medial collateral ligament complex consists of three portions: the anterior bundle, the posterior bundle, and the transverse ligament. The transverse ligament is not considered functional. The posterior bundle is clinically insignificant with regard to the stability of the elbow joint. Contracture of the posterior bundle generates extension contracture of the elbow joint. The anterior bundle functions as the prime stabilizer of the elbow joint against valgus stress (Fig. 2.20).

Instability of the elbow joint

The elbow joint is stabilized by the medial collateral ligament (MCL) complex, the lateral collateral ligament (LCL) complex, the joint capsule, and the osteochondral articulation.

The MCL, joint capsule and osteochondral articulation contribute equally to restrain valgus displacement of the elbow joint when the joint is extended. The MCL contributes more than the osteochondral articulation to restrain valgus displacement when the joint is flexed. The osteochondral articulation contributes more than the LCL to restrain varus displacement, especially in the flexed position.

When examining instability of the elbow joint, the elbow should be placed in a position in which other factors that affect its stability (articulation and tension of the joint capsule) are minimized. To assess collateral ligament integrity, the elbow should be flexed by about 15°. This position relaxes the anterior capsule and unlocks the olecranon from the fossa.

Varus instability of the elbow is therefore assessed with the humerus in full internal rotation and varus stress is applied to the slightly flexed joint. By contrast, valgus instability of the elbow is evaluated with the humerus in full external rotation while valgus stress is applied to the joint in slight flexion (Fig. 2.21).[25]

Clinical tip

Collateral ligament integrity of the elbow should be assessed with the elbow in about 15° flexion, which relaxes the anterior capsule and unlocks the olecranon from the fossa. Varus instability of the elbow is assessed with the humerus in full internal rotation and varus stress is applied to the slightly flexed joint. Valgus instability of the elbow is evaluated with the humerus in full external rotation while valgus stress is applied to the joint in slight flexion.

Posterolateral rotatory instability

Insufficiency (loosening, rupture or laceration) of the lateral ulnar collateral ligament causes posterolateral instability of the elbow joint. Posterolateral rotatory instability (PLRI) is evaluated using the pivot shift test maneuver.[25]

The pivot shift test

The patient is placed in a supine position with the shoulder and elbow flexed at 90°. The examiner stands cephalad to the patient. The examiner grasps the patient's forearm in a fully supinated position and extends the elbow slowly, applying valgus and axial compressions to the joint. If the patient has lateral collateral ligament insufficiency, these maneuvers cause rotatory subluxation in the ulnohumeral joint. The examiner continues to extend the elbow slowly. As the elbow joint approaches extension, the radial head is suddenly dislocated anteriorly. The prominence of the radial head disappears and a skin dimple appears. The dislocated radial head is repositioned by flexion of the elbow (Fig. 2.22).[26]

Measurement of malrotation of the distal humerus

Patients in whom fractures of the distal humerus have not been treated correctly often demonstrate malrotation of the distal humerus, which restricts the functional arc of the shoulder joint. Malrotation of the distal humerus is easily assessed. The patient is asked to stand and flex the trunk more than 90° forward. The patient is then asked to extend both shoulder joints maximally with the elbow joints in 90° of flexion. The angles formed between the floor and the forearms

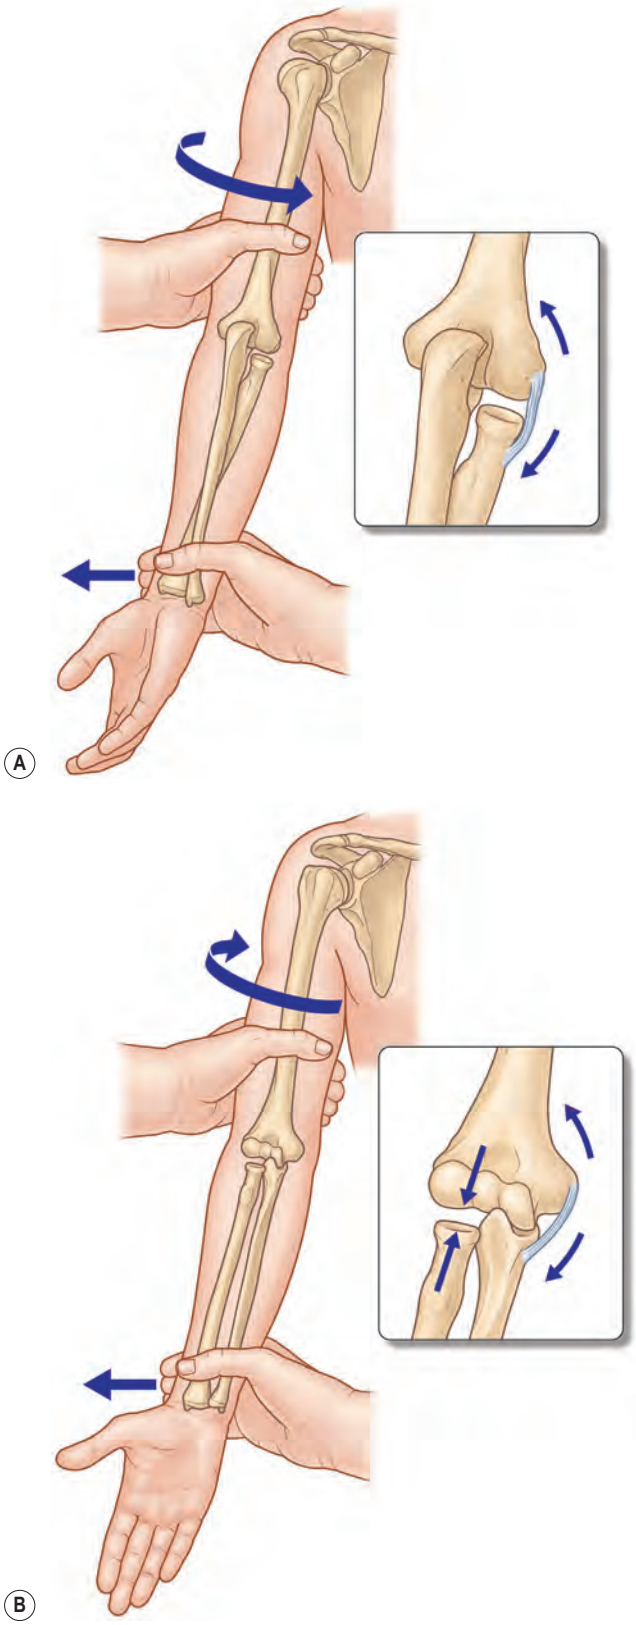

Fig. 2.21 Assessment of the lateral instability of the elbow. **(A)** Varus instability of the elbow is examined with the humerus in full internal rotation. **(B)** Valgus instability is assessed with the humerus in full external rotation.

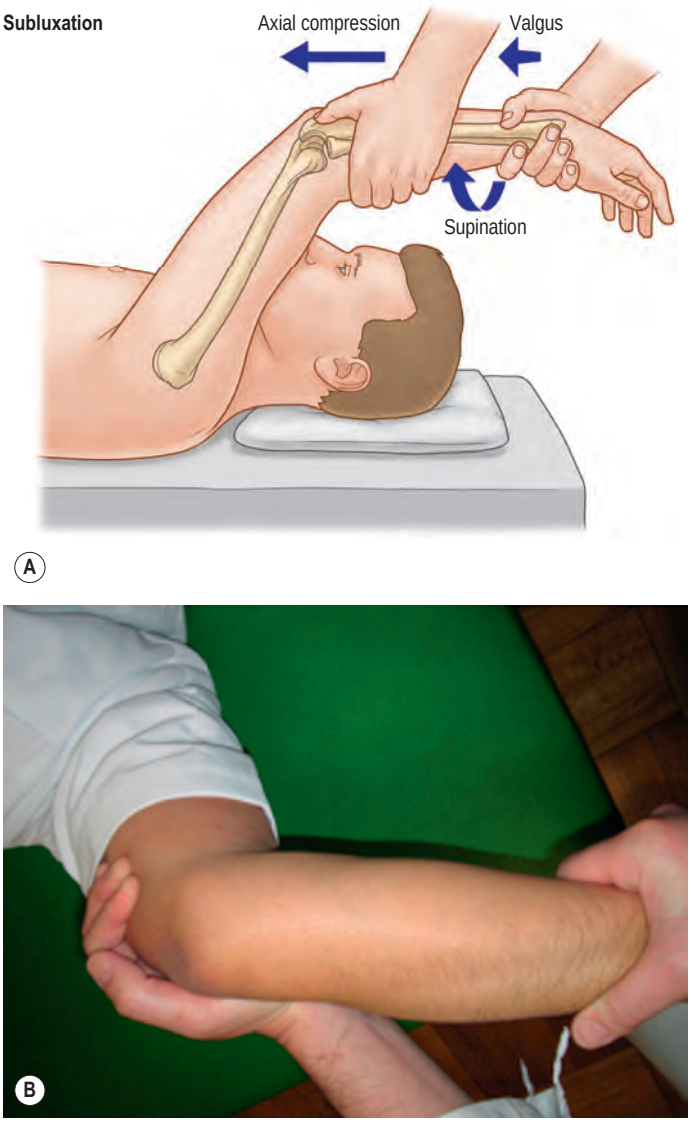

Fig. 2.22 Pivotal shift test of the elbow. **(A,B)** Subluxation.

are measured. The malrotation angle of the affected distal humerus can be measured by comparing it with that of the contralateral normal side (Fig. 2.23).

Physical examination of thoracic outlet syndrome

Thoracic outlet syndrome (TOS) is a broad term that refers to compression of the neurovascular structures in the area just above the first rib and behind the clavicle resulting in upper extremity symptoms. It represents a constellation of symptoms.

Classification

TOS is usually classified into two groups: neurogenic and vascular. The neurogenic group is caused by compression or irritation of the brachial plexus trunks and comprises

Fig. 2.23 Assessment of malrotation of the humerus. The patient is asked to stand and flex the trunk more than 90° forward with the bilateral shoulder joints extended maximally and the elbow joints in 90° of flexion. The angles formed between the floor and the forearms are measured.

90% of the TOS. The neurogenic type can be divided into three types, depending on involvement of cervical nerve roots: the upper type (C5, C6, C7 spinal nerve involvement), lower type (C8, T1 spinal nerve involvement), and the combined type. The lower and combined types comprise 85–90% of all patients with TOS. Some 40–50% of TOS is associated with distal compression neuropathies, such as carpal tunnel, pronator teres, cubital tunnel, and radial tunnel syndromes.[24]

The vascular group is subtyped into the venous type and arterial type. The venous type comprises 70–80% of the vascular group of TOS. The symptoms include pain, swelling, distended vein, and discoloration of the affected upper limb. Compression of the subclavian vein does not occur in the interscalene space because it passes anterior to the anterior scalene muscle, but usually occurs at the area between the anterior scalene insertion to the first rib and at the costocoracoid ligament and subclavius tendon insertion of the first rib. This type sometimes develops into thrombosis formation in the subclavian vein (Paget–Schroetter syndrome). The arterial type comprises only 20–30% of the vascular group and occurs with direct pressure of the cervical rib, or an abnormal middle scalene muscle to the first rib, or anomalous band-like structure under the subclavian artery.[27] Trauma to the neck, shoulder girdle, and upper extremity, particularly the lower trunk and C8–T1 spinal nerves, is thought to play an important role in developing the symptoms of thoracic outlet syndrome. The trauma can be a single blow or a repetitive, strenuous type.[27]

Anatomy

The brachial plexus trunks and subclavian vessels are subject to compression or irritation in three spaces at the thoracic outlet region. The most important of these spaces is the interscalene space (triangle), which is also the most proximal. This space is bordered by the anterior scalene muscle anteriorly, the middle scalene muscle posteriorly, and the medial surface of the first rib inferiorly. This area may be small at rest and may become even smaller in the posture with elevation or hyperabduction of the upper limb, which moves the scapula posteroinferiorly, resulting in the access of the clavicle to the first rib. The anomalous structures, such as fibrous bands, cervical ribs, and anomalous muscles, may constrict this space further. The second space is the costoclavicular space, which is bordered anteriorly by the middle third of the clavicle, posteromedially by the first rib, and posterolaterally by the upper border of the scapula. The last space is the subpectoralis minor space beneath the coracoid process just deep to the pectoralis minor tendon (Fig. 2.24).

Provocative maneuver

Adson test (Video 2.16 ▶)

The patient is asked to inhale deeply with the chin up and tilt the neck toward the involved arm holding the breath. If the radial artery pulsation disappears or is diminished, the test is positive. This test is considered sensitive to compression in the interscalenus space (Fig. 2.25).[28]

The neck tilting

The patient is asked to inhale deeply and tilt the neck to the opposite direction of the involved arm holding the breath. In patients with TOS, this action produces arm heaviness, numbness, and tingling in the fingers or/and arm, with some pain.

The costoclavicular compression test

The patient is asked to inhale deeply and hold the breath. The examiner depresses the patient's shoulder of the involved limb. Patients with TOS complain of symptoms such as heaviness, pain, numbness or tingling in the limb, and the pulsation of the radial artery is often diminished. This maneuver calls attention to compression in the costoclavicular space (Fig. 2.26).

Wright test

The examiner holds the patient's arm in 90° abduction with the elbow 90° flexed, and rotates the arm externally. If the pulsation is diminished and the symptoms are provoked by this maneuver, the test is positive. Entrapment of the neurovascular bundle at the subpectoralis minor space or the costoclavicular space can make the test positive (Fig. 2.27).[29]

Roos extended arm stress test (Video 2.17 ▶)

The patient is asked to hold both arms with the shoulders in 90°-abduction and 90°-external rotation position and open and close the hands repetitively. If the patient develops any fatigue, pain, numbness or tingling in the hand or arm within three minutes, the test is positive.[30]

Morley's test

The patient complains of pain, numbness, tingling or uncomfortable feelings when the examiner pushes the patient's brachial plexus in the supraclavicular fossa.

These provocative tests should be performed on the bilateral upper limbs and the outcomes of the involved limb

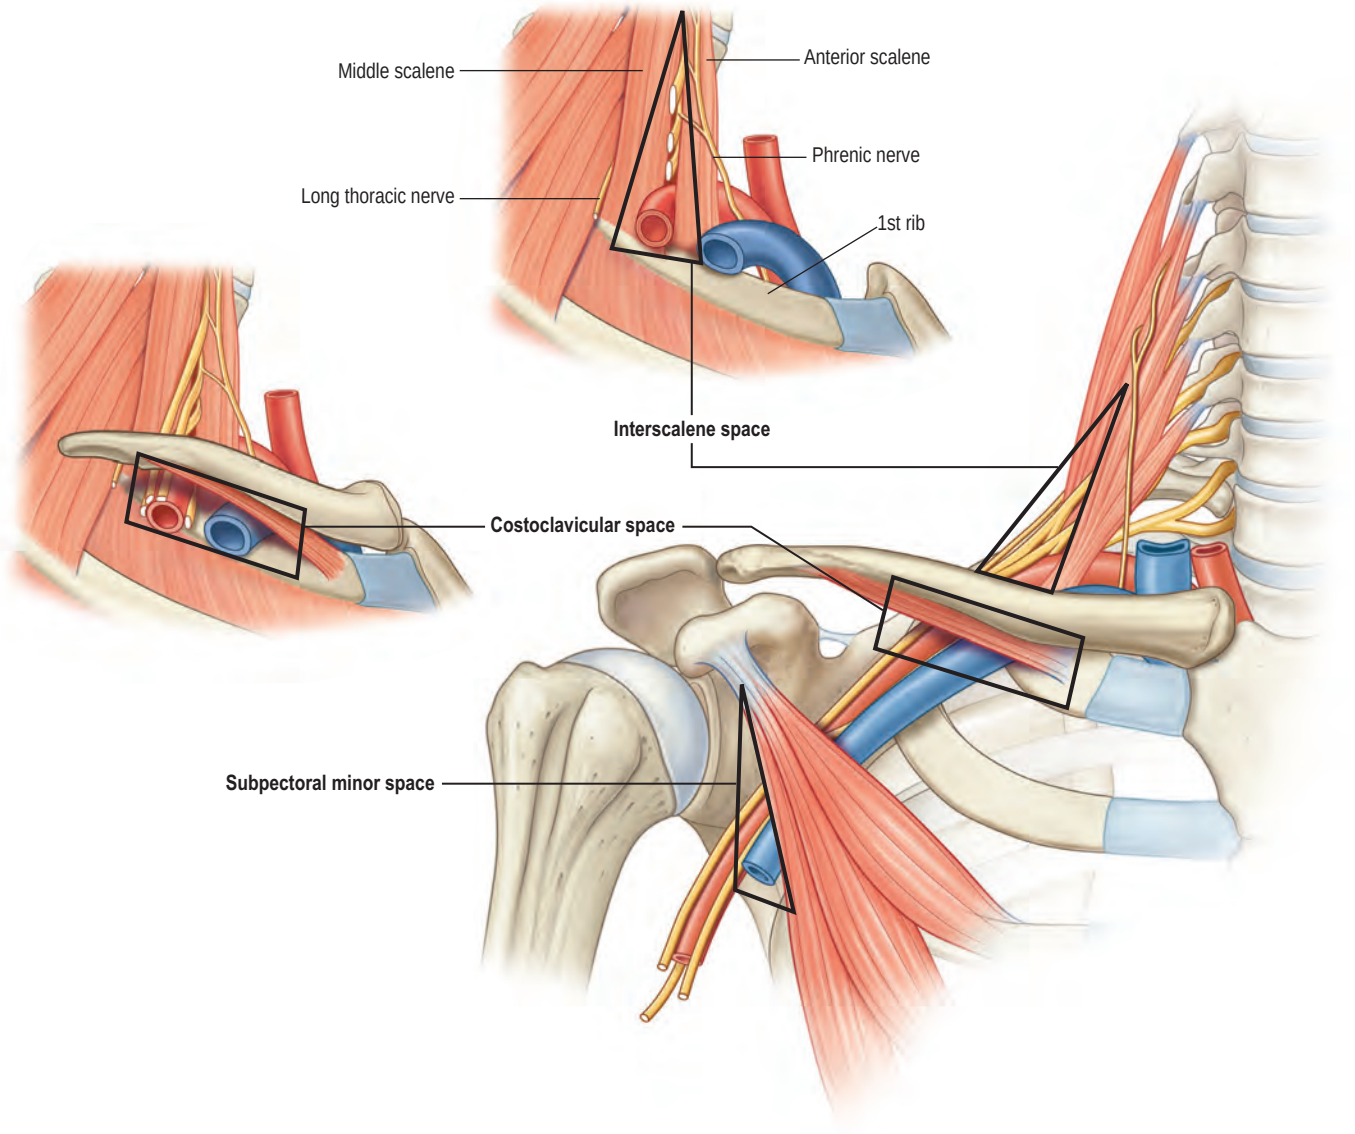

Fig. 2.24 The three spaces that potentially entrap the neurovascular bundle in patients with the thoracic outlet syndrome.

should be compared with those of the opposite one, because the tests can be positive in a normal person.

Physical examination of the upper extremity in children

Communication with very young children is often difficult or impossible and young children are not able to articulate their symptoms. A fatty subcutaneous tissue layer often prevents doctors from identifying a deformity or swelling. It is often difficult to locate the source of pain because children tend to complain that the pain is everywhere. Questioning of the parents and family of the patient is sometimes helpful for making a diagnosis. Physical examination should include observing the child's activities when he or she is held by a parent or is playing. Valuable information in terms of the usage and dexterity of the upper extremity can be obtained by observing children playing with age-appropriate toys or props. The affected limb should be examined from the tip of fingers to the hemithorax, which should be compared with the contralateral limb to confirm the anomaly. The physical examination should include not only a musculoskeletal examination but also a nervous system examination. Primitive reflexes, including the Moro reflex, the systemic tonic neck response, the mouth lip reflex, and palmar grasp stimulation are used to assess neuromuscular function in newborns. As these patients age, gross movement patterns and integration of the affected hand into functional activities can be assessed.

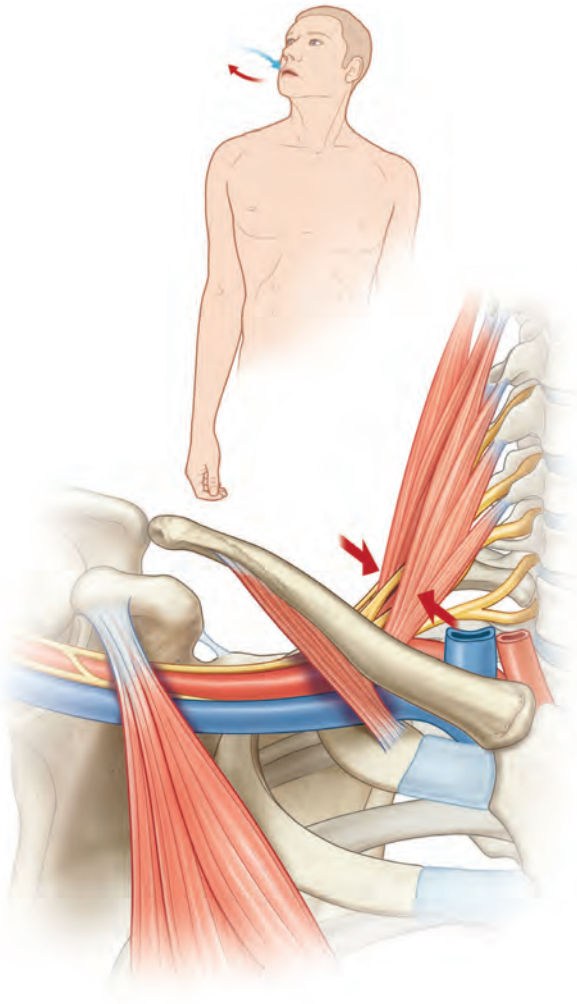

Fig. 2.25 Adson test is sensitive to entrapment of the neurovascular bundle in the interscalene space (arrows) by Adson test.

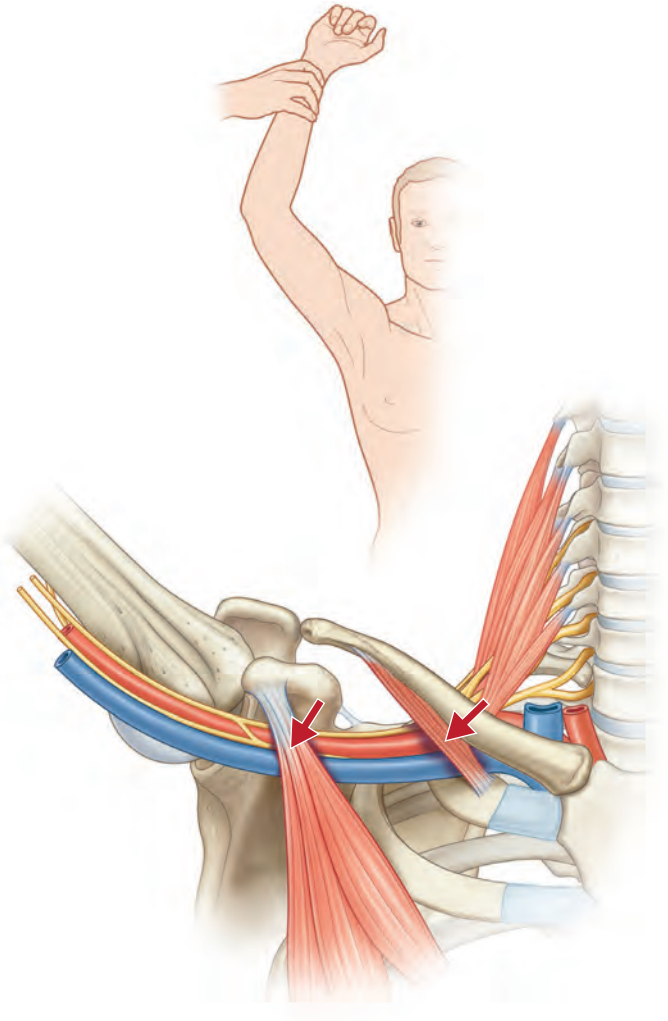

Fig. 2.27 The neurovascular bundle can be potentially entrapped in the costoclavicular space (red arrow) and the subpectoralis minor space (black arrow) by Wright test.

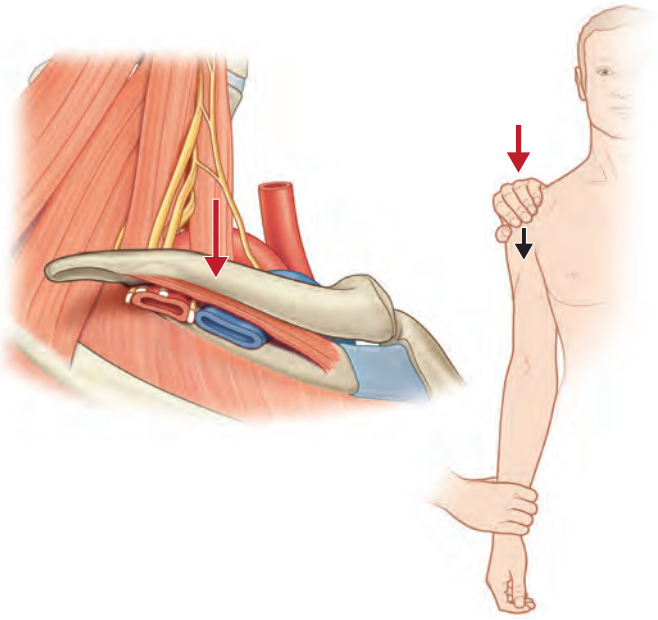

Fig. 2.26 The costoclavicular compression test is considered to detect the entrapment in the costoclavicular space (arrow).

Diagnostic imaging of the hand and wrist

Alphonsus K.S. Chong, Jin Xi Lim, and David M.K. Tan

Access video content for this chapter online at expertconsult.com

SYNOPSIS

- Radiographs form the cornerstone of diagnostic imaging of the hand and wrist, and are usually the first imaging modalities performed following clinical evaluation.
- The keys to obtaining the most information from radiographs are ordering the correct radiographs for the situation, and ensuring the radiograph is appropriately taken.
- A systematic and careful examination of the radiograph is necessary to glean the often subtle findings in the hand and wrist.
- Clinical evaluation with plain radiographs often provides sufficient information for clinical decision-making.
- Computed tomography (CT) scans, ultrasound, magnetic resonance imaging (MRI), and other advanced imaging modalities can supplement information from plain radiographs in selected situations. On occasion, they may be the primary imaging study performed.
- These advanced imaging modalities allow today's clinician to visualize disorders that would previously have required open surgery or biopsy.

Introduction

- A proper and directed history-taking followed by a careful examination of both hands and wrists forms the foundation of making a clinical differential diagnosis in hand conditions.
- Appropriate investigations are then ordered to help confirm the clinical diagnosis.
- Diagnostic imaging modalities are often the first-line investigations ordered, as many clinical conditions in the hand and wrist can be seen visually.
- Technological advances in many advanced imaging modalities like ultrasound, CT, and MRI, have led to them being applied for use in the hand and wrist. This increases clinician choices for diagnostic imaging of a suspected clinical condition.
- The radiograph, despite its simplicity and age, still forms the foundation of imaging of hand and wrist conditions. In many clinical situations, an appropriately chosen and well-taken set of radiographs may be all the diagnostic imaging required.
- The key to obtaining the most information from a radiograph is to understand which radiographs are appropriate for each clinical situation, and how to obtain good-quality radiographs for evaluation.
- Advanced imaging modalities may then be ordered to provide additional information for decision-making.
- This chapter will equip the reader with practical information about the different imaging modalities available for the hand and wrist.
- It will start from the foundation of radiographs, covering the appropriate views, how they are taken, and how best to evaluate them. Following which, the advanced imaging techniques will be described in turn, emphasizing their applications in the hand and wrist.

Access the Historical Perspective section online at http://www.expertconsult.com

Radiography

Radiography is the cornerstone in diagnostic imaging of the hand and wrist. It should be the first imaging modality for the diagnosis of most hand and wrist disorders.[2] The plain radiograph is inexpensive in relation to other imaging modalities, technically easy to perform, and widely available. The correct radiograph taken in an appropriate manner provides much imaging information to the attending clinician. In many hand and wrist conditions, radiography may also be the only imaging modality required for definitive diagnosis and assessment.

Historical perspective

The origins of diagnostic radiology are of particular significance to hand surgery. The first radiograph of human anatomy after the discovery of X-rays by Wilhelm Conrad Roentgen was that of his wife's hand in 1895. The medical community was quick to see the potential applications of this technology, and radiographs were rapidly adopted for clinical use. As a result, Roentgen is considered the father of diagnostic radiology, and his discovery led him to win the first Nobel Prize in Physics in 1901.

Plain X-ray radiographs are still the first-line imaging modality for the diagnosis of most hand and wrist disorders. Plain film radiography has progressed from a tedious process using an acetate-based film to one that applies digital technology. In newer facilities, widespread adoption of digital technology has led to radiographs that are not printed on film, but viewed on the computer screen. Beyond technology, the development of special views through positioning of the patient or machine, and stress application, has enabled improvements in imaging of specific disorders. The development of water-soluble contrast dyes allowed the use of X-rays to perform arthrography.

CT, MRI, and ultrasound are advanced imaging technologies that have become widely adopted for musculoskeletal imaging, including the hand and wrist. Improvements in hardware technology, software, and imaging protocols have resulted in improved imaging of bone, joints, and soft tissue. These technologies have enabled detailed visualization and assessment of the musculoskeletal system and its disorders in a noninvasive manner. Prior to these technologies, many of these disorders would have required open surgery or biopsy for diagnosis.

Improvements in imaging modalities and technology are only part of the equation for the advances made in musculoskeletal imaging. Equally important has been the parallel development of musculoskeletal radiology as a distinct subspecialty.[1] The dedication of musculoskeletal radiologists has been instrumental in developing their field, and subspecialty training of future musculoskeletal radiologists. These radiologists can better appreciate the often subtle findings on imaging, leading to improved diagnosis. This has translated to earlier and more effective clinical care and improved outcomes.

Musculoskeletal radiology continues to progress at a rapid pace as both a clinical specialty and in technological advances. Building on its strong foundations, musculoskeletal imaging will continue to be a crucial pillar in the diagnosis and assessment of hand and wrist disorders.

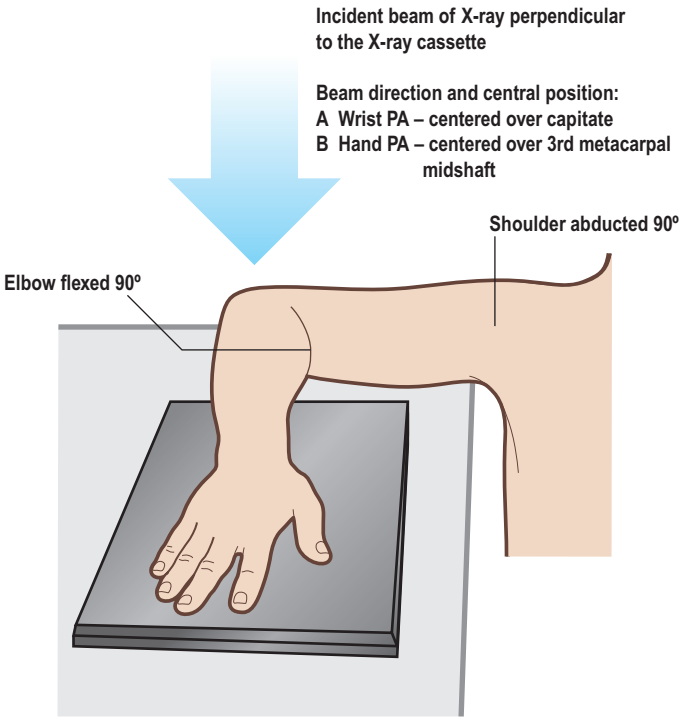

Fig. 3.1 The posteroanterior (PA) radiograph of the hand and wrist is taken in the position shown. For the hand radiograph, the beam is centered over the midshaft of the third metacarpal. For the wrist radiograph, it is centered over the capitate.

Fig. 3.3 This female patient presented with a soft-tissue mass over the ulnar side of the middle finger. The radiograph shows the outline of the soft-tissue mass with scalloping of the ulnar border of the middle phalanx. Histology of the mass showed this to be a pigmented villonodular synovitis.

Evaluation of the hand

The three basic radiographs to evaluate the hand are: posteroanterior (PA), oblique, and true lateral views. The radiographs should be performed in a standardized fashion to allow proper evaluation (Figs. 3.1 & 3.2). Specialized views are required to assess specific areas not well seen in the above views. The PA hand view provides a useful overview of the skeletal structure of the hand. Fractures, osseous tumors, and even soft-tissue masses (Fig. 3.3) can be seen on this view. The oblique view of the hand is useful to assess the metacarpals, as a true lateral view of the hand will lead to an overlapping of the second to fifth metacarpals. In the common boxer's or fifth metacarpal neck fracture, this view allows an assessment of the amount of angulation of the fracture.

In hand radiographs, begin by assessing the overall alignment of the metacarpals and phalanges. The individual bones should then be evaluated in terms of cortical shape and integrity, as well as bony quality. Fractures are usually easy to detect, although a careful review is necessary in the case of undisplaced or minimally displaced fractures. Osseous tumors are identified by an area of different lucency in the bone. There may be changes in the outline of the bone. Enchondromas are common benign bony tumors in the hand. They can result in pathological fractures, so an assessment of the bone for such pathology should be done, particularly if the trauma resulting in the injury is trivial (Fig. 3.4). Osteomyelitis typically occurs in the hand following open injuries (Fig. 3.5).

The joints should then be assessed, starting from the carpometacarpal joints (CMCJs) and working distally. The CMCJs may be dislocated following injury. These injuries are uncommon but are difficult to diagnose. In a normal hand X-ray the second to fifth CMCJs should be clearly visible on the PA view (Fig. 3.6).[3] The loss of these features in the second to fifth CMCJs is usually due to a fracture dislocation of one or more of the CMCJs. However, an improperly performed hand radiograph can also give this impression. Fisher *et al.* described a systematic approach to evaluating the PA view of the hand for dislocations of the fourth and fifth CMCJs.[3] In subluxation of the fifth CMCJ, the base of the fifth metacarpal is usually

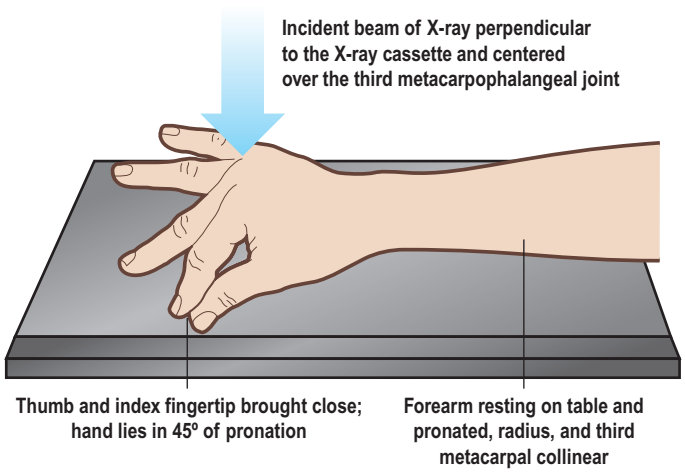

Fig. 3.2 The oblique hand radiograph is taken with the hand positioned as shown. This position provides a good non-overlapping view of the metacarpals. The view is not adequate for assessment of the digits; separate lateral views of the digits should be performed if necessary.

Fig. 3.4 This nurse presented with pain at the base of her right ring finger after transferring a patient from his bed to a chair. The radiograph shows a partial articular fracture of the base of the proximal phalanx of the right ring finger. The area of lucency just at the fracture site and minor trauma were suspicious for a pathological fracture.

Fig. 3.5 This elderly man presented with increasing pain and redness in the finger. The radiograph shows a destructive lesion of the distal phalanx and head of the middle phalanx. This is consistent with osteomyelitis. A differential diagnosis would be that of a malignant bone tumor. These are much rarer, and usually due to metastatic disease in terminally ill patients.

Fig. 3.6 In a normal hand radiograph, the second to fifth carpometacarpal joints should be well visualized, as shown. The articular surfaces should be profiled without overlap, parallel to each other, and have distinct cortical rims.

offset ulnarly compared to the hamate (Fig. 3.7). Several views have been suggested to confirm this diagnosis. The true lateral of the hand provides a useful way to assess the CMCJ for any signs of dislocation and oblique views may also be helpful[4,5]; if the diagnosis is still uncertain, a CT scan of the hand including the CMCJs will confirm the diagnosis.[6] The more distal joints are then evaluated, from the metacarpophalangeal joints to the proximal interphalangeal joints and distal interphalangeal joints. A normal joint should be completely congruent with a visible joint space.

Osteoarthritis commonly affects the interphalangeal joints and thumb CMCJs. It is often demonstrable on radiographs by narrowing of the joint space, subchondral sclerosis, osteophytes, and deformity (Fig. 3.8).

Special views in the hand (Box 3.1)

A true lateral radiograph of the finger is needed to complete an assessment of the digit. Hand radiographs alone are insufficient for assessment. This is because the oblique view of the hand does not provide an adequate lateral profile of the digit and interphalangeal joint spaces to supplement the PA view. With only a PA view, subtle fractures, fracture displacement, or joint subluxation of the fingers may not be apparent. Metacarpal head fractures may also be difficult to assess and the Brewerton view[7] will give additional information in addition to the standard hand radiographs.

To assess the thumb, specialized views are also necessary as the thumb lies in an oblique plane relative to the other digits in the usual hand radiograph. A true PA and lateral view of the thumb is obtained to allow proper radiographic

Fig. 3.7 This radiograph shows a dislocation of the fifth carpometacarpal joint. Note the ulnar offset of the fifth metacarpal with loss of the normal articular space.

assessment of the thumb. One common condition in the thumb for which radiographs are performed is that of basal joint or trapeziometacarpal joint (TMCJ) arthritis (Fig. 3.9). This condition is graded radiologically using the Eaton classification.[8] The irregular saddle shape of the trapezium makes visualization of the bone difficult, and the Betts view will allow all four articulations of the trapezium to be visible without overlap (Fig. 3.10).

The ulnar collateral ligament of the thumb metacarpophalangeal joint is commonly injured in forceful thumb abduction.[9] Less commonly the radial collateral ligament may also

Fig. 3.8 Osteoarthritis of the distal interphalangeal joints of middle and ring fingers. There is loss of joint space, and osteophytes are clearly seen on this lateral view.

BOX 3.1 **Special hand and thumb views**

Brewerton view

Purpose: To obtain tangential views of the metacarpal heads – for evaluation of metacarpal head fractures and erosive changes in rheumatoid arthritis

Positioning: With the palm facing up, the MCPJs are flexed 65° with the posterior aspect of the fingers in contact with the cassette, and beam angled at 15° from the ulnar side of the hand

Betts/Gedda view

Purpose: To obtain a true lateral view of the TMCJ, and see the trapezium in profile

Positioning: Palm of the hand must be placed flat on the cassette with the hand and forearm pronated, with the beam is then directed 5–10° distal to proximal

Robert's view

Purpose: To obtain a true AP view of the TMCJ

Positioning: The hand and forearm is hyperpronated such that the dorsum of the thumb lies on the cassette, with the beam angled 15° from the vertical

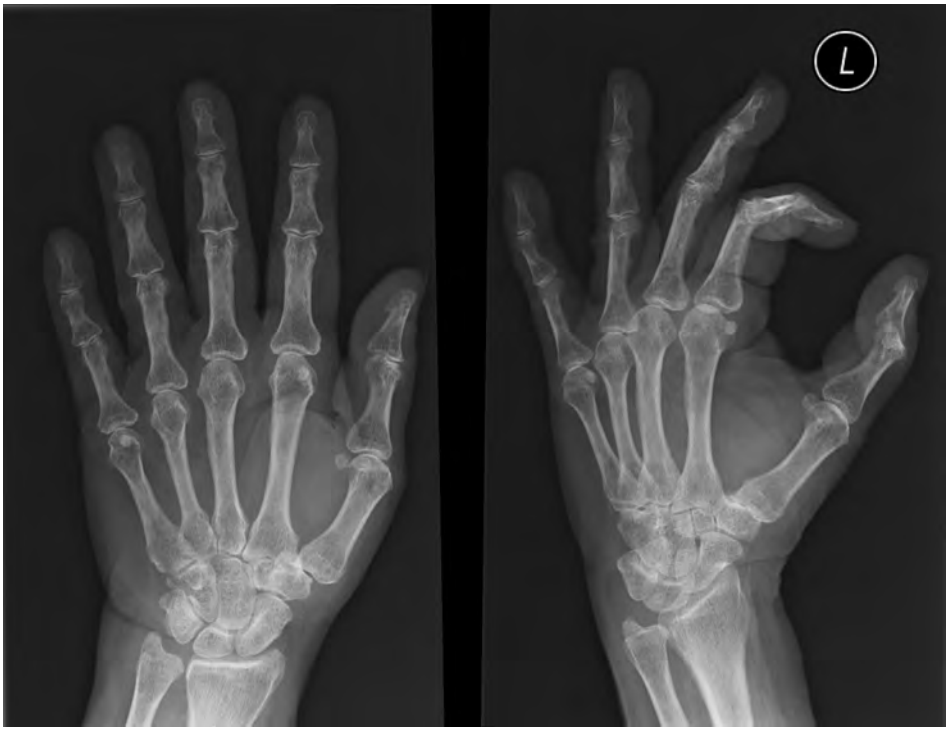

Fig. 3.9 The trapeziometacarpal joint shows narrowing of the joint space with osteophytes and joint subluxation.

Fig. 3.10 **(A)** Hand radiograph showing a trapezium fracture. **(B)** The Bett's view demonstrates the trapezial fracture and the step in the articular surface clearly.

Table 3.1 Appearance of ossification centers and fusion of epiphyses in children

	Females	Males
Appearance of capitate and hamate	3 months	3 months
Appearance of distal radius ossification center	10 months	1 year 3 months
Appearance of phalanges and metacarpal ossification center	10 months to 2 years	14 months to 3 years
Fusion of phalangeal and metacarpal epiphyses	13–15 years	14–16 years
Fusion of distal radius and ulna epiphyses	15–17 years	17–19 years

be injured. Lateral stress application during the posteroanterior thumb radiograph can be helpful to assess if the ligament injuries are complete or partial. Ultrasonography and MRI are alternatives to assess this injury.[10,11]

Pediatric hand radiographs

Evaluation of the pediatric hand, especially after injury, is often more difficult than in adults. All carpal bones and epiphyses in the hand lack ossification in the newborn. The ossification centers then appear in a well-recognized sequence,[12] as detailed in Table 3.1. The staggered ossification of the various carpal bones (Fig. 3.11) and the presence of the growth plate may confuse the examiner as to whether a fracture is present or not.

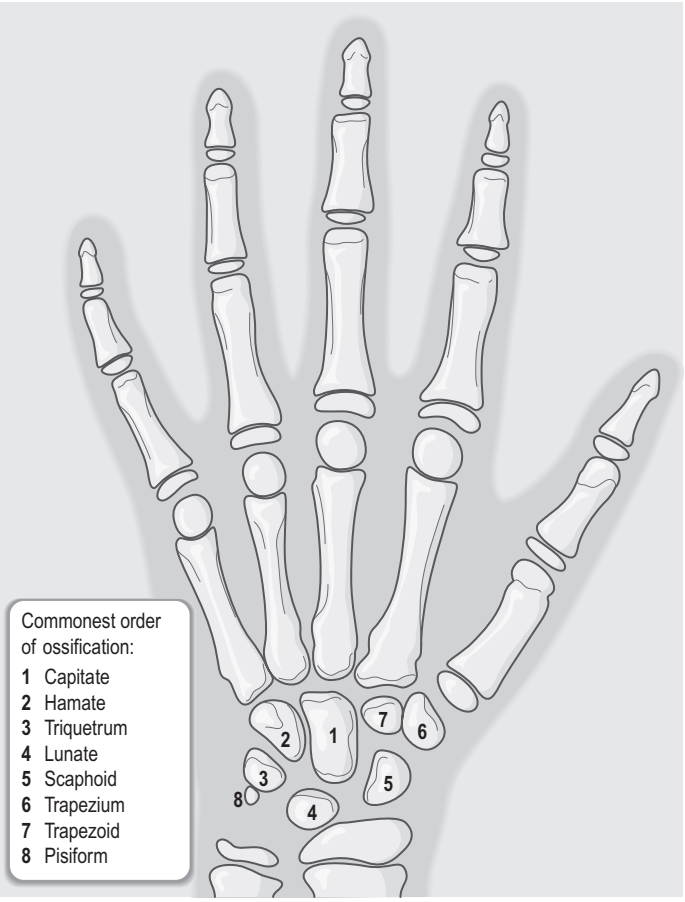

Fig. 3.11 Commonest order of ossification: capitate, hamate, triquetrum, lunate, scaphoid, trapezium, trapezoid, and pisiform. Note the position of the growth plates on the proximal ends of the phalanges and first metacarpal. In the remaining ulnar four metacarpals, the growth plate is on the distal end of the bone.

A misdiagnosis rate of 8% for pediatric hand fractures was found in one study.[13] There are several reasons for this. Clinical evaluation in children is more difficult, the more so the younger the child. It may not be possible to localize the site of the problem clearly, e.g., the site of injury following trauma. Proper standardized views may also be difficult to obtain. Other reasons for misdiagnosis include missing additional fractures and using an X-ray that was obscured by dressings.[13] When the clinical suspicion remains high and the films obtained are inadequate, the radiograph should be repeated, either the same day or at another time when the patient is more cooperative. Similar views taken of the opposite uninjured limb are also helpful for evaluation.

Growth plate-related injuries are common in children. These injuries can be classified according to the system described by Salter and Harris (Fig. 3.12).[14] The Salter–Harris type II fracture injury is the most common type of growth plate injury seen in the hand.

Wrist evaluation

A properly performed set of orthogonal wrist radiographs forms the basis of an effective evaluation of the wrist.[15,16] This is especially important when indices are being measured. The wrist has numerous asymmetrically arranged bones, so a methodical assessment of the bones, joints, and overall alignment of the wrist is necessary.

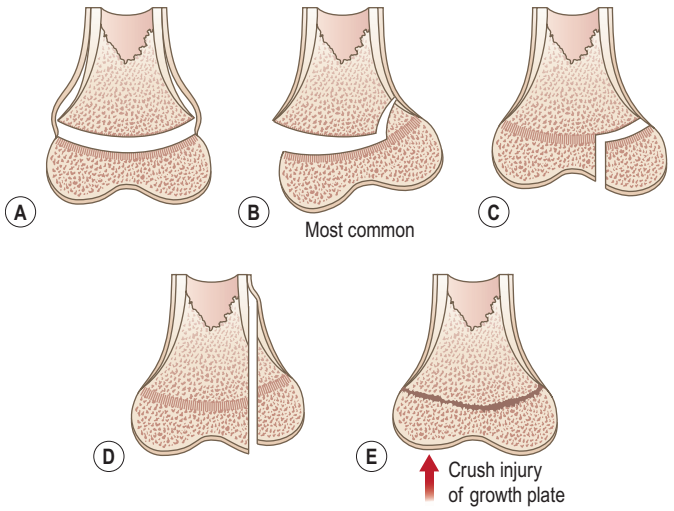

Fig. 3.12 (A–E) The Salter–Harris classification of epiphyseal plate injuries. (Redrawn after *Salter RB, Harris R. Injuries involving the epiphyseal plate.* J Bone Joint Surg Am. *1963;45:587–621.)*

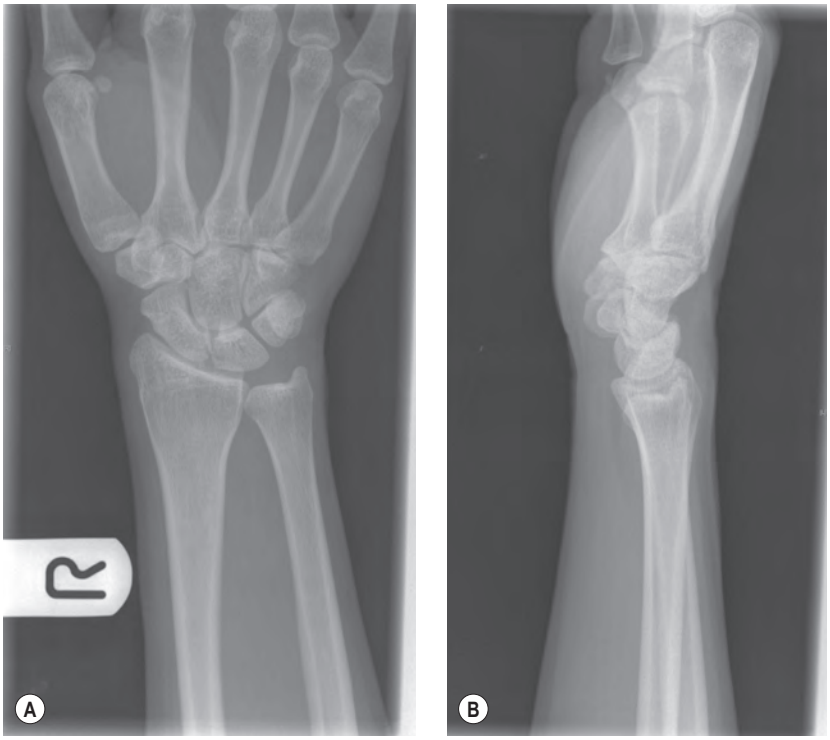

Fig. 3.13 Normal wrist radiograph. **(A)** In the posteroanterior view, note the lateral position of the ulnar styloid and position of the extensor carpi ulnaris groove. It lies radial to the straight line that passes tangential to the radial edge of the ulnar styloid at the fovea. This indicates a good posteroanterior view. **(B)** On the lateral view, there is good radioulnar overlap.

Obtaining proper views for wrist radiographs (***Figs.*** 3.1 & 3.13; see Fig. 3.18, below) requires careful positioning which may be difficult to achieve in patients with pain or limitations in motion of the affected upper limb (Box 3.2).

The wrist radiograph is first evaluated by checking the overall alignment of the bones of the wrist, starting with the distal radius and ulna, progressing to the carpal bones and metacarpal bases. Gilula described three smooth arcs made by the articular surfaces of the proximal and distal carpal row bones in a normal wrist PA radiograph (Fig. 3.14).[17] A loss of the normal contour usually indicates a disruption in the normal arrangement of these carpal bones. A common cause of this is a perilunate dislocation (Fig. 3.15). Lunotriquetral (LT) dissociation is another cause of the loss of the normal Gilula's lines. Care must be taken when interpreting these findings in an asymptomatic patient as radial or ulnar deviation of the wrist can introduce a break in the arcs.[18]

The overall relationship between the different bones can also be assessed using two common parameters: the carpal height ratio and ulnar variance. These provide a quantitative assessment of the structural integrity of the carpal rows, and the relationship of the distal radius and ulna articular surfaces, respectively.

The carpal height ratio (Fig. 3.16)[19,20] gives a measure of the distance between the distal articular surface of the radius to the proximal articular surface of the third metacarpal base. A loss of this distance is seen in collapse of a carpal bone, for example Kienbock's disease (avascular necrosis (AVN) of the lunate) or in malrotation of the carpal bones, for example in rheumatoid arthritis or scapholunate (SL) dissociation. A ratio is used instead of actual dimensions to correct for variability in carpal bone sizes.

The ulnar variance provides a measure of the height difference between distal radius and ulnar articular surfaces. There are several ways to measure the ulnar variance.[21,22] We prefer the technique of the perpendiculars (Fig. 3.17). It is easy to perform and has been shown to have higher intra- and interobserver reliability.[23]

BOX 3.2 **Assessing quality of wrist radiographs**

There are criteria for acceptable wrist views. The PA view is assessed using the position of the ulnar styloid and extensor carpi ulnaris tendon groove.[15] The lateral view is assessed using the radioulnar overlap and scaphopisocapitate relationships.[16]

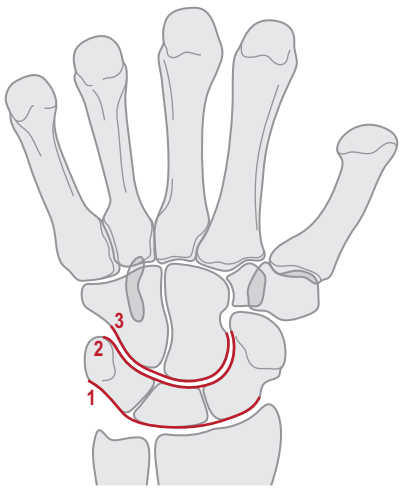

Fig. 3.14 In a normal posteroanterior wrist radiograph, three smooth curved non-overlapping lines can be drawn on the proximal and distal cortical surfaces of the proximal carpal bones (lines 1 and 2) and proximal surface of the distal carpal row (line 3). A disruption or step-off indicates a loss of the normal carpal bone relationships.

Fig. 3.15 This radiograph shows a perilunate fracture dislocation with disruption of the normal smooth carpal arcs. There are associated radioulnar shaft fractures.

A proper PA and lateral radiograph of the wrist (Fig. 3.18; see Fig. 3.13) is the first necessary imaging for the evaluation of a suspected distal radioulnar joint (DRUJ) instability. Radiographic findings associated with this injury include widening of the DRUJ, a fracture of the ulnar styloid base, or a displaced fracture from the ulnar fovea. On the lateral view, there is loss of the normal radioulnar overlap. A comparison

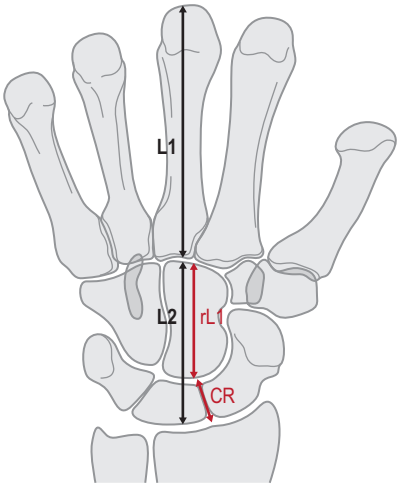

Fig. 3.16 (1) Carpal height ratio = carpal height (L2)/third metacarpal length (L1). Normal is 0.54 ± 0.03. (2) Revised carpal height ratio = carpal height (L2)/heights of capitate (rL1). (3) Capitate–radius index (CR). This is the shortest line between two eccentric arches of the carpal rows. The line is moved until the shortest distance is measured. Mean CR index 0.999 ± 0.034. Values less than 0.92 are abnormal.

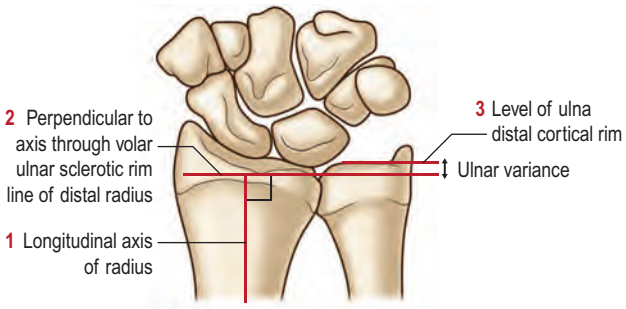

Fig. 3.17 Ulnar variance is measured on a true neutral posteroanterior view of the wrist. First a line along the longitudinal axis of the radius is drawn. Next a line perpendicular to this line through the volar ulnar sclerotic rim of the distal radius is drawn. Finally a line parallel to this second line at the level of the distal cortical rim of the ulna is drawn. The distance between these two parallel lines is the ulnar variance.

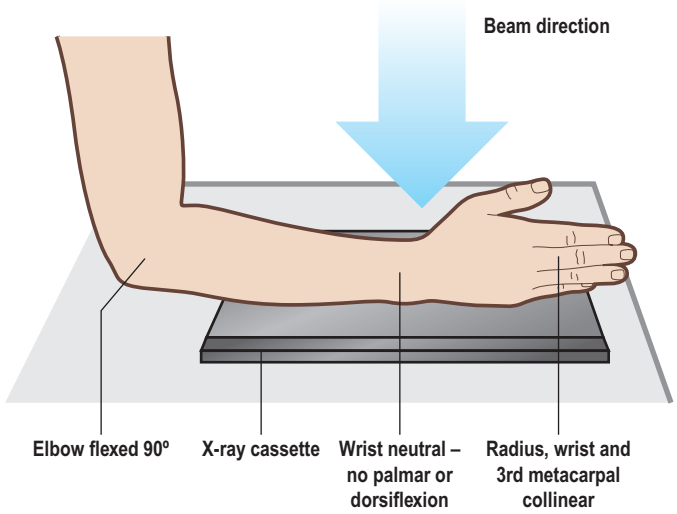

Fig. 3.18 A true lateral view of wrist is taken in the position shown.

radiograph of the contralateral normal wrist is helpful if the findings are unclear. The application of volar or dorsal-directed stress is also helpful in cases of suspected DRUJ instability (Fig. 3.19).

Scaphoid fractures are the commonest carpal fracture. The shape of the scaphoid bone does not lend itself well to evaluation by just two orthogonal views, so a "scaphoid series" of X-rays is usually done (Fig. 3.20 and Box 3.3).

Fractures of the hook of the hamate are uncommon but disabling. A carpal tunnel view is helpful to diagnose this injury (Fig. 3.21), although a CT scan can also provide the definitive diagnosis.

BOX 3.3 **Scaphoid series**

The scaphoid view of the wrist addresses the normal foreshortening of the scaphoid seen on the conventional PA wrist radiograph. The view is taken with the wrist ulnarly deviated and the X-ray tube angled 20–30°. Several other views are helpful for assessment of the scaphoid: a pronated oblique view (to view the distal third and tubercle of the scaphoid better), a supinated view (to assess the dorsoradial ridge of scaphoid and pisiotriquetral articulation), and a lateral view to help assess a humpback deformity.

Fig. 3.19 Stress view: true lateral of the wrist. Notice the loss of radioulnar overlap due to the dorsal subluxation of the distal radioulnar joint. The pisiform lies between the volar aspect of the scaphoid and capitate, so the view is accurate.

Injuries to the wrist ligaments, for example the SL ligament, can lead to carpal instability. In severe cases, this can be seen on the usual wrist views as loss of the normal relationships between the carpal bones. In SL instability, this is typically seen as a dorsal intercalated segmental instability deformity (Fig. 3.22) with an increase in the SL angle, and dorsal tilt in the radiolunate angles (Fig. 3.23). However, in milder forms of instability, application of loads and/or positioning of the wrist are necessary to bring out these dynamic changes in carpal relationships. The clenched-fist PA series of the wrist is one technique used to diagnose dynamic carpal instability (Fig. 3.24).

Ulnar abutment syndrome is a common cause of ulnar-sided wrist pain. The use of a clenched-fist pronated view of the wrist enhances the ulnar variance and may demonstrate the abutment (Fig. 3.25).[24]

Wrist evaluation in distal radius fractures

Distal radius fractures are the commonest fractures encountered in the emergency room.[25] Loss of the normal distal radius indices (Figs. 3.26 & 3.27) due to fracture displacement can affect final outcome. Unstable and displaced fractures are commonly treated with plates and screws. Screws placed subchondrally offer the greatest rigidity in fixation. However, conventional wrist views do not allow accurate assessment of screw position, especially when a distal fracture line compels the surgeon to place the screws in close proximity to the radiocarpal joint. This is because standard views do not compensate for the normal anatomic tilt of the radius. Radiographs angled 22 degree lateral and 11 degree posteroanterior (Fig. 3.28) enable tangential X-ray exposure to the articular surface and facilitate this assessment after fixation. With increasing using of volar plates for treatment of distal radius fractures, extensor tendon rupture from screw protrusion dorsally is a concern. Detection of dorsal screw protrusion from a lateral X-ray has a sensitivity of only 56%[26] and on average, protrusion of the radial-most screw can only be detected at a minimum of 6.5 mm of protrusion.[27] Special X-ray views can be done to improve detection of screw protrusion (Box 3.4 and Fig. 3.29)

The availability of fluoroscopy in many clinics and operating rooms allows the dynamic assessment of many hand and wrist conditions. Smaller, lower cost, and radiation[28] mini c-arms have also lowered the barrier to acquiring such facilities. The clinician can operate the c-arm to obtain the best view and view changes in the relationships of the bones "live" with motion, loading, or application of stress. Fluoroscopy is helpful for assessing carpal instability, including SL injuries[29] (Video 3.1 ▶) and midcarpal instability (Video 3.2 ▶), guiding percutaneous insertion of implants, and assessing the position of implants.[30]

Ultrasonography

Diagnostic ultrasound has advanced much recently. New ultra-high frequency probes and smaller probe sizes allow higher-quality images of the hand and wrist.[31] Ultrasound's safety, portability, and relatively low cost have led to wider use, especially by clinicians operating the machines themselves.[32] One additional advantage over other forms of imaging, like CT scanning or MRI, is that it allows dynamic and real-time assessment. The addition of Doppler imaging enhances the information provided by the ultrasound study.[31]

Ultrasound uses the acoustic properties of generated sound waves to form images.[32] The ultrasound transducer generates the sound waves in pulses. When the transducer is applied over the surface of the part to be examined, the sound waves pass through tissues. At the junction of two tissues, an acoustic interface occurs. When the sound waves meet an acoustic interface, some of the sound wave energy is reflected, while the rest continues to be transmitted deeper. The greater the differences in material properties of the adjacent tissues, the

BOX 3.4 **Additional views for assessment of dorsal screw penetration from distal radius**

Supinated

This view aligns the X-ray beam to the radial side of the dorsal cortex, allowing easier detection of prominent screws in the first and second dorsal compartment.

Pronated

This view aligns the X-ray beam to the dorsal-ulnar corner of the distal radius and allow easier detection of prominent screws in the fourth extensor compartment.

Dorsal horizon view

This view is done with the wrist hyperflexed and the X-ray beam aimed along the longitudinal axis of the radius.

Fig. 3.20 Scaphoid series to assess for a scaphoid fracture. Notice the fracture is best seen in the scaphoid view on the lower left corner of the series.

more energy is reflected. The reflected sound wave is received in the transducer. This is then converted to an electrical signal for processing. The greater the sound reflected, the larger the amplitude of the reflected wave, and consequently, the brighter the image.

Ultrasound has its disadvantages (Table 3.2). It only allows a small field of view, so is best used for a focused examination of a small area. Differentiation of different soft-tissue tumors of the hand and wrist, apart from ganglia, is also inadequate.[33] The problem of anisotropy can lead to reduced echogenicity when tendons are being imaged. Anisotropy is a phenomenon where the echogenicity of the tendon changes when the incidence of the sound beam changes. This can lead to the operator mistaking anisotropy for pathology like tendon degeneration. A careful complete assessment of suspected tendon lesions will detect this phenomenon.[34]

One major advantage of musculoskeletal ultrasound is the ability to do real-time and dynamic assessments. An area in the hand and wrist where this is particularly useful is in the assessment of tendons. For example, flexor tendon bowstringing due to pulley rupture can be dynamically demonstrated on ultrasound by the patient. Tendinopathies, partial and complete tendon tears, or lacerations can be demonstrated (Fig. 3.30). Ultrasound has also been shown to be able to detect changes in trigger finger[35] and DeQuervain's tenosynovitis.[36]

Table 3.2 Advantages and disadvantages of ultrasound

Advantages	Disadvantages
• No ionizing radiation • Allows real-time and dynamic assessment by operator • Relatively cheap to acquire and operate	• Very limited field of view • Highly operator-dependent • Limited usefulness for assessment of soft-tissue masses

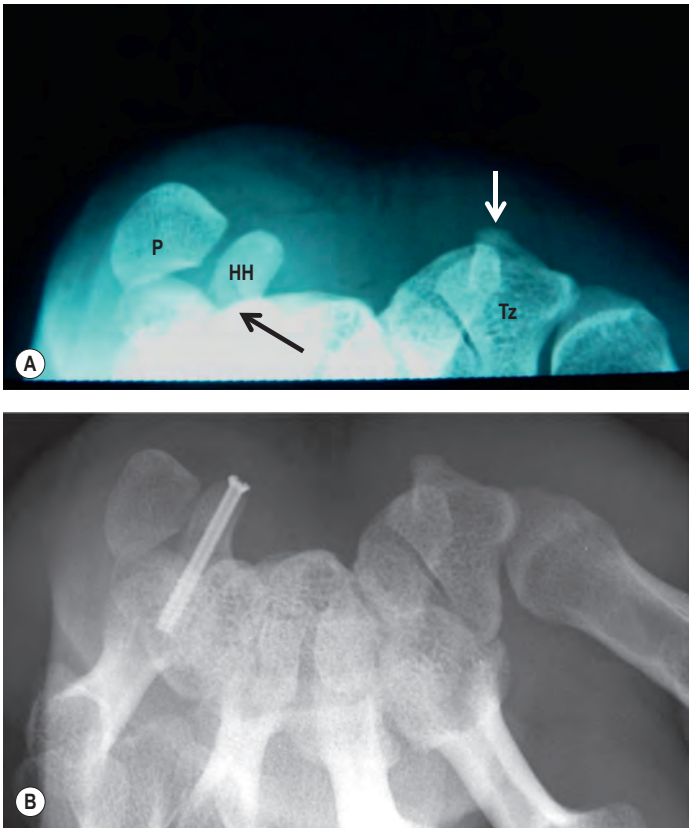

Fig. 3.21 **(A)** Carpal tunnel view of the wrist demonstrating several structures: trapezium (Tz), pisiform (P), and hook of hamate (HH). A fracture across the hook of the hamate is indicated by the black arrow. The trapezial ridge (indicated by white arrow) is an unusual site for fractures that is best seen on this projection. **(B)** Same patient with carpal tunnel view of the same wrist following open reduction and screw fixation. Notice that the fracture line is no longer visible.

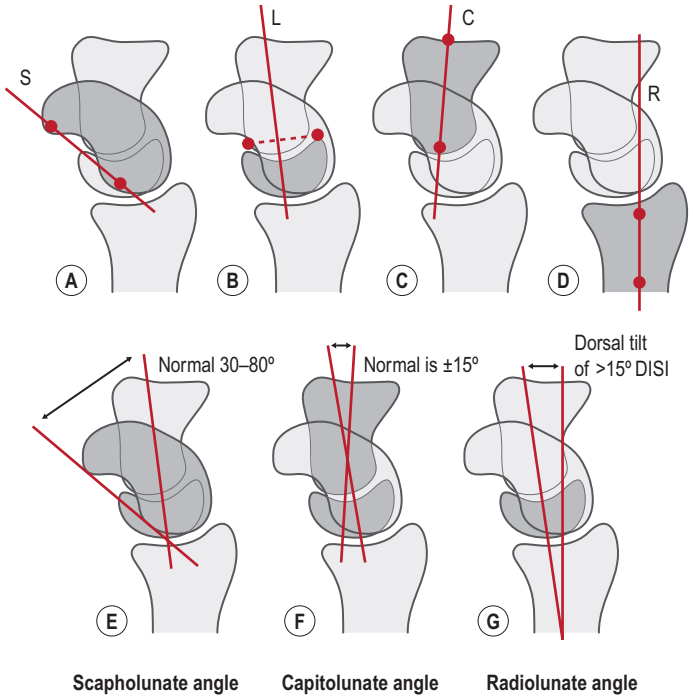

Fig. 3.23 Carpal indices. Axes are drawn based on the true lateral wrist radiograph. **(A)** The scaphoid (S) is represented by a tangential line that connects the two palmar convexities of the bone. **(B)** The lunate (L) axis is perpendicular to a line that joins the two distal horns of the bone. **(C)** The capitate (C) axis is determined by the center of the two proximal and distal articular surfaces. **(D)** The axis of the radius (R) is obtained by tracing perpendicular lines to its distal third and connecting the center of these lines. **(E)** Normal scapholunate angles. **(F)** Normal capitolunate angles. **(G)** Normal radiolunate angles. DISI, dorsal intercalated segmental instability.

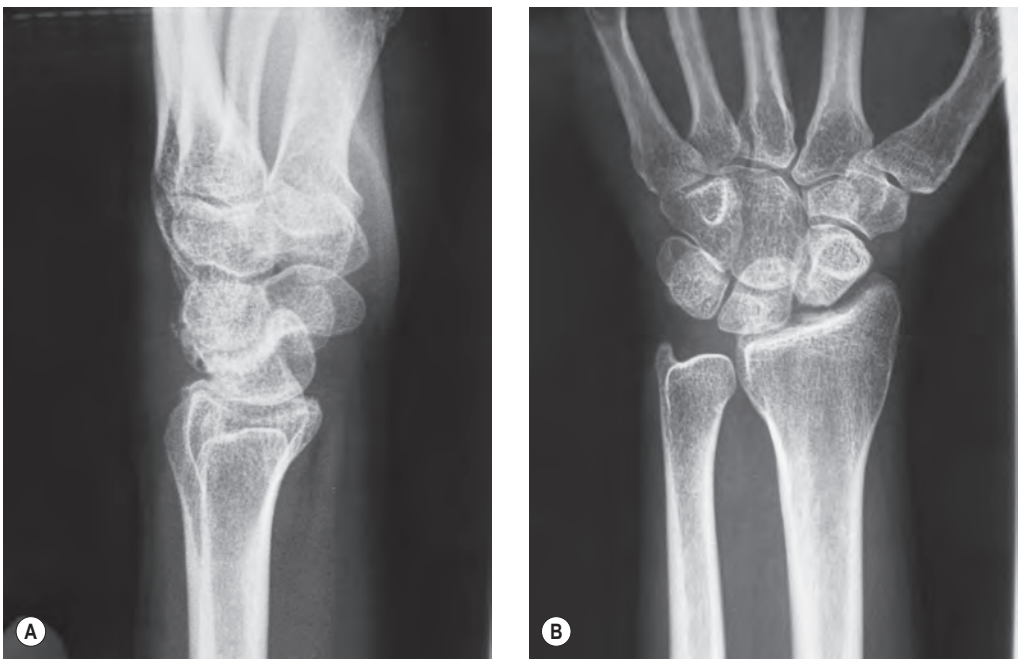

Fig. 3.22 DISI is the acronym for dorsal intercalated segmental instability. The term "intercalated segment" refers to the proximal carpal row bones. **(A)** This row has no direct musculotendinous insertions, hence it is "intercalated." "Dorsal" refers to the dorsiflexion of the lunate seen in the radiograph. A scapholunate dissociation is the commonest cause of a DISI deformity, and will show an increased scapholunate angle as above. **(B)** On the posteroanterior view, the scaphoid will appear flexed and foreshortened with a positive cortical ring sign as seen.

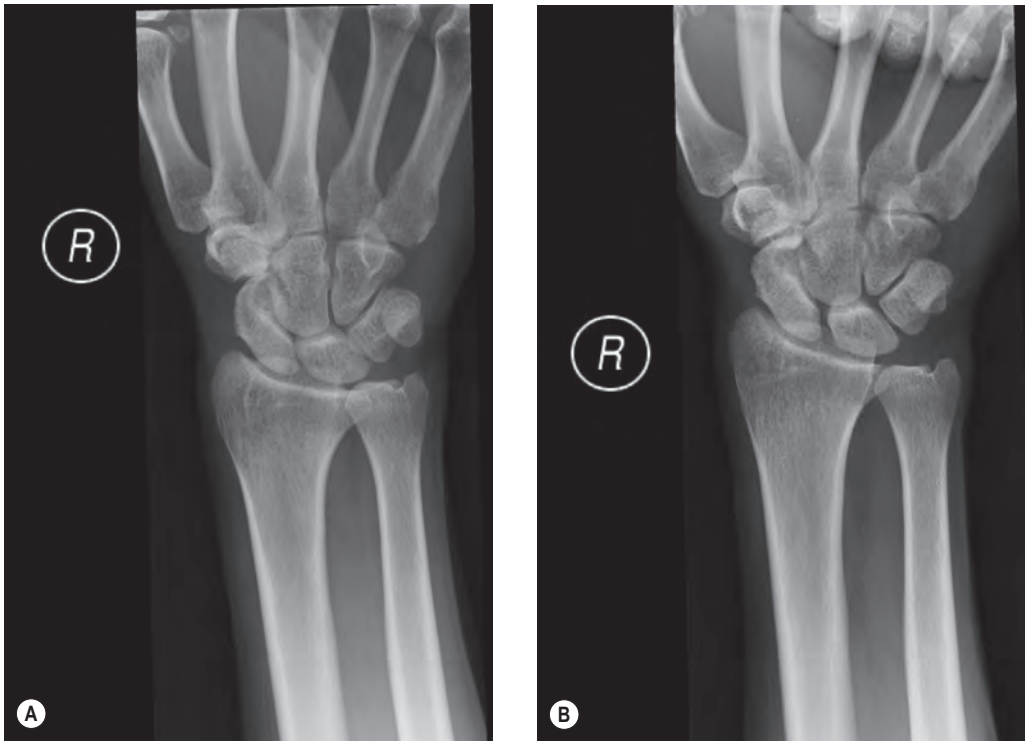

Fig. 3.24 These radiographs show a patient with dynamic scapholunate instability. The scapholunate interval is normal on an unloaded wrist **(A)**, but widens on clenching the fist **(B)**.

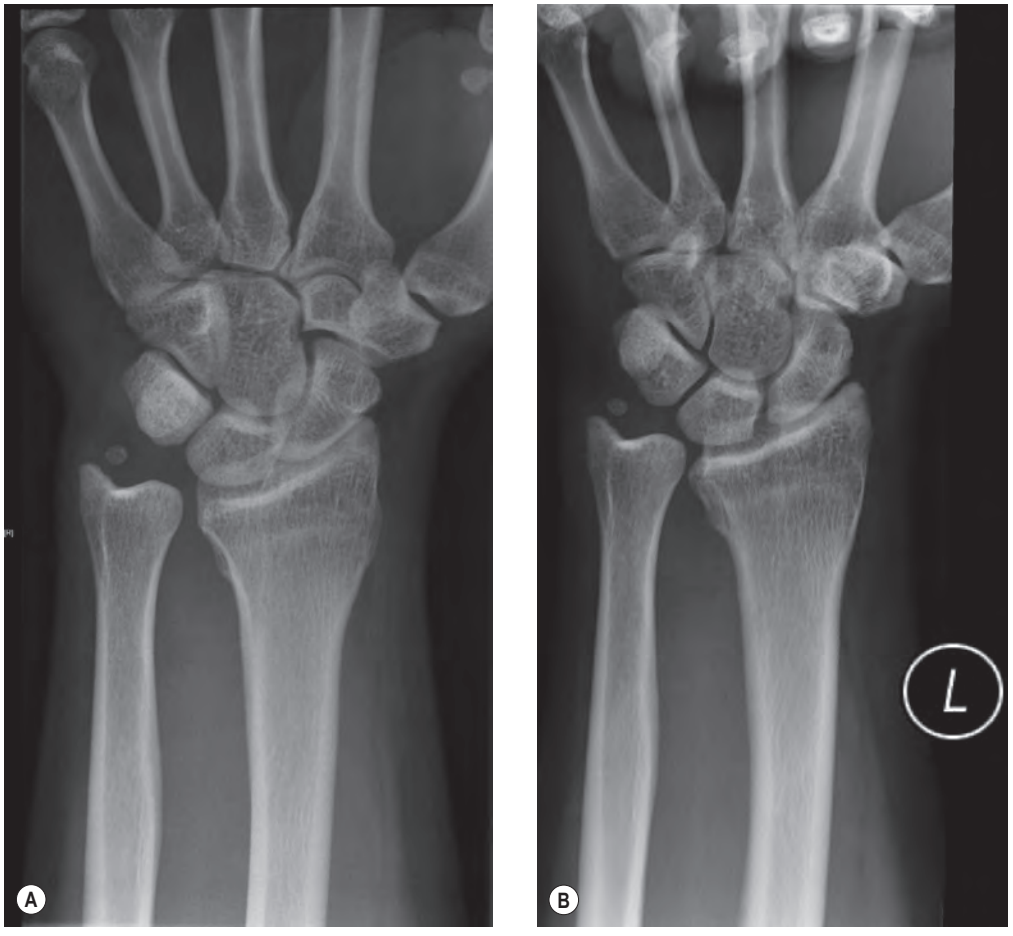

Fig. 3.25 This patient presented with signs and symptoms of ulnar carpal abutment. The positive ulnar variance **(A)** is increased with the pronated clenched-fist view **(B)**.

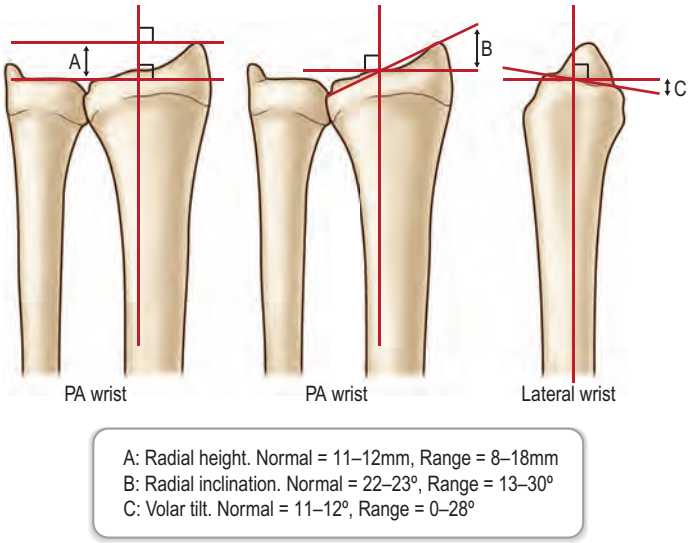

Fig. 3.26 Normal distal radius indices. PA, Posteroanterior.

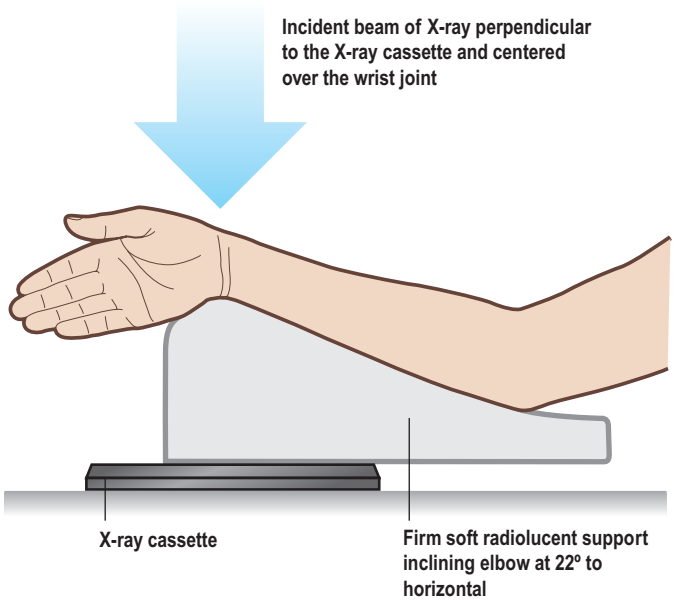

Fig. 3.28 Position of the limb and direction of X-ray beam for an anatomical tilt lateral view of the distal radius. This view is very helpful for assessing screw position when applying plates and screws close to the articular surface in distal radius fractures.

In trigger finger, ultrasound has also been used to guide steroid injection and percutaneous release.[37,38]

Diagnostic ultrasonography has also been applied to other wrist and hand disorders. Carpal ligament injuries and triangular fibrocartilage (TFCC) tears can be assessed using ultrasonography.[39] For TFCC tears, ultrasonography has been shown to have good correlation with MRI.[40] Ultrasonography of the carpal tunnel may be helpful to assess carpal tunnel syndrome. The median nerve is enlarged in carpal tunnel syndrome, with changes in the echogenicity of the nerve. The most consistent finding across the studies is the increase of the cross-sectional area of the median nerve at the level of the pisiform bone.[41] Ultrasound is also useful for clinical assessment if other causes of carpal tunnel syndrome are suspected (e.g., mass lesions in the carpal tunnel or tenosynovitis).

Computed tomography

CT is a key advanced imaging modality for the assessment of hand and wrist disorders, particularly those affecting the

Fig. 3.27 Distal radius fracture with loss of the normal radial height, inclination, and volar tilt.

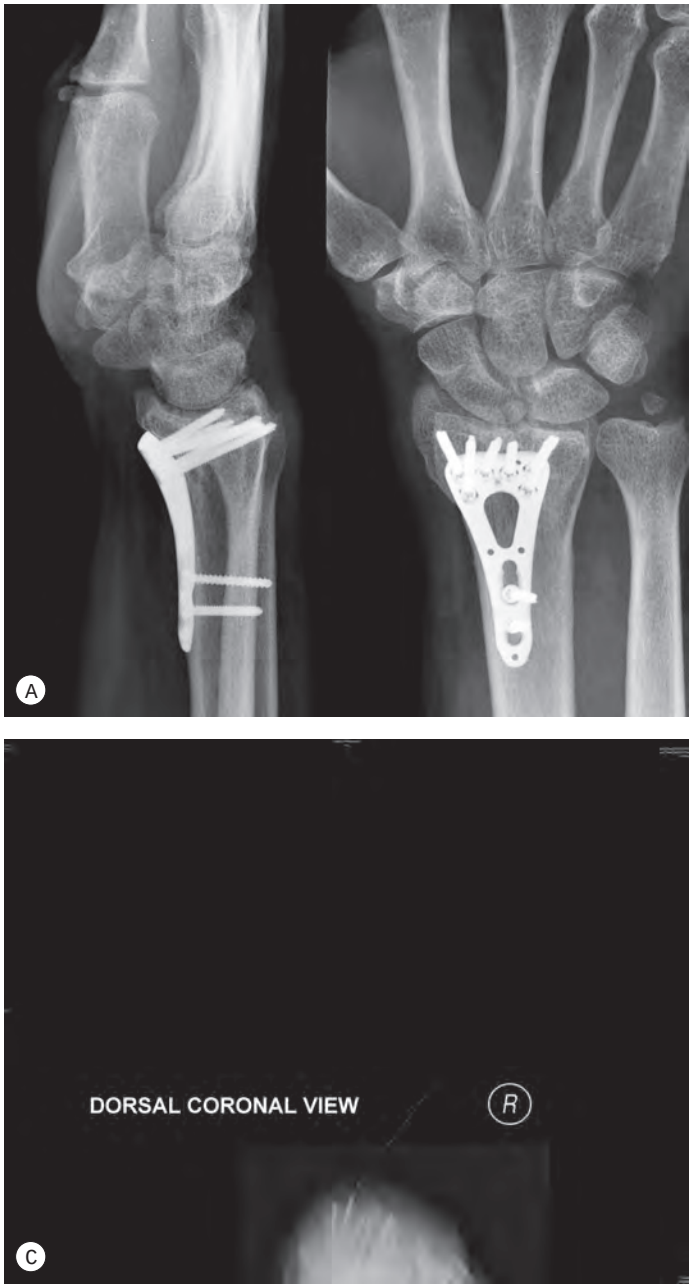

Fig. 3.29 **(A)** Standard PA and lateral wrist X-rays showing a distal radius fracture post-fixation. **(B)** Supination and pronation views showing dorsal screw penetration. **(C)** Dorsal horizon view showing dorsal screw penetration.

bones and joints. Advances in CT scanning technology have resulted in shorter scanning times, and allow manipulation and reformatting of the CT data for image reconstruction in multiple planes and the development of three-dimensional images. The advantages and disadvantages of CT are shown in Table 3.3.

Fractures and dislocations

CT is useful in evaluation of the hand and wrist for bony and joint injuries that are not well visualized or assessed using radiographs. Examples of these include scaphoid fractures, CMC joint injuries (see discussion in radiography section, above), and other articular fractures (Fig. 3.31).

Scaphoid fractures are often difficult to detect on plain radiology after an acute injury. A repeat radiograph several weeks later or other radiological investigations like CT scan, MRI, and bone scans are often employed to detect an occult scaphoid fracture.[42] In one study, multidetector CT was shown to be as effective as MRI in the detection of such occult fractures.[43] In the management of scaphoid fractures, CT scan is useful in evaluating fracture union,[44] as plain radiography has been shown to have poor interobserver agreement for assessing scaphoid union.[45] CT scans along the long axis of the scaphoid[46] improve the ability to evaluate the scaphoid for fractures, and assess for any displacement or humpback deformity.[47] CT scan is also useful for the evaluation of other carpal fractures.[48]

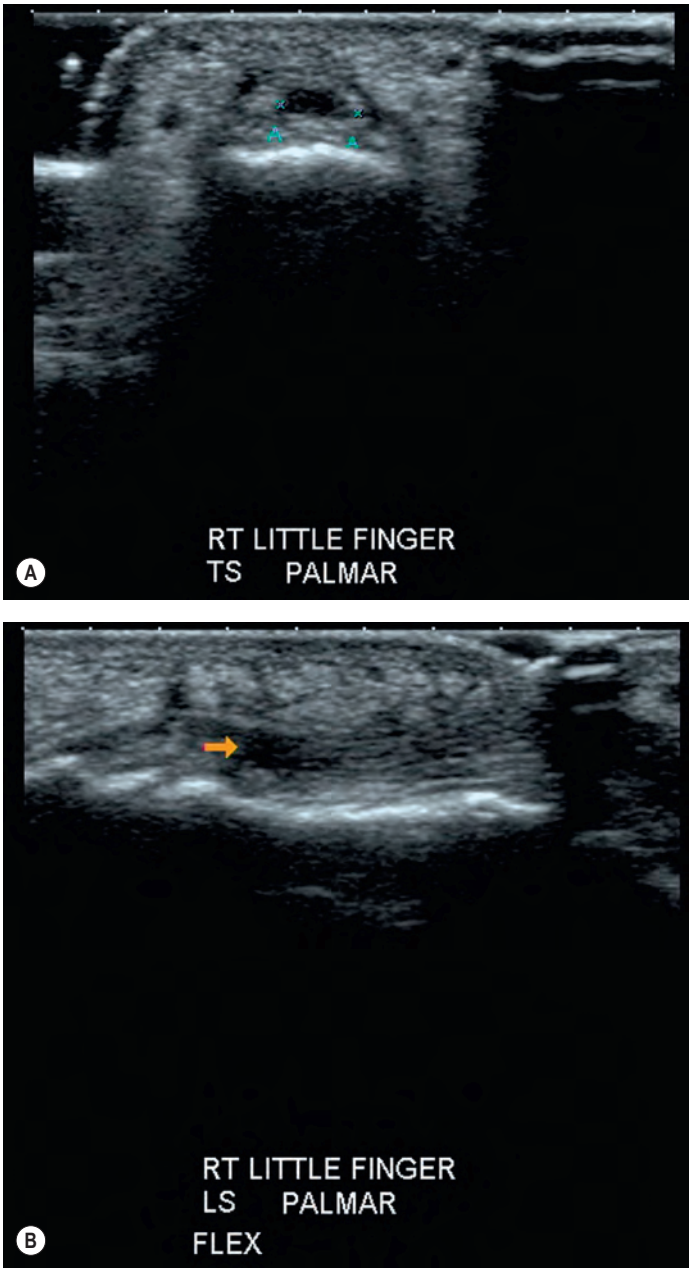

Fig. 3.30 This patient presented with difficulty in finger flexion after an injury. Ultrasonography showed a partial tear of flexor tendon at the level of the head of middle phalanx, more obvious on flexion against resistance (dark area, arrowed on longitudinal section image and between calipers on transverse section image). *(Courtesy of Dr. Ian Tsou, Singapore.)*

Wrist radiographs provide a first evaluation of the distal radius fractures. In an acute fracture, patient positioning is hindered by pain, and suboptimal radiographs are common. Radiography can over- and underestimate the articular step-off in 30% of intra-articular fractures.[49] CT scans of the wrist can improve assessment, which has an impact on clinical decision-making (Fig. 3.32). CT scanning and three-dimensional reconstruction are also helpful in complex fractures of the distal radius and ulna to help in surgical planning. In distal radius malunion, CT is recommended to assess the deformity[50] and as a basis for computer-assisted surgical techniques.[51,52]

Table 3.3 **Advantages and disadvantages of computed tomography (CT)**

Advantages	Disadvantages
• Quick scanning with modern machines • Capacity to image in any anatomic plane (multiplanar imaging) and three-dimensional reconstruction • Excellent for assessing complex or poorly visualized fractures in the hand and wrist • CT angiography can be performed at the same sitting to assess the vascular tree	• Inferior to magnetic resonance imaging for imaging of soft tissue • Requires expose to ionizing radiation • Prone to artifacts from patient movement and implants

CT is also helpful in suspected DRUJ instability. A proper lateral view of the wrist is the key initial imaging. There are several pitfalls associated with this. Proper positioning of the wrist for a proper lateral wrist radiograph or stress views may not be possible because of pain or other factors. The instability may be subtle, manifesting only in certain wrist positions or under load. Bilateral axial cut CT scans of the wrists in the

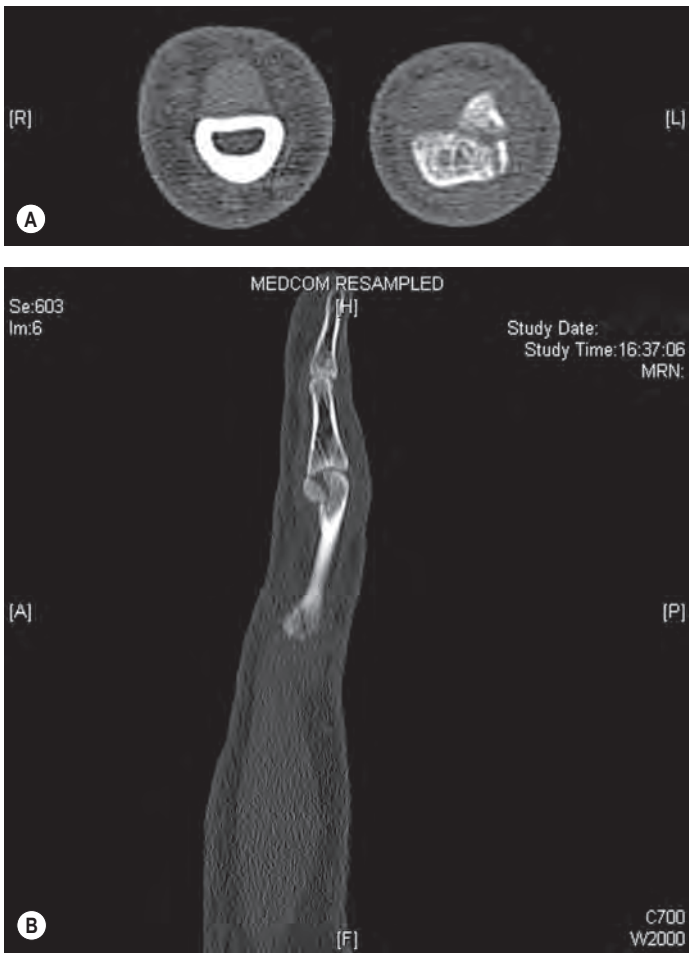

Fig. 3.31 This displaced fracture of the radial condyle of the proximal phalanx (small finger) is well visualized on the computed tomography **(A)** and **(B)**, but obscured on plain radiograph. There is a concomitant fracture of phalanx base, seen in **(B)**.

Fig. 3.32 Coronal computed tomography (CT) image of distal radius fracture. Extension into the radiocarpal joint is seen here but not on the plain radiograph. CT is helpful for the assessment of intra-articular distal radius fractures with respect to articular involvement and incongruity, fragment number, and fragment orientation.

neutral, pronated, and supinated position provide critical information to allow better evaluation of these injuries (Fig. 3.33). For CT evaluation of DRUJ instability, different radiographic parameters have been described.[53–56] Our institution uses the subluxation ratio method described by Park and Kim.[57]

Other applications of CT

CT is also helpful for the evaluation of bony tumors in the hand. CT can help characterize the bony tumor and assess for bony destruction. In these situations, MRI is often complementary. Fine-cut CTs are the modality of choice for osteoid osteoma.[58]

There are limitations to the use of CT. Soft-tissue resolution is limited, so it is less useful than MRI for imaging soft-tissue disorders. Artifacts from various sources, including patient movement and metal implants, hinder evaluation. Software techniques can be used to limit these artifacts, but often at the cost of resolution at the site of interest.[59]

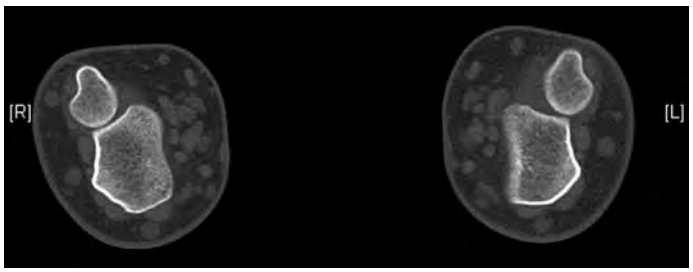

Fig. 3.33 Axial computed tomography cut of distal radioulnar joint in neutral position shows dorsal subluxation of the left joint (right image). This can be quantified by the use of indices.

The usefulness of CT is often enhanced when coupled with volume-rendering techniques. These allow clearer imaging of subtle fractures and complex injuries. They are also helpful in the evaluation of suspected infections or neoplastic disease. After operative fixation of fractures, volume rendering can improve the quality of imaging by eliminating streak artifacts.[60] Using intravenous contrast, CT angiography can be performed (see section on vascular imaging techniques for the upper extremity, below).

Magnetic resonance imaging

MRI of the hand and wrist has come to the forefront in the last decade. It is the preferred modality for imaging soft tissue, particularly those associated with trauma and neoplastic conditions. Larger and more powerful magnets, improved gradient strength and speed, dedicated coils providing favorable signal-to-noise ratios, and the capability of supporting small fields of view enable visualization of pathology in exquisite anatomic detail. The advantages and disadvantages of MRI are shown in Table 3.4.

MRI basics

MRI employs magnetic fields and radiowaves rather than ionizing radiation. The magnetic field is generated by an electromagnetic coil with field strengths ranging from 1.5 to 3.0 Tesla (T) (15000–30000 gauss). Gradient (secondary) magnets fine-tune and focus the MRI on specific areas of interest. MRI coils send and receive radiofrequency pulses that are used to create images. In general, the smaller the coil and the more centrally located an anatomic structure is within the coil, the sharper the image and the higher the signal-to-noise ratio.

MR differentiates tissues such as fat, muscle, bone, blood, and water on the basis of their innate magnetic characteristics and the varying tissue concentration of hydrogen ions (protons). Each proton spins like a top, around an axis. In the absence of a magnetic field, their axes are randomly oriented and produce no net magnetic effect. In the MRI scanner, the magnetic field generated causes the axes of rotation of the protons to align themselves with the longitudinal axes of

Table 3.4 Advantages and disadvantages of magnetic resonance imaging (MRI)

Advantages	Disadvantages
• Capacity to image in any anatomic plane (multiplanar imaging) • High soft-tissue contrast with indication of tissue composition • No ionizing radiation • Acquisition of three-dimensional volume data using gradient echo sequences • Noninvasive imaging of blood vessels and other structures without the use of contrast (e.g., MR arthrography)	• The high cost of equipment • Image artifacts from motion and ferromagnetic objects • Inferior to computed tomography for imaging of cortical bone • Contraindicated in patients with cardiac pacemakers, aneurysm clips, metallic foreign body, claustrophobia

Table 3.5 Signal intensities of tissues on T_1- and T_2-weighted magnetic resonance images

Tissue	Signal T_1-weighted image	Signal T_2-weighted image
Fluid (free water)	Low	High
Fluid (proteinaceous)	Intermediate	High
Fat	High	High
Muscle	Intermediate	Intermediate
Cartilage	Intermediate	High
Cortical bone	Low	Low
Bone marrow (yellow)	High	Intermediate
Bone marrow (red)	Low	Intermediate

the magnet. Gradient magnets change the alignment of the rotating protons whilst radiofrequency pulses from the coils excite the protons to a higher energy level. Cessation of radiofrequency stimulation induces a tiny current within the surrounding coil which can be detected and amplified to give a signal. The time taken for a proton to become magnetized is known as the T_1 relaxation time and the time taken for the proton to be demagnetized is known as the T_2 relaxation time. The amount of energy released by a tissue is directly proportional to its concentration of protons. It is also the varying concentration of protons between different tissues that allows them to be magnetized and demagnetized differentially. This is the basis of differentiating the soft tissues. The relevant signals of different tissues on T_1- and T_2-weighted images are shown in Table 3.5.

Water can be categorized into free water and bound water. Free water is found mostly in extracellular fluid whilst bound water is mostly in intracellular fluid. Free water has long T_1 and T_2 relaxation times. Hence it typically shows low signal intensity on T_1-weighted images and high signal intensity on T_2-weighted images. Water that is not free is usually bound to proteins which inhibit motion. This preferentially shortens the T_1 relaxation time more than the T_2 relaxation time, hence the T_1 signal is usually of intermediate to high intensity. Examples of proteinaceous fluid include abscesses, synovial fluid, and purulent collections.

Clinical applications of MRI

MRI for soft-tissue masses

MRI is the preferred modality for imaging soft-tissue masses in the hand and wrist. The majority of soft-tissue masses in the hand and wrist are benign.[61] MRI characteristics of the common tumors are well described in literature and references.[62–64] MRI, with its multiplanar imaging capability, tissue characterization of lesions, and ability to define relationship of lesions to surrounding tissue and vessels (including tumor invasion), allows one in many circumstances to arrive at a specific diagnosis.

Ganglion cysts

Ganglia show low to intermediate signals on T_1-weighted images and high signals on T_2-weighted images. They may be uniloculated or multiloculated and contain proteinaceous synovial fluid. This accounts for its isointense or slightly hypointense signal on T_1-weighted images compared to muscle (Fig. 3.34). Demonstration of a stalk can usually reveal its site of origin. Hemorrhage into a ganglion cyst can result in high signal intensity on T_1-weighted images. A ganglion

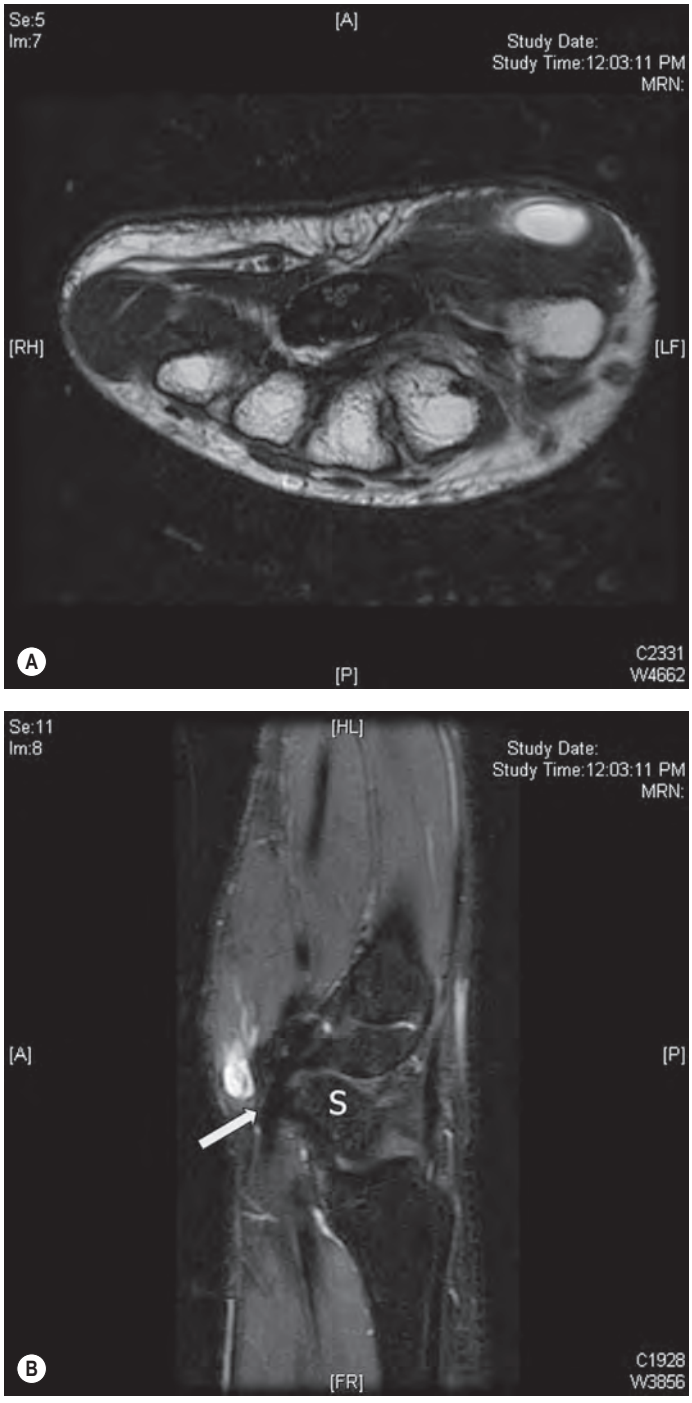

Fig. 3.34 This patient presented with a firm mass in the left thenar eminence that was difficult to characterize clinically. Radiographs were normal. **(A)** Magnetic resonance imaging shows a mass with typical high signal intensity during the T_2-weighted sequence. **(B)** A sagittal fat suppression short tau inversion recovery sequence shows the stalk of the ganglion connecting to the sheath of the flexor carpi radialis (indicative arrow) with the scaphoid (S) in close relation.

shows no enhancement on administration of intravenous gadolinium; however, its capsule and septa will usually show enhancement. Ganglion cysts occurring in "classic" locations such as the dorsum of the wrist can usually be diagnosed clinically and do not require MRI.

Giant cell tumors of the tendon sheath (GCTTS)

Synonymous with focal pigmented villonodular synovitis, these benign tumors of synovial origin typically occur in the digits over the volar aspect, and arise from the tendon sheath, joint capsule, fascia, or ligaments. They contain multinucleated giant cells and have intra- and extracellular hemosiderin deposition. On MRI, GCTTS appear as solid masses, hypointense on both T_1- and T_2-weighted images. The low signal is due to the paramagnetic effect of hemosiderin deposition. On T_1-and T_2-weighted images, these masses appear isointense with skeletal muscle. Uniform enhancement is seen following administration of intravenous gadolinium contrast (Fig. 3.35).

Lipomas

Lipomas are less common in the hand and wrist than in other parts of the body. In the hand, they usually occur over the palmar aspect, either in the thenar or hypothenar eminence or in the mid-palmar space. They show the same homogeneous high signal intensity as fat on T_1-weighted images and superficial lipomata can appear inconspicuous. They show low signals on short tau inversion recovery (STIR) and T_2-weighted sequences. The presence of distinct nodules or solid components may suggest a liposarcoma.

Hemangiomas

Hemangiomas are benign tumors classified into capillary, cavernous, and venous types. T_1-weighted signal intensity varies from low, to high, depending on the amount of fat contained. On T_2-weighted sequences, they tend to be lobulated with well-defined borders and very high signal intensity from pooled blood. A lace-like pattern of enhancement may be seen on T_1-weighted images due to fibrofatty elements. Signal voids may be present on all MR sequences as a consequence of phleboliths within the hemangiomas. The heterogeneous nature of hemangiomas thus makes preoperative diagnosis by MRI less certain.[61]

Enchondromas

Enchondromas are the most common benign tumors of bone that are found in the hand. Problems associated with enchondromas are pathological fractures and the rare occurrence of malignant transformation. Radiography demonstrates a lytic expansile lesion with a clear zone of transition and speckled calcifications. Cortical thinning is present and may be associated with a pathological fracture. On MRI, they appear as high-signal-intensity lobulated tumors on fat suppression (FS) STIR and T_2-weighted sequences. They show low to intermediate signal intensity on T_1-weighted sequences.

MRI for wrist and hand trauma

This application of MRI has become more widespread in the last two decades, in particular for ligamentous injuries. A further advantage of MRI is its superior imaging of bone marrow and vascularity of bone with a wide range of applications, including diagnosing AVN, marrow edema, and inflammation, as well as infection.

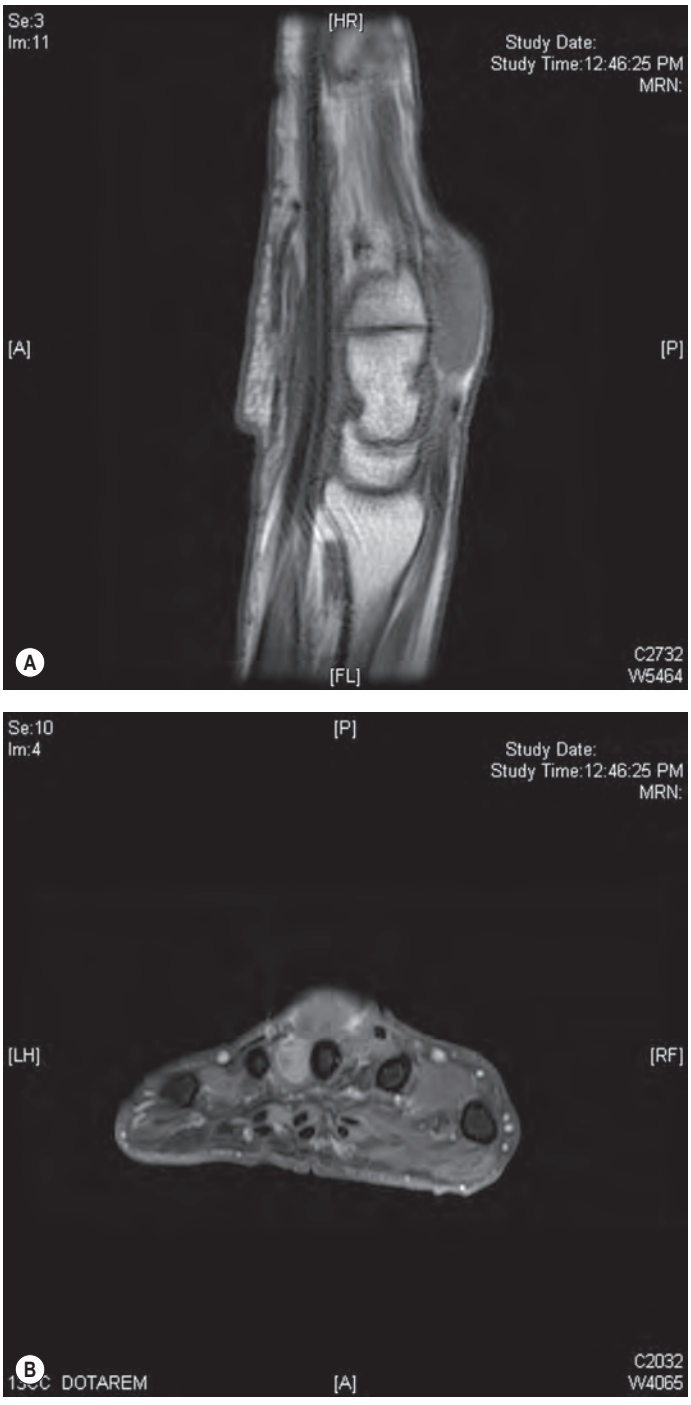

Fig. 3.35 This man presented with a firm painless enlarging mass over the dorsum of the left hand. Magnetic resonance imaging shows a low signal intensity mass over the third carpometacarpal junction, seen on **(A)** sagittal T_1-weighted sequence and **(B)** axial T_2-weighted sequence.

Occult scaphoid and carpal fractures

MRI is the most sensitive and specific imaging modality for occult scaphoid fractures, although its cost may be greater or

equitable compared to the classic diagnostic algorithm.[65,66] An area of a linear band of low signal intensity on T_1-weighted sequences, coupled with an area of high signal intensity on FS T_2-weighted sequences or STIR sequences, has the highest combined sensitivity and specificity. Cortical fracture lines are best seen on a STIR or gradient echo (GRE) sequence. Use of MRI for diagnosis of radiographically occult fractures is not limited to the scaphoid, but includes other carpal bone fractures which are difficult to image on radiography.[67] The added value of using MRI for detection of occult carpal bone fractures is that it also demonstrates ligament injuries which can clinically mimic carpal fractures (Fig. 3.36). Bone bruising, a term synonymous with bone contusion, exhibits exactly the same MRI findings as occult fractures do with the exception of a cortical break. This diagnosis is made in the setting of a positive history of preceding trauma and positive MRI findings, as described above.

Ligamentous injuries of the hand and wrist

Suspected ligamentous injures of the hand and wrist are probably the most common indication for ordering an MRI. SL and LT ligament tears as well as tears of interphalangeal or metacarpophalangeal joint ligaments are frequent clinical problems. Another large group of wrist pathologies – ulnar-sided wrist pain, including but not limited to tears of the TFCC, ulnocarpal abutment, DRUJ and tendinitis – is considered separately in the next section.

Fig. 3.36 This patient presented with persistent dorsoradial-sided wrist pain after a fall. He had initially been seen by a general practitioner and diagnosed as having a sprain. Magnetic resonance imaging coronal fast spin echo proton density sequences with fat suppression showed two areas (white arrows) of high signal intensity in the scaphoid proximal pole and waist (associated with fracture). The signal enhancement in the proximal pole is due to an injury of the scapholunate ligament, noting a normal ligamentous structure of the lunotriquetral ligament (black arrow).

An intact ligament is shown as a homogeneous black signal or band on a proton density-weighted GRE sequence or a T_1-weighted spin echo sequence on coronal slices. An abnormal ligament shows increased signal intensity on T_2-weighted sequences or STIR sequences, segmental defect, increased length, thickening, thinning, and nonvisualization.[68] MR arthrography can be performed with saline or dilute gadolinium injected into the joint, enhancing the detection of ligaments and TFCC perforations.

Thumb ulnar collateral ligament injuries

A poorly treated complete tear of the ulnar collateral ligament of the thumb metacarpophalangeal joint can lead to painful and chronic instability. MRI is valuable in assessing for complete ligamentous disruption, a diagnosis that may be difficult to make in early or acute presentations (Fig. 3.37). Such imaging helps exclude a Stener lesion,[69] where the adductor aponeurosis becomes interposed between the two ends of the ruptured ligament, preventing ligament healing.

Scapholunate interosseous ligament injury

This is the most common intrinsic wrist ligament injury. Presentations vary from occult SL joint ganglions, dynamic SL instability, to static SL dissociation. SL dissociation is the commonest cause of carpal instability. Early recognition of SL instability allows treatment and prevention of late arthritis. Features which support a tear of the SL ligament include widening of the SL interval, fluid signal traversing the SL or LT ligaments on the fat-suppressed fast spin echo (FSE) T_1-weighted sequence, or STIR sequence (Fig. 3.38). Proton density sequences as well as T_2-weighted sequences with FS can also reveal morphological abnormalities and absence of the SL ligament. The same criteria also apply for evaluating the less common LT ligament injuries.

MRI for evaluating ulnar-sided wrist pain

Ulnar-sided wrist pain is a common and challenging problem. Causes of ulnar-sided wrist pain include injuries to the TFCC, LT ligament injuries, and ulnocarpal abutment syndrome. Other diagnoses include fractures and nonunion of fractures, especially of the ulnar styloid, DRUJ problems, and tendinopathies.

TFCC tears

TFCC injuries are classified into two groups: those occurring acutely and degenerative lesions. In the latter group, lesions occur in the central portion of the TFCC and the incidence increases with advancing age. Acute traumatic tears of the TFCC usually occur following a forced axial load of the wrist in an extended and ulnar-deviated position. Acute tears of the TFCC resulting in detachment from the fovea or detachment from its radial border can result in DRUJ instability. The gold standard for evaluation of TFCC injuries is arthroscopy. MRI has been increasingly used for imaging the TFCC. The sequence which best demonstrates the TFCC is the FS FSE T_1-weighted and GRE T_2 sequence.[70] GRE sequences which mimic FS FSE T_1-weighted sequences such as the proton density-weighted GRE sequence depicts TFCC disruptions even more distinctly (Fig. 3.39). With the advent of 3.0-T MRI

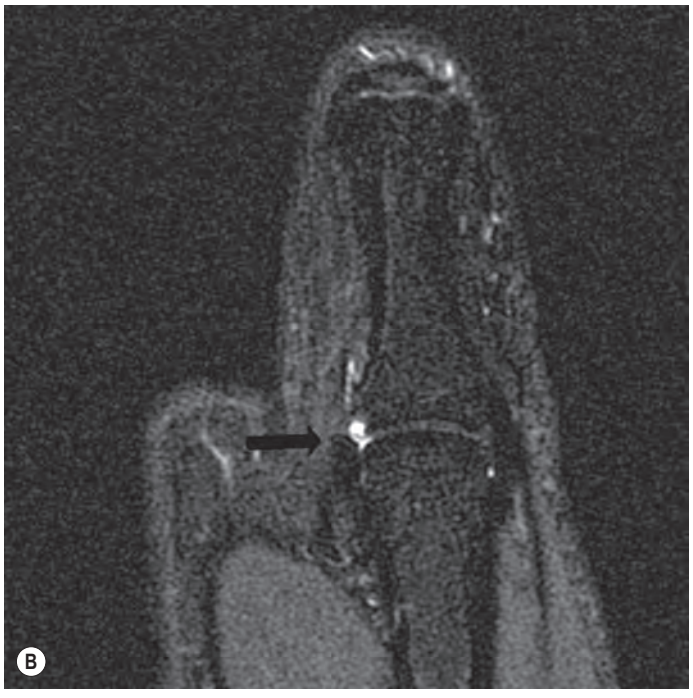

Fig. 3.37 This 15-year-old girl presented with pain at the ulnar aspect of the metacarpophalangeal joint of her right thumb after an abduction injury from a fall. Plain posteroanterior and lateral radiographs showed no abnormalities. Clinical assessment for joint instability was difficult because of her anxiety and pain and a magnetic resonance imaging scan was performed. The coronal fast spin echo proton density sequence, a variant form of gradient echo sequences, reveals a distal avulsion/rupture **(A)** of the ulnar collateral ligament (black arrow). The radial collateral ligament on the other hand is intact and smoothly inserts or joins the base of the proximal phalanx of the thumb. **(B)** The short tau inversion recovery sequence shows bright signal intensity at the site of rupture seen on the proton density sequence, correlating with an acute tear or rupture of the ligament.

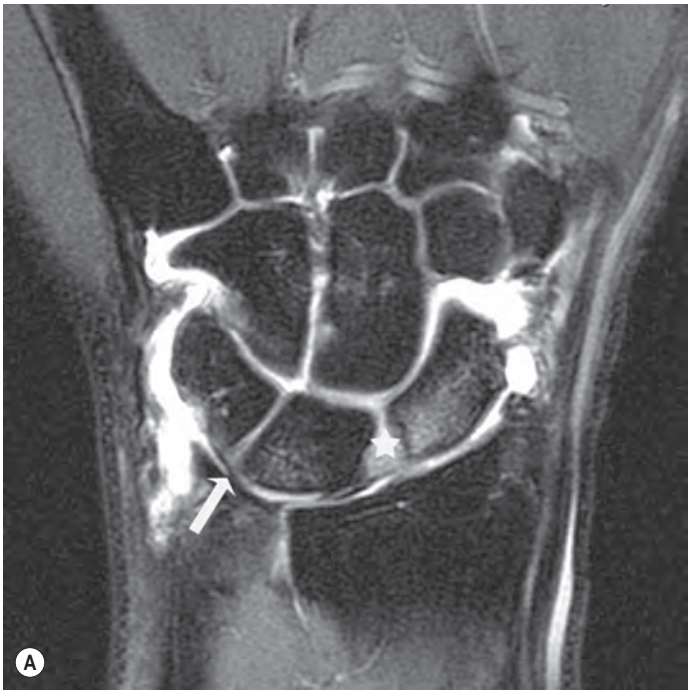

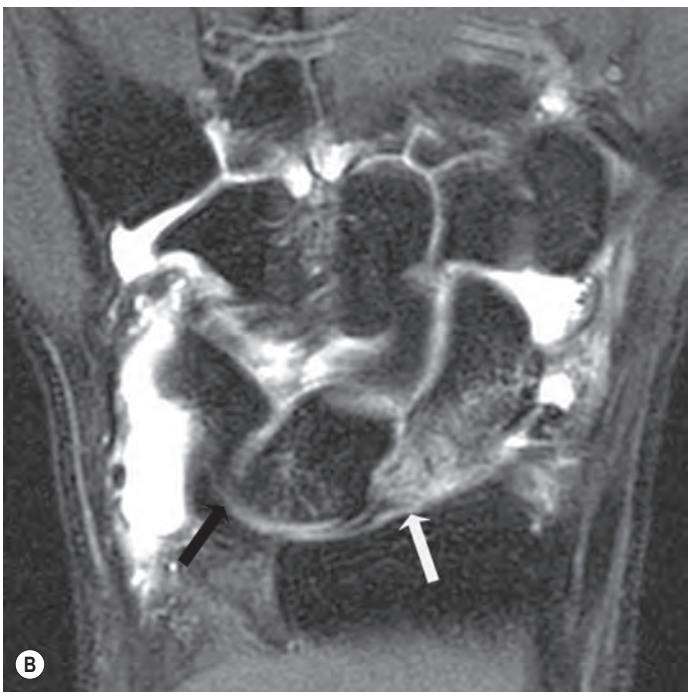

Fig. 3.38 This patient presented with right-sided wrist pain. He had tenderness over the scapholunate junction over the dorsum of the wrist. Radiography showed a normal scapholunate angle on lateral wrist projections and no widening of the scapholunate interval on posteroanterior projections of the wrist. Magnetic resonance imaging coronal fast spin echo proton density sequences with fat suppression **(A)** showed widening of the scapholunate (SL) interval (star) with absence of the membranous portion of the ligament. The membranous portion of the lunotriquetral (LT) ligament is intact (white arrow). The next sequence shows a more dorsal section of the proximal carpal row with an intact LT ligament (black arrow) and disrupted SL ligament with abnormal fluid signal traversing it and a thickened and fibrillar morphology (white arrow) **(B).**

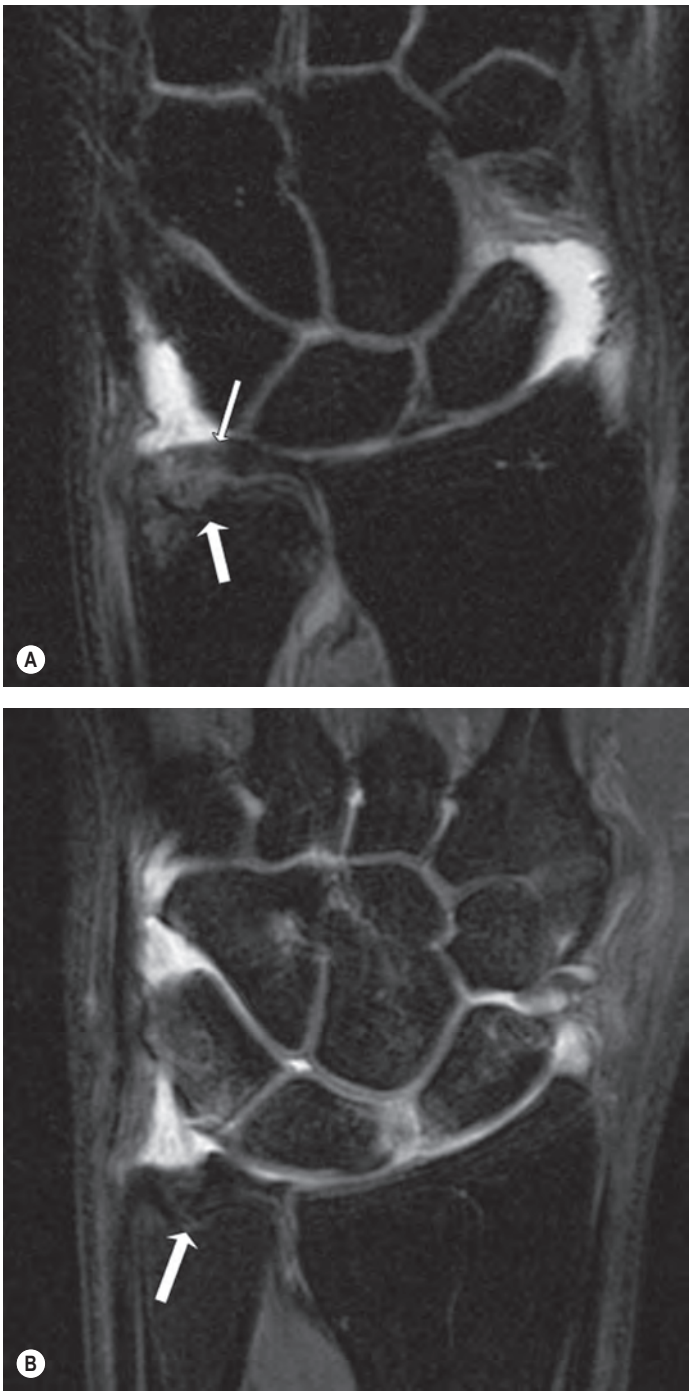

Fig. 3.39 This 27-year-old male presented with right ulnar-sided wrist pain of 1 year's duration. There was a preceding history of a fall during rollerblading. Magnetic resonance imaging proton density-weighted sequences show that the portion of the triangular fibrocartilage (small arrow) that inserts into the fovea (big arrow) has been avulsed off its insertion **(A).** In a different patient, the triangular fibrocartilage with its insertion into the fovea preserved (white arrow) is shown **(B).** This patient had instead a scapholunate ligament injury.

machines, the sensitivity and specificity of MRI for detection of TFCC lesions exceed that of 1.5-T machines.[71,72]

Ulnocarpal abutment

This is a degenerative condition related to excessive load-bearing across the ulnar side of the wrist. An ulna positive variance may be present. Radiography may be normal or may show subchondral cyst formation in the lunate and/or triquetrum. Stress films can demonstrate dynamic increase in ulnar length relative to the radius (pronated grip film of the wrist). MRI shows foci of low signal intensities in the lunate and triquetrum and occasionally in the ulnar head, reflecting chondromalacia. On FS STIR or FS T_2-weighted sequences, these same areas show bright signal intensities from bone marrow edema or secondary to the presence of cyst formation (Fig. 3.40).

DRUJ instability and tendinopathies

CT is the preferred imaging modality for DRUJ instability and subluxation. MRI however allows visualization of the ligaments and the insertion of the TFCC into the fovea, which contributes to stability of the DRUJ. Furthermore, high signal intensities on FS STIR sequence will suggest reactive marrow edema from persistent DRUJ instability and synovitis. The relationship of the ulnar head to the distal end of the radius and DRUJ subluxation is best assessed on an axial FSE T_1-weighted sequence. A halo of high signal enhancement can be seen in tendinopathies on axial slices during an FS STIR sequence or an FS T_2-weighted sequence. In addition, there may be thickening of the tendon and abnormal signal within the tendon itself on coronal slices.

MRI for evaluation of fracture nonunion

Scaphoid fractures are prone to nonunion. Radiography to assess for fracture healing lacks a high degree of sensitivity and specificity. The MRI criterion to assess union is the presence on T_1-weighted sequences of normal signal intensity crossing the previous fracture line.[73] Nonunion is shown by the presence of high signal intensity at the fracture line on FS STIR or FS T_2-weighted sequences or the GRE equivalents.

MRI for avascular necrosis (AVN) in scaphoid fracture nonunion

The proximal pole of the scaphoid is prone to AVN following a fracture due to its retrograde vascular axis pattern.[74] Radiographs can show changes associated with AVN, including sclerosis of the proximal fragment, osseous absorption, and cysts. MRI can detect AVN at an earlier stage. Knowing the vascularity of the proximal fragment guides clinical decision-making, including whether to use vascularized or nonvascularized grafts. Low signal intensity of the proximal fragment on T_1-weighted sequences indicates replacement of the normal marrow with fibrous tissue. High signal intensity of the proximal pole on gadolinium contrast-enhanced study suggests that vascularity is preserved. This finding has not been consistently proven in all studies, and the relative enhancement should be significantly greater than the surrounding carpal bones.[73]

Kienbock's disease

Idiopathic AVN of the lunate is relatively uncommon when compared with post-traumatic AVN of the scaphoid. A negative ulnar variance has been shown to be associated with an increased risk of Kienbock's disease. MRI is of value in detecting early disease, prognosticating, and for monitoring

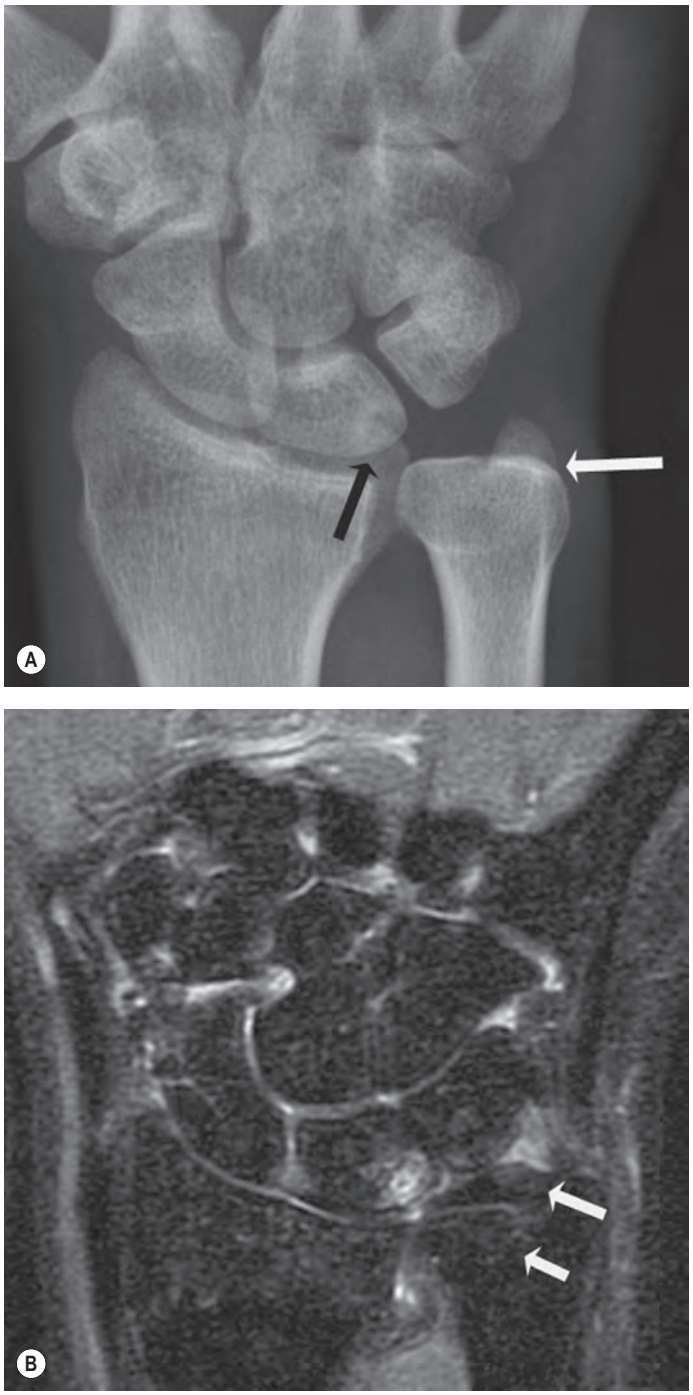

Fig. 3.40 This patient presented with persistent right ulnar-sided wrist pain of 6 months' duration and he complained of inability, in particular in hammering objects. He had tenderness over the ulnar fovea and a positive ulnocarpal grind. Plain film radiography **(A)** showed no fractures of the ulnar styloid. There was, however, a subchondral cyst seen in the proximal ulnar corner of the lunate (black arrow) and there was positive ulnar variance (white arrow). On magnetic resonance imaging, the fat suppression short tau inversion recovery sequence showed high signal intensity in the same corresponding area of the lunate **(B).** Note that the triangular fibrocartilage and the ulnar head (white arrows) show no signal enhancement which would typify more advanced involvement.

revascularization of the lunate following treatment.[75] AVN of the lunate is suggested by low signal intensity on T_1-weighted sequence as marrow is replaced by fibrous tissue. Areas of high signal intensity may be seen on FS T_2-weighted sequence or FSE FS STIR sequences, suggesting marrow edema or neovascularization (Fig. 3.41). Low signal intensity on such sequences likely indicates established ischemic necrosis without any further bone reactive changes.

Osteomyelitis

Osteomyelitis of the hand and wrist bones is relatively uncommon. It is usually a consequence of previous surgical intervention for fractures or other procedures. Traditionally, either scintigraphy or MRI has been used when plain film radiography has been negative in suspected osteomyelitis. MRI has the advantage of discriminating marrow abnormalities from joint and soft-tissue changes. Areas of marrow involvement will show low signal on T_1-weighted sequence and high signal intensity on T_2-weighted sequence.

Vascular imaging techniques for the upper extremity

Digital subtraction angiography (DSA) is the gold standard for vascular imaging of the extremities.[76,77] Improvements in CT angiography and magnetic resonance angiography (MRA) make them increasingly viable alternatives in vascular imaging of the upper extremity. Arterial imaging of the upper limb is usually performed in two different clinical settings: the detection of extremity vascular injury following trauma to the limb, and assessment of vascular disorders involving the upper limb.

The indications for angiography following trauma are: decreased or absent pulse or blood pressure, cold limb, bruit or murmur, uncontrolled bleeding or increasing hematoma, neurologic deficit, and proximity of the injury to vascular structures.[78] When the clinical condition warrants immediate surgery, conventional angiography is contraindicated. Knife injuries (80%) and blunt trauma (67%) are more likely to be associated with vascular abnormalities, followed by gunshot wounds (44%).[78]

DSA has a role in the assessment of the vascular tree in peripheral arteriosclerotic disease, connective tissue diseases, thoracic outlet syndrome, and Raynaud's phenomenon. It is also useful for assessing arteriovenous fistulae and vascular tumors and malformation of the upper limb.

CT angiography (CTA) is less invasive than DSA and can additionally assess vessel wall and extraluminal pathology. The data obtained allow reconstruction in three-dimensional and multiple planes. The advancements in CT technology, new protocols, and availability of CTs in proximity of many emergency departments have made CTA an increasingly attractive option for the assessment of the extremity vascular tree following trauma.[79,80] In extremity trauma, CTA can identify arterial injuries, including pseudoaneurysm, active arterial hemorrhage, arteriovenous fistulae, occlusion, intimal injury, or vasospasm.[81] Venous injury may also be assessed. CTA has also been shown to be useful in the evaluation of suspected extremity vascular trauma in pediatric patients.[82] In

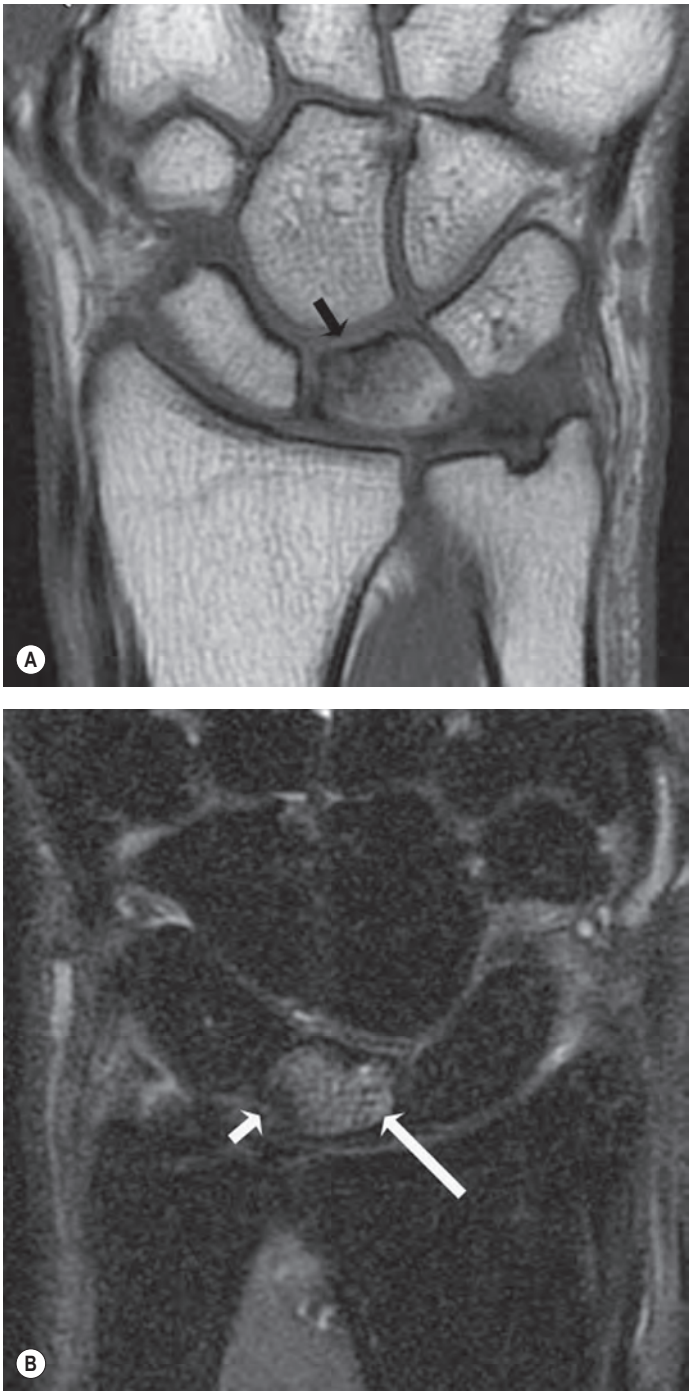

Fig. 3.41 A karate enthusiast presented with right wrist central dorsal pain of gradual onset that was associated with morning stiffness as well as weakness of grip over the passage of time. Radiography was normal aside from the suggestion of an area of faint linear sclerosis in the lunate. Magnetic resonance imaging fast spin echo T_1-weighted sequence showed loss of normal marrow signal affecting the radial corner of the lunate **(A)**. Fast spin echo fat suppression short tau inversion recovery sequences showed diffuse marrow enhancement, sparing only the proximal ulnar tip of the lunate **(B)**.

pediatric patients, CTA allows imaging of the vascular tree where DSA is often not possible.

The indications for CTA are similar to that of DSA. There are limitations with use of CTA for evaluation following trauma. For example, differentiation of a tapered contour deformity of CTA, which may variously represent dissection, intimal injury, vasospasm, or adjacent hematoma, is difficult.[79] Imaging of the distal vascular tree is also difficult. DSA also offers an advantage where there is a possibility of endovascular treatment, for example in an arteriovenous fistula. The sensitivity and specificity of CT arteriography have been shown to be 95.1% and 98.7% in cases of suspected vascular injury following blunt or penetrating injury.[83]

MRA offers advantages over conventional DSA for extremity vascular imaging. MRA is less invasive, does not require iodinated contrast, and can simultaneously demonstrate extraluminal disease.[84] The angiographic effect in MRA is created by various techniques with or without contrast enhancement with gadolinium chelate agent. The use of contrast-enhanced MRA with a dedicated surface coil enables quick and high-quality examination of the hand vascular tree.[85]

MRA of the wrist and hand has a potential number of indications for its use and has been employed successfully in imaging of vascular malformations, vascular trauma, and vascular occlusion.[86] MRA is performed making use of a coronal volume three-dimensional spoiled GRE time-of-flight sequence and dynamic administration of intravenous gadolinium contrast with image acquisition using a wrist coil. The inherent contrast from protons in flowing blood relative to the saturated protons in the stationary soft tissue produces the image which is formulated based on an MR algorithm which deletes the signal from the soft tissue. MRA has the potential to depict pathologic change in vessels of up to 1 mm in diameter and can reliably show the superficial and deep palmar arches of the hand (Fig. 3.42). Some of the disadvantages of MRA include the inferior resolution of vasculature at 1 mm diameter or less, susceptibility to motion artifacts, as well as flow artifacts at sites of severe stenosis or thrombosis where a high signal intensity may be mistaken for flowing blood. MRA is useful in patients with renal impairment where intravascular ionic contrast could cause further nephrotoxic damage, as well as in pediatric patients.

Radionuclide imaging

Radionuclide imaging is a highly sensitive imaging modality[87] with applications in hand and wrist conditions. It can be positive even when conventional imaging techniques are unable to visualize the condition. The main limitation of radionuclide imaging is its lack of specificity. This is because the tracers used reflect function.[88] The imaging detail required to differentiate physiological and pathological processes is often lacking in these scans. Therefore it is most useful as a screening tool. The most common radionuclide musculoskeletal imaging is bone scintigraphy with technetium-99m-labelled diphosphonates. The three-phase bone scan is highly sensitive for osteomyelitis. However, similar findings can be mimicked by conditions such as tumors, fractures, and joint neuropathy. The use of indium-111-labeled autologous leukocytes can improve its specificity.[89] Bone scintigraphy is also useful for diagnosis of complex regional pain syndrome (reflex sympathetic dystrophy),[90] occult fractures of the scaphoid,[91] and metastatic disease.[92] Newer modalities, such as the combination of scintigraphy with morphologic information, e.g., single-photon emission CT/CT can improve diagnostic yields in the extremity.[93]

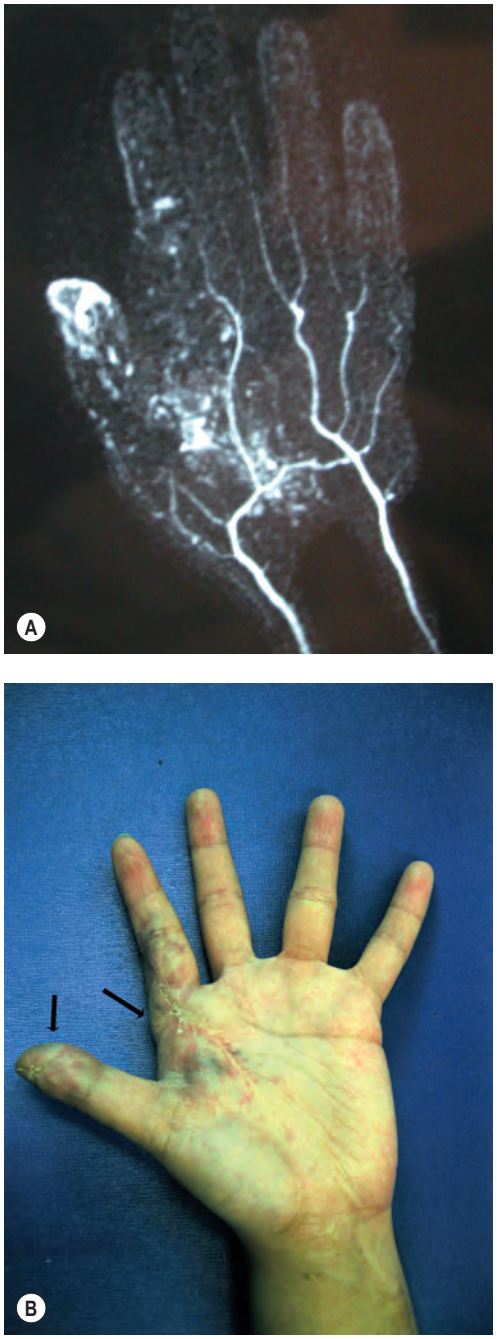

Fig. 3.42 This 23-year-old female had a previous excision of arteriovenous malformation more than 5 years ago and now presents with skin changes suggestive of recurrence. Magnetic resonance angiography delineates the palmar arch well and in addition shows blushes of bright signal intensity over the thumb pulp, the first web area, and over the index finger **(A).** This correlated well with the pigmented changes seen on the clinical photo **(B).**

Future directions – safety in fluoroscopy

Fluoroscopy is a powerful imaging tool allowing operative and dynamic assessment of the bones and joints of the hand. As the surgeon is often the operator of the machine, this causes exposure to both direct and scattered radiation. Such radiation exposure is an occupational risk, with potential serious effects. There was a report suggesting an increased cancer risk in orthopedic surgeons working in an institution with poor compliance to use of radiation protective measures when working with standard c-arm devices.[94] Another study found a 1.9-fold increased prevalence of cancer and 2.9-fold increased prevalence of breast cancer in female orthopedic surgeons when compared with the women of similar age and race.[95]

Radiation exposure is directly related to the distance from the X-ray source. This relationship is described by the inverse square law. In practical terms, a doubling of the distance from the source reduces the exposure 4 times. Conversely, a halving of the distance results in a four-fold increase in radiation exposure. Some basic knowledge and precautions will minimize radiation to the worker during its operation (Box 3.5).

The choice of fluoroscopy affects the potential radiation exposure. Compared to conventional fluoroscopy, mini c-arm fluoroscopy has been shown to emit about half the radiation exposure.[96] However, if the surgeon places his or her hand in the path of the X-ray beam during intraoperative use of the mini c-arm, there is a decreased source-to-skin distance resulting in higher radiation exposure to the hand than when using the standard c-arm.[97,98] While the mini c-arm fluoroscopy has been widely adopted in hand surgery, we need to exercise caution during its use to ensure safety of both the surgeon and the patient. Technological advances will improve the resolution and utility of these devices, while aiming to mitigate radiation risks. In tandem, there should be more research into the long-term risks of exposure during use of such devices.

BOX 3.5 Methods to reduce radiation exposure

Increasing the distance between the personnel and the source of radiation is key, as it has been shown that the rate of radiation exposure drops significantly beyond the path of the radiation beam and is minimal beyond 15 cm from the point of focus on the image intensifier.[99]

1. Increasing distance from radiation source
   - Placement of the limb directly on the image intensifier (when using mini C-arms)
   - Uninvolved personnel to position themselves away from the radiation source
2. Shielding
   - Lead gowns
   - Lead-lined operating rooms
   - Protective goggles
   - Radiation attenuation gloves for operators placing their hands near radiation source
   - Shielding for anaesthetists and patients
3. Minimizing radiation use
   - Increasing accuracy of fluoroscopy by using laser beams
   - Collimation
   - Avoiding long exposure time

Anesthesia for upper extremity surgery

Jonay Hill, Vanila M. Singh, and Subhro K. Sen

Access video content for this chapter online at expertconsult.com

SYNOPSIS

- Optimal perioperative anesthetic outcomes are achieved by a thorough understanding of anatomy, pharmacology, techniques, and potential complications.
- Local anesthetics (LA) make regional anesthesia possible by preventing the propagation of nerve conduction and by inhibiting or relieving pain.
- Ultrasound guidance in the use of regional anesthesia has decreased the need for high volumes of anesthetic.

Introduction

The goal of anesthesia for hand and upper extremity procedures is to provide a comfortable and safe experience for the patient during surgery. Many options are available for anesthesia, with respective benefits and risks. The decision regarding which anesthetic technique is chosen depends on various factors, including the extent, site, and expected duration of surgery; need for sedation; general medical health of the patient, and personal preference.

General anesthesia techniques can be applied for hand and upper extremity procedures the same as for procedures elsewhere. In addition, regional anesthesia techniques can be applied for procedures involving the upper extremity when used in the proper setting and patient population. Adjunctive measures are used to augment local anesthetics to provide longer duration of action, lower risk of adverse systemic effects, and less bleeding at the surgical site.

Optimal perioperative anesthetic outcomes are achieved by a thorough understanding of anatomy, pharmacology, techniques, potential complications, and general pain management.

Anatomy

The brachial plexus arises from the ventral rami of nerves C5–8 and T1, with variable contributions from C4 and T2 (Fig. 4.1). These rami unite and diverge forming the roots, trunks, divisions, cords, and terminal nerves of the brachial plexus. C5 and C6 roots form the superior trunk, C7 becomes the middle trunk, and C8 and T1 form the inferior trunk between the anterior and middle scalene muscles. The three trunks then divide into anterior and posterior divisions, coursing over the first rib and lateral to the subclavian artery. The divisions then reunite to form cords. The anterior divisions of the superior and middle trunk form the lateral cord, while the anterior division of the inferior trunk forms the medial cord. The posterior divisions of all three trunks form the posterior cord. The cords are named according to their anatomic relationship with the axillary artery. The cords then divide once again to become the terminal branches of the brachial plexus. The lateral cord gives rise to the musculocutaneous nerve and contributes to the median nerve. The medial cord also contributes to the median nerve and gives rise to the ulnar nerve and the medial brachial and antebrachial cutaneous nerves. The posterior cord becomes the axillary and radial nerves.[1]

Additional nerves outside the brachial plexus can be important for complete anesthesia of the upper extremity. The supraclavicular nerve (C3–4) provides sensory innervation to the "cape" of the shoulder, and the intercostobrachial nerve (T2) innervates the skin of the medial upper arm and axilla.

Knowledge of brachial plexus anatomy and the dermatomes supplied (Figs. 4.2 & 4.3) enables selective regional anesthesia.

Perineurial environment

The axillary sheath is the connective tissue surrounding the neurovascular structures of the brachial plexus. It originates as a continuation of the prevertebral fascia and joins the fascia of the biceps and brachialis muscles distally. This connective tissue extends inward, forming septa between components of the plexus and creating fascial compartments for each nerve.[2] Controversy exists regarding the ability of the septa to limit the spread of local anesthetics within the sheath. Some investigators report that these fascial compartments limit the

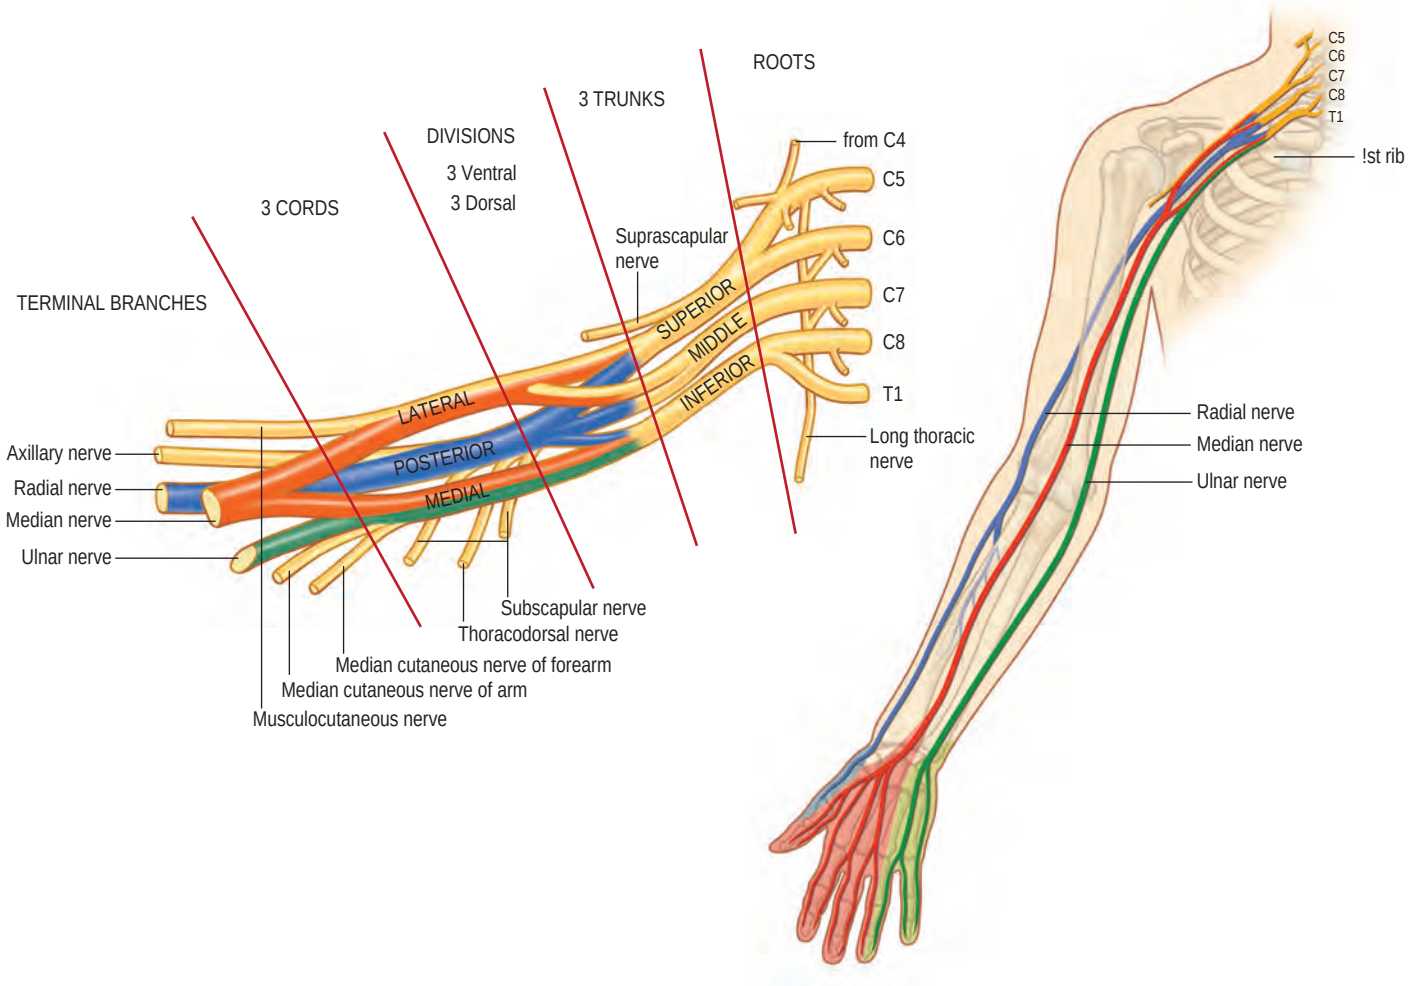

Fig. 4.1 Brachial plexus anatomy.

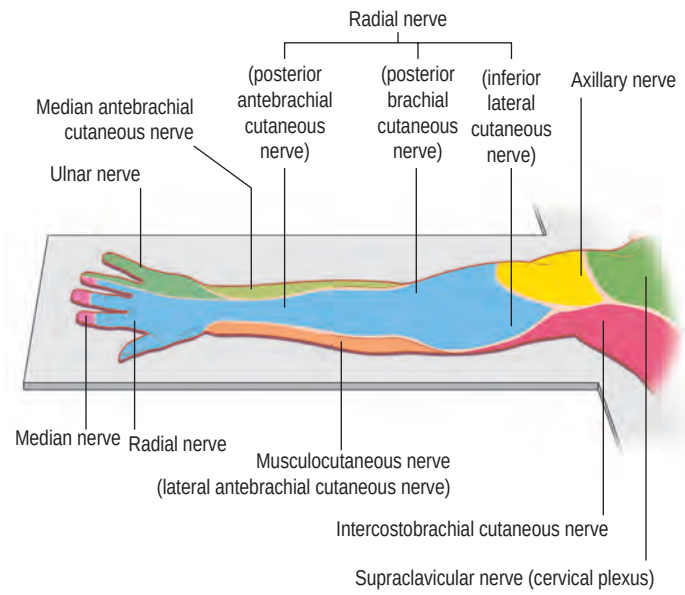

Fig. 4.2 Upper extremity nerve innervation (arm pronated).

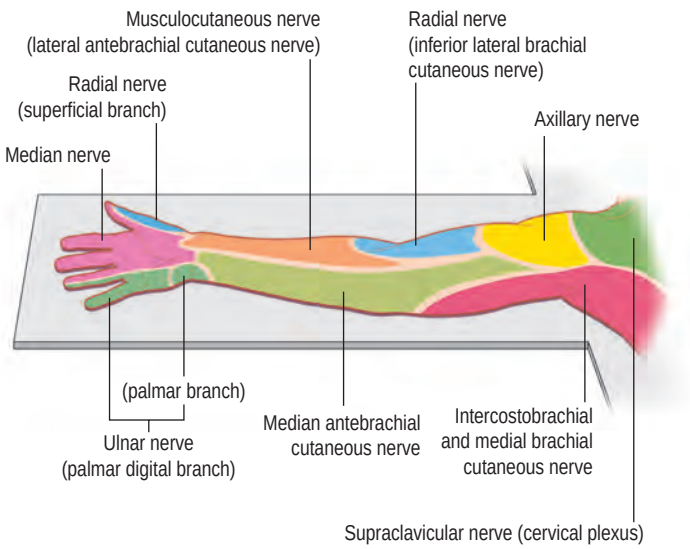

Fig. 4.3 Upper extremity nerve innervation (arm supinated).

circumferential spread of local anesthetics and that injected solutions spread longitudinally up and down the nerve and remain compartmentalized. This concept provides a rational explanation for the occurrence of a rapid and profound block of one nerve, yet partial or absent block in other nerves during brachial plexus blockade.[3] Other investigators propose that these septa are incomplete and form small bubble-like pockets when solution is injected. They found that single injections of dye solutions into the axillary sheath resulted in immediate staining of median, radial, and ulnar nerves, despite the presence of septa. These data demonstrate that there are connections between compartments within the sheath, and may explain why single injection techniques have success rates comparable with multiple injection techniques during blockade of the brachial plexus.[4]

Microneuroanatomy

Peripheral nerves are composed of fascicles of individual nerve fibers surrounded by endoneurium. Groups of fascicles are contained within the epineurium. As the nerve travels away from the spinal cord, fascicle numbers increase, while fascicle size decreases.[5] The nerve roots contain large fascicles, demonstrating a monofascicular or oligofascicular pattern, while a multifascicular pattern is found more distally.[6,7] While the amount of neural tissue remains constant, the amount of non-neural connective tissue increases from proximal to distal. The ratio of neural to non-neural tissue changes from 1:1 in the proximal plexus to 1:2 in the more distal plexus.[2,7] The presence of non-neural tissue may explain why injections within the epineurium rarely result in neural injury.[6]

Sonoanatomy

The shape and echogenicity of a nerve determine its ultrasound appearance. Structures that strongly reflect ultrasound waves generate large signal intensities and appear white or hyperechoic. In contrast, hypoechoic structures weakly reflect ultrasound waves and appear darker.[8] Peripheral nerves show a mixture of hypoechoic and hyperechoic structures constituting a typical "honeycomb" structure.[9] Hypoechoic structures seen with ultrasound correspond to neural tissue, while hyperechoic areas correlate with connective tissue.[10] Ultrasound imaging of the proximal brachial plexus usually shows hypoechoic structures reflecting an oligofascicular pattern. Distal brachial plexus structures display a more hyperechoic, honeycomb appearance, reflecting a multifascicular pattern.[7]

Pharmacology of local anesthetics

Local anesthetics (LA) make regional anesthesia possible by preventing the propagation of nerve conduction and inhibiting or relieving pain.[11] LA are primarily weak bases that attach to sites of the sodium channel in nerves and prevent the movement of the sodium ion through the nerve pores, which temporarily halts nerve conduction.[12]

Local anesthetics are classified as amides or esters, based on the chemical structure. Most local anesthetics used in regional anesthesia are amides (e.g., "-caines"). The structure of a typical local anesthetic consists of a lipophilic head, a hydrophilic tail, and a chain linking the head and tail which is either an amide or ester and determines the classification of the type of LA. Alteration of the structure of the LA affects the various actions of the LA itself and is important when making the choice of which LA to use. For example, increasing the alkyl substitution on the aromatic ring increases its lipid solubility, thereby increasing its potency. Allergic reactions to local anesthetics are more common with esters and rare with amides.

Pharmacokinetics

Local anesthetics differ from other drugs because they are directly delivered at their site of action. Efficacy depends on the amount of LA that reaches the nerve and proximity to the nerve. Diffusion of local anesthetic is dependent on the amount of connective tissue and adipose tissue that is present in the area of the block.

Toxicity

Local anesthetic toxicity has been a concern since its first use in nerve blockade. Regardless of which local anesthetic is injected, traditional methods have required large volumes for successful regional anesthesia such as with brachial plexus blockade or Bier blocks. Frequent aspiration and incremental dosing are imperative, as is communication with the patient to detect early signs of potential intravenous injection before progression to signs and symptoms of toxicity. Factors such as drug dose, rate of absorption, biotransformation, and elimination of the drug from the circulation are determinants of the plasma concentration of local anesthetics. Fortunately, one of the benefits of ultrasound guidance in the use of regional anesthesia has been the decreased need for large volumes.[13]

High plasma levels may be a consequence of direct intravascular injection, plasma absorption, and/or certain underlying medical conditions of the patient (i.e., hypoproteinemia in renal or hepatic disease). Elevated intravascular levels of LA may result in minor CNS symptoms such as dizziness, ringing in the ears, and may proceed to more intense symptoms of loss of consciousness, and seizures. At even higher levels, cardiac arrhythmias ensue, including complete cardiovascular collapse. Use of LA in regional anesthesia demands an appreciation of these toxicities. Understanding agent-specific toxic levels is vital – as much as the preparation for these unintended events.

Adjuncts such as epinephrine affect absorption and elimination. The use of epinephrine as a marker of intravascular injection is warranted in almost all situations. Exceptions include those cases where the vasoconstriction resulting from epinephrine may in fact compromise the blood flow to the area.

Physicians must be prepared with monitors, emergency drugs, and airway supplies to facilitate treatment of LA-related toxicity. Toxicity related to LA can include but is not limited to oxygen desaturation, hypotension, bradycardia, and seizures. The extent of toxicity is determined by the specific drug's intrinsic properties as well as the plasma level of the LA. The safety of LA is an essential aspect of regional anesthesia and is dependent on the skill of the physician, placement of the needle, the drug utilized, and patient health. All

of these factors must be considered when determining the appropriate procedure and LA dose.[14]

Bupivacaine has been in use for many years and has the highest cardiotoxicity potential due to its intrinsic properties. Although the cardiac system is generally resistant to the effects of LA, bupivacaine is the notable exception. An overdose is more likely to result in cardiovascular collapse compared with other LA. This cardiac collapse is difficult to treat traditionally with ACLS/CPR alone. Recent case studies have demonstrated that IV infusion of Intralipid, an emulsified fat, may be successful in ameliorating cardiotoxicity associated with local anesthetics by acting as a "sink".

Vasoconstrictors

With the addition of vasoconstrictors such as epinephrine or phenylephrine to the LA anesthetic solution, the systemic absorption rate of an LA can be decreased.[14] The dose of bupivacaine increases from 3.5 to 4.0 mg/kg. This action of epinephrine is more significant with lidocaine as the upper limit increases from 3.0 to 7.0 mg/kg. Vasoconstrictors allow the physician to identify an intravascular injection sooner rather than later, due to the development of tachycardia with an intravascular injection.[15] The block can be halted immediately, possibly preventing a more serious intravascular complication. Vasoconstrictors result in decreased plasma uptake and increased duration of local anesthetic effect.[16]

LA selection

The choice of a LA depends on toxicity (as discussed previously), duration of effect, and time to onset (Table 4.1).

Duration is important when considering surgical times when the block is the primary anesthetic. In such instances, the longer-acting agents such as ropivacaine or bupivacaine have the distinct advantage as they often can outlast the surgery and offer the greater benefits of postoperative pain management.

Time to onset is also an important factor. Most of the time, regional anesthesia is done prior to the surgery and a fast time to onset is highly desirable. Each LA has its own time to onset or latency. Various factors can shorten this latency, including the addition of bicarbonate, higher dose, and needle location. The recent use of ultrasound allows for a more precise needle placement, which in turn allows for quicker onset.

The choice of local anesthetic affects the quality of the block, time to onset, and duration of action (Table 4.2).[15] Quicker onset generally leads to quicker clearance. Lidocaine and mepivacaine, agents with intermediate duration, have a short latency period which is further shortened by the addition of bicarbonate as mentioned above. In comparison, bupivacaine and ropivacaine, two long-acting agents used commonly in regional anesthesia, have a longer latency period, and are not able to mix with bicarbonate due to precipitation concerns. Some may consider mixing two agents together to achieve the quicker onset effect and the longer duration of anesthesia/analgesia. These mixtures can be about 50:50; however, it can vary depending on the experience and training of the anesthesiologist. The toxicity of mixtures are additive and the mixture does not lower the overall toxicity.[17]

Another consideration is the differential blockade, as nerves are blocked unequally and at different rates. Nerve blockade proceeds in the following order: sympathetic nerves, pin-prick sensation, touch, temperature, and finally motor.[18] This is an important attribute of bupivacaine, as one can provide improved analgesia without much motor blockade in the postoperative period if an infusion is run at analgesic doses. Optimally, an LA with sensory selectivity is desired.

Table 4.1 Commonly used agents in upper extremity regional anesthesia

Lidocaine	Most widely used local anesthetic Prototype amide Can be used in almost any peripheral block 1.5% or 2% with or without epinephrine is most commonly used for surgical anesthesia
Mepivacaine	Intermediate duration Similar to lidocaine Less vasodilation Ineffective as topical agent 1.5% mepivacaine is the most commonly used agent in regional anesthesia
Bupivacaine	One of the most commonly used local anesthetics in regional and infiltration anesthesia Long-acting High quality sensory anesthesia relative to motor blockade Most commonly used for epidural and spinal Refractory cardiac arrest with 0.75% concentration. Interaction with cardiac Na+ channels "fast in, slow out" Disruption of atrioventricular nodal conduction Depression of myocardial contractility Indirect effects mediated by CNS Limitations on total dose of bupivacaine given
Ropivacaine	Developed due to cardiotoxicity related to bupivacaine Long-acting Slightly less potent than bupivacaine Higher concentrations fastens its onset and density of block Reduced CNS/CV toxicity compared to bupivacaine

Table 4.2 Comparative pharmacology and current use of local anesthetics

Classification and compounds	pKa	Non-ionized (%) at pH 7.4	Potency[a]	Max. dose (mg) for infiltration[b]	Duration after infiltration (min)	Topical	Infiltration	Intravenous regional	Peripheral block	Epidural	Spinal[c]

Ropivacaine	8.1	17	6	200	240–480	No	Yes	No	Yes	Yes	Yes

[a]Relative potencies vary based on experimental model or route of administration.
[b]Dosage should take into account the site of injection, use of a vasoconstrictor, and patient-related factors.
[c]Use of lidocaine, mepivacaine, prilocaine, and chloroprocaine for spinal anesthesia is controversial and evolving (see text).

Regional anesthesia techniques

Regional anesthesia has been shown to be an excellent anesthetic modality for upper extremity surgery. This relates to long-lasting pain relief, reduced opioid-related side effects during the first 24 hours after surgery, and expedited hospital discharge.[2,19] Despite this, many patients still receive other types of anesthesia for a variety of reasons. Alternatives to regional anesthesia include general anesthesia, monitored anesthetic care (MAC), Bier block or simple local anesthetic infiltration without blockade of the brachial plexus. The factors involved in determining suitability of an anesthetic include patient preference, surgeon preference, relative and absolute contraindications to regional anesthesia, as well as type of surgery. General anesthesia has been utilized for many years with a safety record that has improved significantly over the past decades.[20] Due to respiratory depression, general anesthesia requires airway management not routine in regional anesthesia, local anesthesia or in monitored anesthetic care. Additionally, patients who undergo general anesthesia may experience hemodynamic variations that may be significant in those with cardiac disease. All patients who will undergo any type of anesthesia need to have standard ASA monitors, which include pulse oximetry, blood pressure monitoring, and electrocardiogram monitoring as well as intravascular access established in the non-operative limb.

The use of ultrasound-guided blocks has gained significant momentum in the last decade. The benefits of ultrasound include shortened time to onset, enhanced visualization of the nerve target and surrounding structures such as arteries, veins, muscle, and other soft tissues, needle visualization, visualization of the local anesthetic and its spread, anomalies of anatomy.[21] Combining the traditional technique of peripheral nerve stimulation with ultrasound has not demonstrated notable benefits, although that has been a common practice, particularly for difficult cases. Surprisingly, there have been no studies that demonstrate improved safety with ultrasound over the technique of peripheral nerve stimulation.[22,23]

Digital block

Digital nerve blockade is easy to perform and provides useful anesthesia for a variety of surgical procedures or injuries isolated to a digit. Many techniques for performing digital nerve blocks have been described. These techniques rely on anesthesia of the volar common digital nerves derived from the median and ulnar nerves as well as the dorsal digital branches of the radial nerve.

The authors' preferred technique for digital blockade involves volar and dorsal injections. The hand is placed palm up and the skin is cleansed. Using a small needle, 5 mL of local anesthetic such as 1% lidocaine or 0.25% bupivacaine is injected into the subdermal space directly overlying the A1 pulley of the involved finger. A wheal is slowly raised. The hand is then turned palm down and an additional 2–3 mL of local anesthetic is injected into the subcutaneous tissue over the dorsum of the finger, just distal to the metacarpophalangeal joint.

The use of epinephrine in digital blocks was, in the past, a controversial subject. Despite the admonition against epinephrine use in numerous medical textbooks, no case of digital gangrene has been reported in the literature resulting solely from the use of epinephrine with a local anesthetic. A number of studies have demonstrated epinephrine can be safely used as an adjunct for digital block anesthesia. A randomized, prospective, blinded study with over 3000 consecutive cases showed no cases of infarction, necrosis or tissue loss.[24] Epinephrine can be added to local anesthetics to lengthen the duration of action, lessen bleeding, reduce the need for a tourniquet, and reduce the risk of adverse systemic effects.[25]

Clinical tip: injection technique

Use a small needle such as 27- or 30-gauge and a slow injection technique to deliver the local anesthetic. Smaller needle size with gentle insertion have been shown to result in less painful injections.[26]

Wrist block

When the entire hand requires anesthesia, a wrist block is appropriate. A wrist block is the technique of blocking the median, ulnar and radial nerves at the level of the wrist. Similar to the digital block, it is easy to perform, has minimal complications, and is highly effective.

The patient should be supine with the arm abducted and wrist in slight dorsiflexion. The median nerve is located between the tendons of the palmaris longus (PL) and the flexor carpi radialis (FCR). The palmaris longus tendon is usually the more prominent of the two; the median nerve passes just radial to it. The ulnar nerve passes between the ulnar artery and tendon of the flexor carpi ulnaris (FCU). The tendon of the flexor carpi ulnaris is superficial to the ulnar nerve. The superficial branch of the radial nerve runs along the medial aspect of the brachioradialis muscle. It then passes between the tendon of the brachioradialis and radius to pierce the fascia on the dorsal aspect. Just above the radial styloid process, it gives digital branches for the dorsal skin of the thumb, index finger, and lateral half of the middle finger.

The median nerve is blocked by inserting a 25-gauge needle between the tendons of the palmaris longus and flexor carpi radialis at a 30° angle. The needle is inserted until it pierces the deep fascia. Piercing of the deep fascia may be appreciated with a fascial "click". Local anesthetic, 3–5 mL, is injected. There should be no resistance to the injection as the local anesthetic travels up and down the carpal tunnel.

The ulnar nerve is anesthetized by transversely inserting the needle under the tendon of the FCU muscle close to its distal attachment proximal to the ulnar styloid. The needle is advanced 5–10 mm past the FCU tendon. The syringe is aspirated to confirm that it is not intravascular in the ulnar artery. Local anesthetic solution, 3–5 mL, is then injected. A subcutaneous injection of 2–3 mL of local anesthesia just above the tendon of the FCU is also advisable in blocking the cutaneous branches of the ulnar nerve.

The radial nerve is essentially anesthetized with a field block. This blockade requires a more extensive infiltration because of the less predictable anatomic location and division into multiple, smaller, cutaneous branches. Local anesthetic, 5 mL, is injected subcutaneously just above the radial styloid,

aiming medially. The infiltration is then extended laterally, using an additional 5 mL of local anesthetic.

Intravenous regional anesthesia (Bier block)

A Bier block is indicated for brief surgery of the hand or forearm (up to 1 h). This technique relies on diffusion of local anesthetic from the venous system to nearby nerves. The operative extremity is exsanguinated using an Esmarch bandage. A double tourniquet is inflated sequentially from distal to proximal. The distal tourniquet is then deflated to allow local anesthetic to penetrate that area. Local anesthetic solution is then injected through a small IV catheter placed in the hand of the arm to be anesthetized. A total of 50 mL of 0.5% lidocaine is commonly used. Of note, the patient should have a separate IV on the nonoperative limb to be available for sedation and/or emergency access. Anesthesia onset is within minutes. Patients may complain of tourniquet pain after 30 min, at which time the distal cuff is inflated and the proximal cuff is released. At the conclusion of surgery, the tourniquet is deflated, and there is a rapid resolution of anesthesia. To prevent local anesthetic toxicity, the tourniquet should not be deflated before 30 min have elapsed after drug infusion. Advantages of a Bier block include its safety profile, simplicity and reliability. However, its use is limited to short procedures due to tourniquet discomfort, and it offers no postoperative analgesia.

Interscalene block

Indications for an interscalene block include surgery of the shoulder, distal clavicle, acromioclavicular joint, and proximal humerus. The block is performed at the level of C5–C7 nerve roots, providing anesthesia to the shoulder and upper arm. Proximal spread of local anesthetic to C3–4 will also anesthetize the cape of the shoulder. Ulnar nerve distribution is usually spared with this technique. The nerve roots lie in a groove between the anterior and middle scalene muscles, posterolateral to the sternocleidomastoid muscle and phrenic nerve.

To perform the block, the patient is placed in a semi-recumbent position. When using the nerve stimulation technique, the interscalene groove is palpated at the level of C6 and the needle is advanced in a slight posterocaudad direction. A twitch of the bicep, tricep, or distal muscle is sought. When using ultrasound, the C5–7 roots form a characteristic "stoplight" appearance as they lie sequentially between the scalene muscles. The nerves are identified, and local anesthetic is deposited circumferentially around the nerves (Fig. 4.4).

Complications and side effects specific to this block are ipsilateral phrenic nerve palsy, Horner's syndrome, hoarseness from blockade of the recurrent laryngeal nerve, and vascular puncture or injection; the carotid artery, internal and external jugular veins, and vertebral artery are in close proximity to the nerves of interest.

Supraclavicular block

The supraclavicular approach to the brachial plexus provides more reliable and effective regional anesthesia to the upper extremity than other approaches.[27] Indications for the supraclavicular approach include surgery of the upper extremity including the arm, elbow, and hand. Though the supraclavicular block can also be used for shoulder surgery, it may require some supplementation of the supraclavicular nerve (C3–C4).[2]

With ultrasound assistance, it is easy to appreciate the continuum that exists within the brachial plexus. Moving the ultrasound probe up or down, the brachial plexus will change a block from an interscalene block to a supraclavicular block. With the gain in popularity with ultrasound, there has been a resurgence in the supraclavicular block as the concerns of pneumothorax have diminished. In a recent study of 510 patients who underwent ultrasound-guided supraclavicular blocks, none were found to have a pneumothorax.[28]

The supraclavicular block is performed with the probe placed in the supraclavicular fossa (Video 4.1 ▶). The sonoanatomy includes the subclavian artery, which is the primary landmark in this block. The brachial plexus (trunks and/or divisions of the plexus) lies superior (posterior) and lateral to the artery in a majority of patients and appears as a "bunch of grapes" or several round structures with a dark interior (hypoechoic) and a bright outline (hyperechoic outer circle). Once an adequate view is identified, the area is prepped and draped in a sterile fashion. The needle is then aligned with the probe in what is referred to as an "in-plane" technique. The needle appears on screen to move in a lateral to medial fashion. Once the needle is seen, placement should be carefully done with frequent aspiration. It may take 2–3 needle placements to ensure adequate coverage of the brachial plexus (Fig. 4.5).

The most common side effects include hemi-diaphragmatic paresis secondary to phrenic nerve block, ipsilateral Horner's syndrome, and ipsilateral nasal congestion. Other risks include infection, bleeding, nerve injury, and pneumothorax.

Nerve stimulation technique of the supraclavicular block is less frequently performed due to the concerns and risk of pneumothorax. There are other suitable alternatives if the ultrasound view is difficult to obtain.

Infraclavicular block

Indications for an infraclavicular block are the same as for the supraclavicular approach. The main difference is that the infraclavicular approach generally preserves pulmonary function by avoiding a block of the diaphragm, which is possible with the supraclavicular approach. The infraclavicular approach is a block of the brachial plexus at the level of the lateral, medial and posterior cords. These cords are named for their relationship to the axillary artery, although this relationship can have many variations.[29] In the United States, the most common approach for the infraclavicular block is using the coracoid process as a landmark, both with ultrasound guidance, as well as with peripheral nerve stimulation. Ultrasound-guided infraclavicular blocks are performed with the probe placed just medial to the coracoid process and below the clavicle. Important sonoanatomy includes the axillary artery with the three cords surrounding the artery in a U-shaped fashion. The approach includes an in-plane technique with the needle aligned with the probe in a 45° angle aiming in a cephalad to caudad direction. The needle is placed just posterior to the axillary artery, which, when the LA is injected, provides coverage to all three cords in a U-shaped spread (Fig. 4.6).

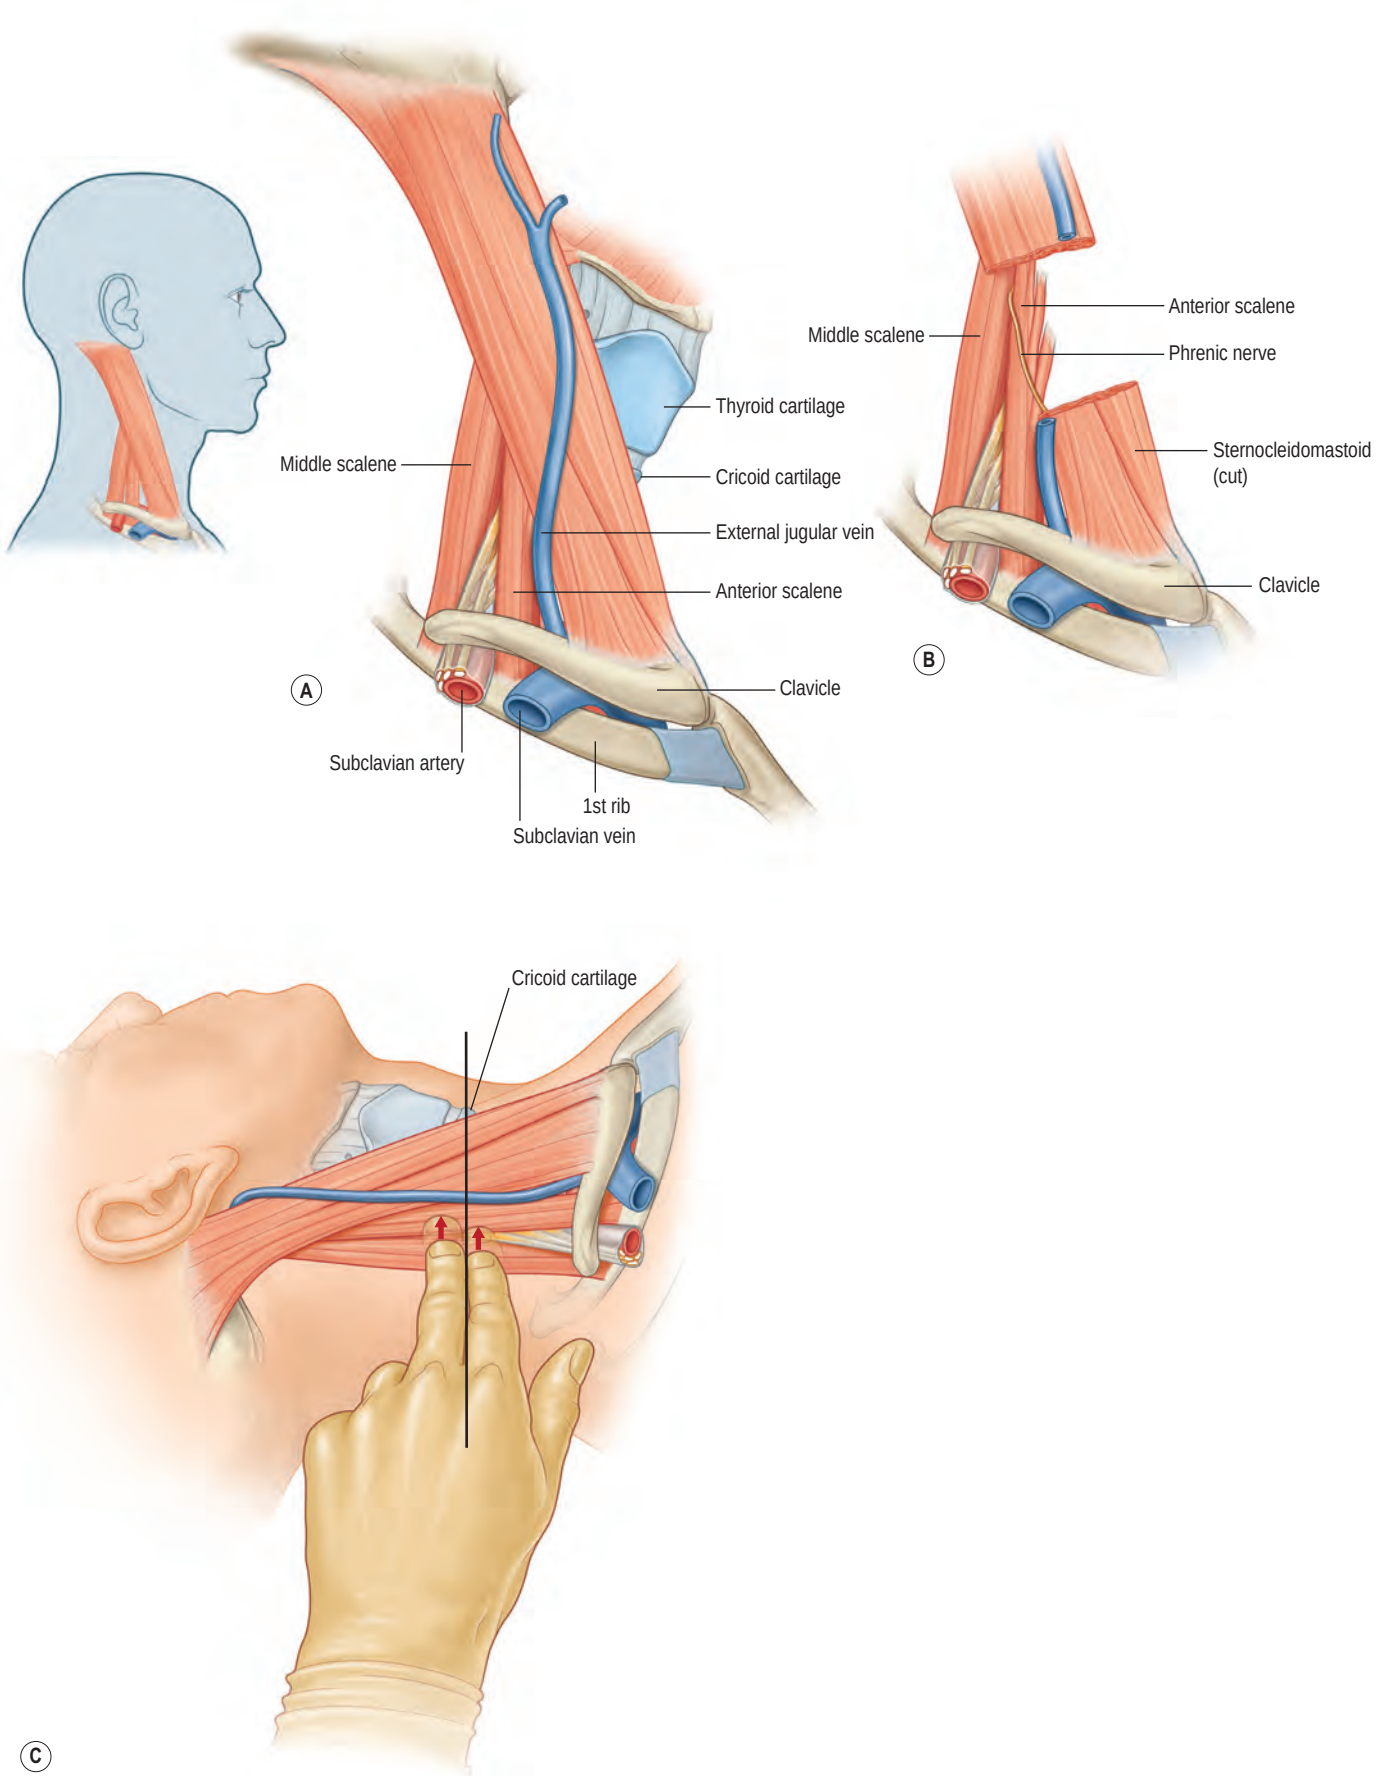

Fig. 4.4 **(A,B)** Interscalene block, functional anatomy and **(C)** technique.

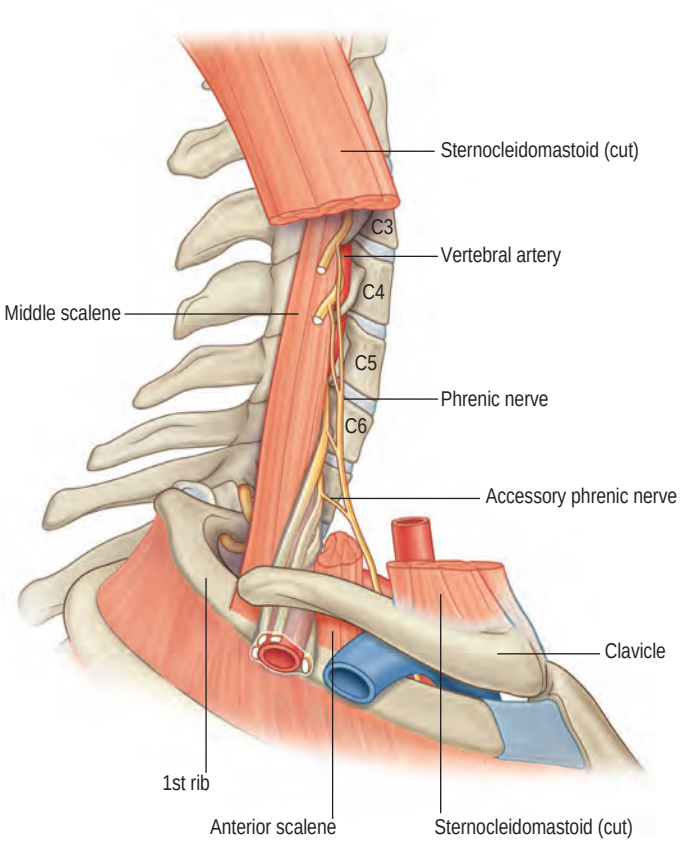

Fig. 4.5 Functional anatomy of supraclavicular block.

Use of the nerve stimulator with the infraclavicular approach is quite common and may be considered to be less difficult by some than ultrasound-guided infraclavicular block. In order to perform the infraclavicular block, the coracoid process is identified and marked. Once this is achieved, the physician will measure 2 cm medial and 2 cm inferior – this marks the nerve stimulator needle entry point. The nerve stimulator is turned to 1.0 mA. The needle is advanced in a direction that is perpendicular to the floor. It is important to note, as with other blocks, that there should be frequent aspiration throughout the block in order to minimize the risk of intravascular injection. As the needle is advanced, stimulation of the posterior cord is sought (extension of the elbow, wrist or fingers) and maintained at 0.5 mA. If the correct stimulation of muscle groups is not achieved, the needle's direction should be redirected by 5° at a time. Some anesthesiologists may seek both the medial and lateral cord if the posterior cord is difficult to find in order to improve success rates. The risks of the infraclavicular block include infection, bleeding, nerve injury, and pneumothorax.

Axillary block

An axillary block is indicated for surgery of the hand and forearm. It is performed at the level of the terminal branches of the brachial plexus. The radial, median, and ulnar nerves are positioned around the axillary artery, and the musculocutaneous nerve resides in the coracobrachialis muscle, lateral to the neurovascular bundle. The distribution of anesthesia includes the entire arm, except for the medial strip of skin in

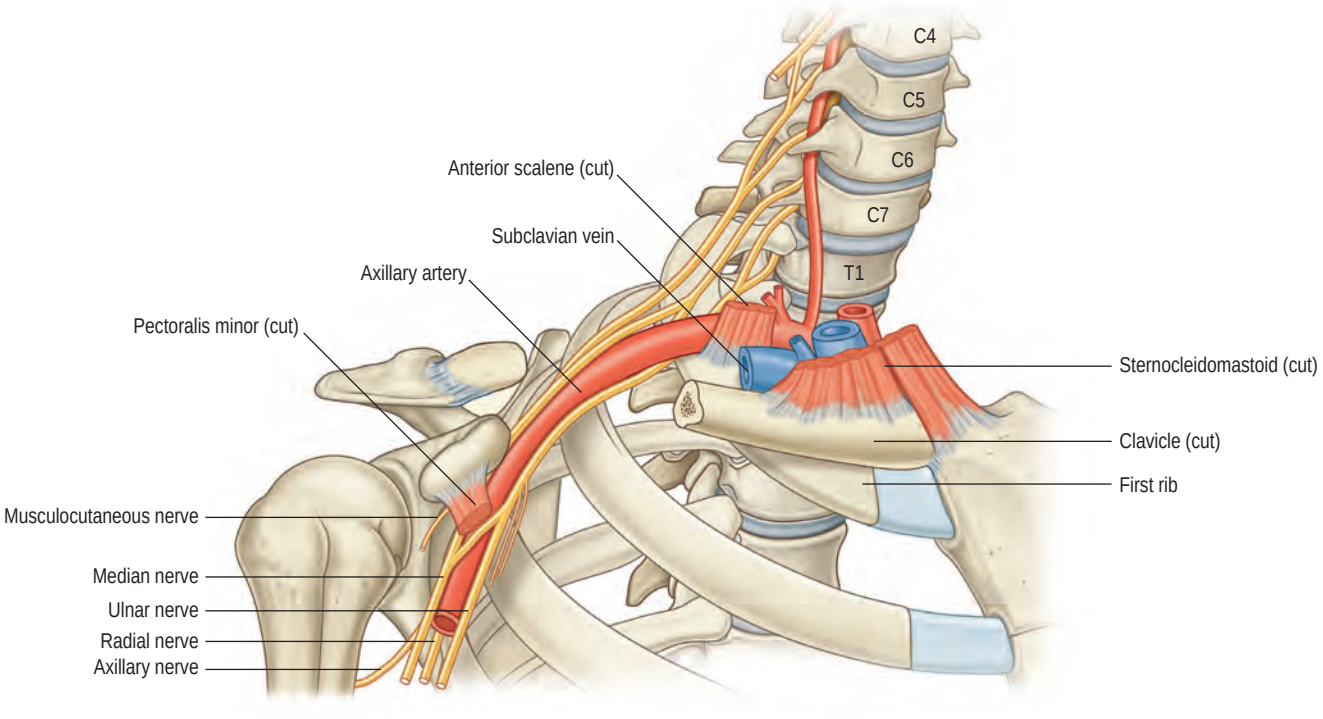

Fig. 4.6 Functional anatomy of infraclavicular block.

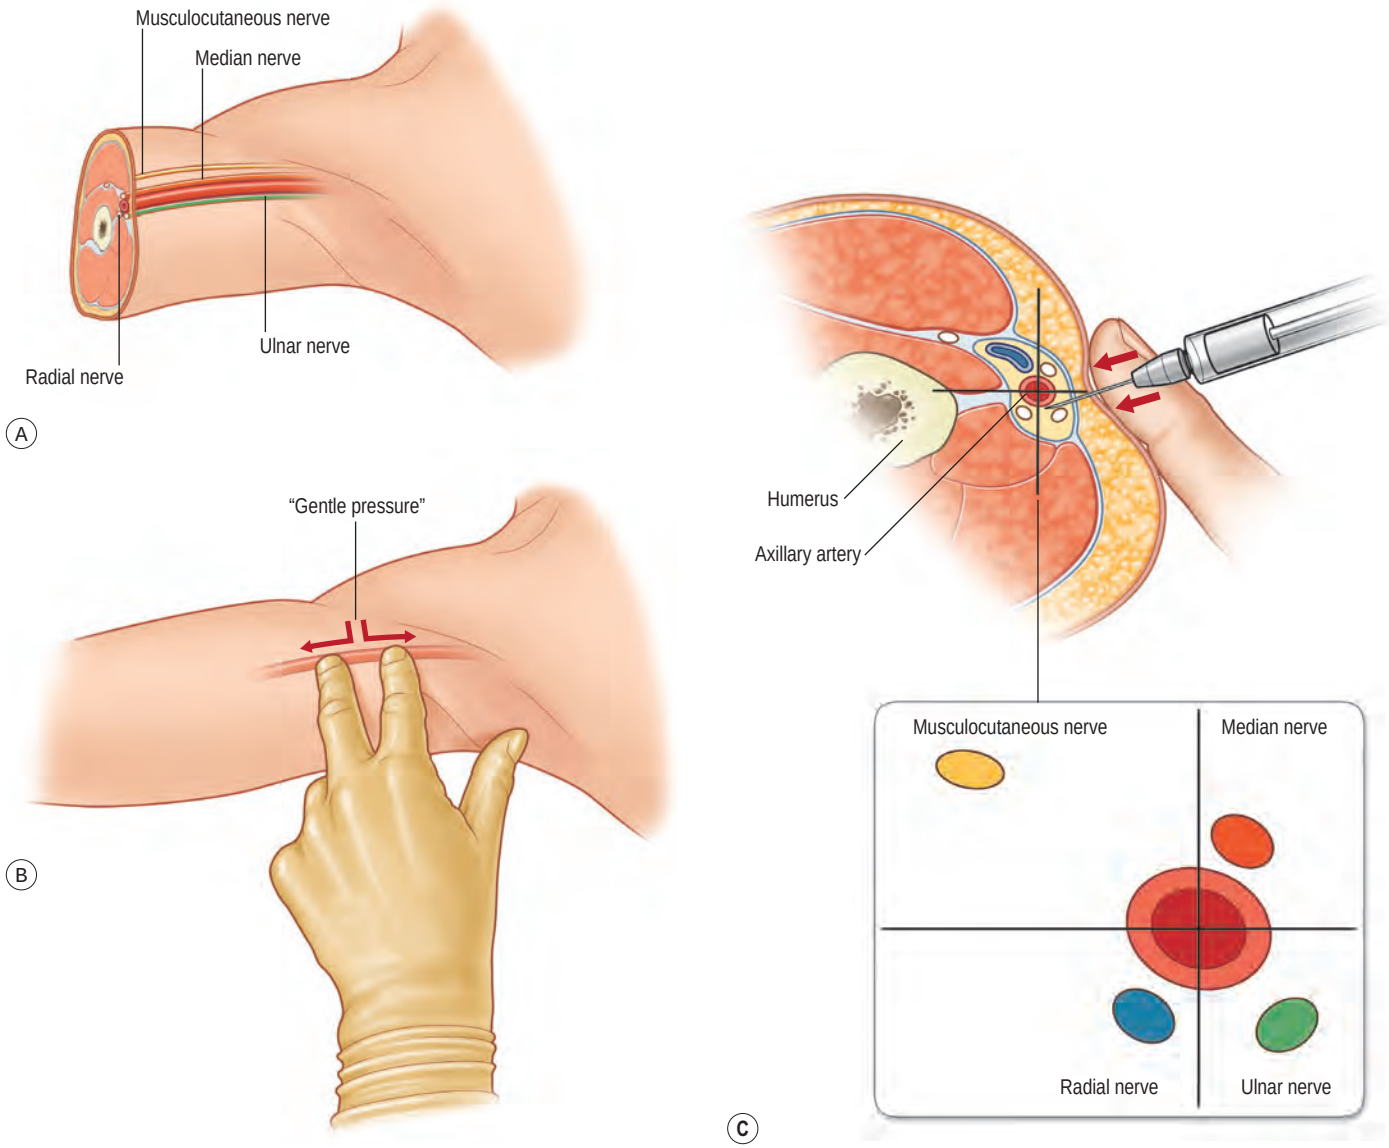

Fig. 4.7 (A,B) Functional anatomy and (**C**) technique of axillary block.

the upper arm, which is supplied by the intercostobrachial nerve from T2 (Fig. 4.7).

For this block, the arm is abducted and the elbow flexed. When using the nerve stimulation technique, the axillary artery is palpated high in the axilla and the needle is directed lateral, medial, and posterior to the artery to stimulate the median, ulnar, and radial nerves, respectively. Obtaining two or more separate twitches, and therefore injecting local anesthetic near two or more nerves, improves block success.[30] The musculocutaneous nerve is then blocked by directing the needle laterally into the coracobrachialis muscle, obtaining a twitch of the bicep muscle, and depositing additional local anesthetic. When using ultrasound, the probe is placed transversely on the upper arm near the axilla, perpendicular to the axillary artery. The artery and nerves of interest are visualized. The needle is advanced in a lateral to medial direction, and local anesthetic is deposited around each nerve.

The axillary approach to the brachial plexus has potential benefits for certain patient populations, such as patients with pulmonary disease, because the phrenic nerve will not be affected. This block may also be superior in patients with coagulopathies, since the area is superficial and easily compressible if vascular puncture occurs. One disadvantage of this block is that the needle must be repositioned multiple times to adequately block all of the nerves, potentially increasing the risk of vascular puncture or causing more patient discomfort. Additionally, the arm must be abducted in order to have adequate access to the upper arm and axilla, which may be difficult in some patients such as those with injuries.

Complications

Complications associated with regional anesthesia present a rare but significant risk to patients undergoing surgery of the upper extremity. Serious complications include neurologic injury, seizures, and cardiac arrest. Other risks associated with regional anesthesia are hematoma, infection, and block-specific complications such as pneumothorax. A large French prospective study reported an incidence of severe complications related to peripheral nerve blocks to be <5/10000 and an incidence of serious neurologic injury to be 2.4/10000.[31]

Neurologic complications

Peripheral nerve injury can present as pain, sensory disturbances, or motor deficits. Most of these are transient, with 95% resolving within 4–6 weeks and over 99% resolving within 1 year.[2,30] The pathophysiology and mechanisms of peripheral nerve injury are mechanical, injection, ischemic, and neurotoxic. Recovery and prognosis are related to the location of injury. If the axon is damaged, recovery is slow and often incomplete, relying on collateral reinnervation or axonal regrowth. Damage to the myelin sheath disrupts the nerve action potential and tends to have faster recovery and a better prognosis. Mechanical injury from needles or catheters can disrupt the axon, although nerves tend to move away from approaching needles.[32] Needle to nerve contact or intraneural injection can result in ischemia and neurotoxicity if the perineurium is disrupted. Local anesthetics can cause acute inflammatory reactions and be neurotoxic to exposed axons via cellular cytotoxic effects, dependent on the concentration and duration of exposure.[31] Finally, ischemic injury may be caused by vascular injury, prolonged tourniquet use, or the use of vasoconstrictors. Intraneural injection can result in elevated pressure leading to ischemia. Ischemia causes metabolic stress and is associated with axonal damage and a poorer prognosis.

Peripheral nerve injury

A suspected peripheral nerve injury warrants an immediate evaluation, including a complete history and physical examination to screen for any pre-existing problems and to determine the location of the lesion. The 2008 American Society of Regional Anesthesia and Pain Medicine (ASRA) Practice Advisory on Neurologic Complications recommends that a complete or progressive deficit should be evaluated immediately by a neurologist or peripheral nerve surgeon. Mild or resolving symptoms without evidence of a neural deficit can be monitored and may only require patient reassurance. However, if symptoms fail to improve, a neurological consultation is recommended. Incomplete lesions with evidence of a neural deficit should initially be evaluated by a neurologist and may require referral to a peripheral nerve surgeon if symptoms persist or worsen.[32] Neurologic tests such as nerve conduction studies, electromyography, and MRI may be helpful in establishing the degree of nerve damage, location, and prognosis.

The Second ASRA Practice Advisory on Neurologic Complications Associated with Regional Anesthesia and Pain Medicine provides updates to the 2008 advisory. Similar to reports from the first advisory, the incidence of peripheral nerve injury has remained stable regardless of the localization technique used. The reported range of long-term injury is 2–4 per 10000 blocks. Long-term injury is rare, but transient postoperative neurologic symptoms are common in the first days to month following peripheral nerve blocks and decrease over time. The current advisory continues to advise against placing blocks in deeply sedated or anesthetized adults, as paresthesias reported by patients are considered a valuable warning sign for potential nerve injury.[33]

Local anesthetic toxicity

Local anesthetics used for peripheral nerve blocks have the potential to cause serious harm. Systemic absorption of local anesthetic from an appropriately placed and dosed nerve block may result in mild symptoms, while an unintentional intravascular injection can lead to severe neurologic or cardiac toxicity causing major disability or even death. Risk factors that increase the potential for local anesthetic systemic toxicity (LAST) include local anesthetic potency and dose, peripheral nerve block location and technique, and patient risk factors such as age, pre-existing disease, and medications. Methods to prevent LAST revolve around avoiding intravascular injection and limiting the total dose of local anesthetic. Intravascular injection can be limited or avoided by incrementally injecting local anesthetic to monitor for symptoms of systemic absorption, aspirating prior to injection, and using an intravascular marker such as epinephrine. If systemic toxicity does occur, the classic symptoms present as auditory changes, circumoral numbness, metallic taste, and agitation. Symptoms may then progress to seizures, CNS depression and, finally, cardiac excitation followed by depression. However, cardiac toxicity may occur simultaneously or even before neurological symptoms. The treatment of LAST is circulatory and airway support to minimize hypoxia and acidosis. Seizures can be controlled with benzodiazepines, although succinylcholine may be necessary for persistent seizures. Cardiac arrest requires rapid restoration of cardiac output and oxygen delivery. If standard ACLS measures such as epinephrine or amiodarone fail to provide an adequate response, lipid emulsion therapy should be administered. Cardiac arrest refractory to vasopressor and lipid emulsion therapy should prompt institution of cardiopulmonary bypass.[34]

Vascular injury

Vascular complications include hematomas, vasospasm from arterial puncture or local anesthetic-induced vasoconstriction, and arterial dissection from intramural injection. Hematomas have the potential to cause ischemic injury to nearby neural structures from compression, although they are usually small and inconsequential.[35] The severity of symptoms and progression are related to the rate and duration of hematoma formation. Risk factors include the extent of arterial injury (number of needle punctures), intrinsic vascular elasticity, and presence of diabetes, hypertension, or anticoagulation.[36] The presence of a hematoma should prompt evaluation of neurological function. Surgical decompression and evacuation may be necessary for severe cases, although conservative management is often appropriate.

When considering peripheral nerve blocks in the anticoagulated patient, significant blood loss, rather than neural deficits, may be the most serious complication. The expansile nature of the neurovascular sheath may decrease the chance of irreversible neural ischemia. Although neuraxial regional anesthesia presents significant risk to the anticoagulated patient, the risk after peripheral techniques remains undefined. Published case reports of clinically significant bleeding after peripheral regional anesthesia techniques demonstrate that all patients presenting with neurodeficits had complete recovery within 6 months to 1 year.[37] The 2010 ASRA Guidelines on Regional Anesthesia in the Anticoagulated Patient suggest that brachial plexus blockade in this patient population is not contraindicated, but should be evaluated on a case-by-case basis with increased caution.[2]

Infection

Infectious complications associated with regional anesthesia of the upper extremity are rare. Localized infection and bacteremia have been reported after both single-shot and continuous catheter techniques. One study reported catheter tip colonization in 29% of peripheral catheters, with 3% resulting in local inflammation.[38,39] Patient risk factors for infectious complications include underlying sepsis, diabetes, immunocompromised status, steroid therapy, localized bacterial infection, chronic catheter maintenance (>48 h), and ICU admission.[40,41] A careful evaluation of the risk-to-benefit ratio should be made prior to placing nerve blocks in infected or immunocompromised patients.[2,39]

Outcomes

Upper extremity surgery can be performed successfully under both general anesthesia (GA) and regional anesthesia (RA). The potential benefits of RA techniques in outpatient surgery include improved clinical outcomes, patient satisfaction, efficiency, and reduced cost.[42] However, GA is still widely used for outpatient surgery, and many of the newer anesthetic agents are short-acting with fewer side effects and better recovery profiles as compared with older agents. Additionally, many anesthesiologists are more familiar and comfortable with providing GA compared with RA.[43,44]

Clinical outcomes and patient satisfaction

Several studies comparing regional anesthesia to general anesthesia for upper extremity surgery have demonstrated more favorable clinical outcomes with regional anesthesia, in terms of improved pain control, less nausea and vomiting, and fewer opioid-related side effects. Other benefits include patients feeling more alert, tolerating oral intake sooner, and ambulating sooner.[42,43]

While improved clinical outcomes have been shown for RA in the immediate postoperative period, long-term benefits are still undefined. In a study comparing RA to GA in patients undergoing outpatient hand and wrist surgery, patients having RA had better initial analgesia and faster recovery but both groups had a similar degree of pain and need for oral analgesics 48 h postoperatively.[42] In another study comparing RA to GA in ambulatory hand surgery, patients in the RA group had significantly less postoperative pain before hospital discharge, but on postoperative days 1, 7, and 14, there were no differences in pain, opioid consumption, adverse effects, pain–disability index, or satisfaction.[43] Improved functional capacity has been demonstrated in patients having lower extremity surgery with continuous RA techniques. A study of patients undergoing outpatient shoulder and foot surgery under RA with continuous outpatient perineural infusions of local anesthetics demonstrated optimized functional recovery, analgesia, and patient satisfaction for 3 days postoperatively.[45] Further studies are necessary to determine if RA for upper extremity surgery has a benefit after the immediate postoperative period in terms of pain control, adverse effects, and functional capacity.

Patient satisfaction, although difficult to define, is usually high, with both regional and general anesthesia. Improved patient satisfaction with RA techniques may be a result of improved analgesia and fewer side effects.[46] Studies showing lower patient satisfaction with RA techniques often cite tourniquet pain and discomfort during the nerve block placement as causes of dissatisfaction.[47]

Clinical tip: benefits of a regional anesthesia service and outpatient clinic

A 24-hour regional anesthesia service can expand care to patients who present during off-hours with traumatic injuries. Blocks are placed in the emergency department for patients with fractures, traumatic amputations, and other injuries hours prior to their scheduled surgery. This offers the benefit of decreased opioid use during admission and decreased side effects such as delirium.

A regional anesthesia outpatient clinic permits walk-ins from home or from their surgeon's office to be evaluated for postoperative neuropathies, catheter management, or other related concerns. The benefits of a regional anesthesia clinic include reduced emergency department admissions, early diagnosis and management of neuropathies, and improved patient satisfaction.

Operating room cost and efficiency

Several investigators have sought to determine if regional anesthesia is superior to general anesthesia in terms of operating room (OR) efficiency and costs. Some potential areas to improve efficiency and reduce costs are OR utilization time and recovery room time.

Some studies suggest that in order to save OR time through the use of regional anesthesia techniques, nerve blocks must be performed outside the operating room. In this case, the cost of valuable OR time is spared and efficiency is maximized because patients are ready for surgery as soon as they enter the operating room.[43] Others have reported similar OR times for RA versus GA techniques even when the blocks were performed in the operating room. This was attributed to the combination of fast-acting local anesthetics, the ability for surgeons to prepare the patients while the nerve blocks took full effect, and faster emergence time compared to GA.[42]

Clinical tip: benefits of an out-of-OR regional team

Having a separate, out-of-OR regional anesthesia team offers several benefits. Efficiency is improved when blocks are placed in the preoperative holding area rather than the operating room. An out-of-OR team has the freedom and availability to place rescue blocks in the recovery room and bolus, reposition, or replace catheters placed preoperatively. Additionally, blocks can be placed in the emergency department, hospital ward, or intensive care unit for patients with acute pain such as dressing changes and other non-operative pain.

The addition of a block nurse to the regional anesthesia service improves efficiency. The block nurse assists the team by placing IVs, applying monitors to the patients, preparing drugs and supplies, and directing the pre-procedure "time-out". Other responsibilities include assisting with documentation and patient follow-ups.

Patients having RA for upper extremity surgery who experience superior pain control and fewer side effects may potentially have a shorter PACU stay. A meta-analysis of RA versus GA for ambulatory anesthesia showed that patients receiving RA had an increased ability to bypass the PACU and/or a decreased PACU time.[46]

To date, studies demonstrating an overall cost reduction for intraoperative and postoperative care during upper extremity surgery have compared GA to intravenous regional anesthesia (Bier block). The IVRA group had significant cost-savings attributed to lower anesthetic drug and equipment costs, shorter OR times, shorter PACU times, and shorter nursing times.[48,49] In contrast, a retrospective comparison of costs for RA and GA techniques demonstrated a cost disadvantage for brachial plexus regional anesthesia, although recovery room costs were not included in this analysis.[50] More research is needed to determine if RA techniques for upper extremity surgery show a significant cost reduction when compared with other anesthetic techniques.

Special considerations

Cardiac patients

Patients with cardiac disease, including those with cardiac dysfunction and low ejection fractions, conduction abnormalities or ongoing ischemia, should be given consideration for regional anesthesia for upper extremity cases when indicated. Regional anesthesia allows patients the usual advantages of perioperative analgesia and possibly avoidance of general anesthesia.[20] General anesthesia, while very safe, can cause hemodynamic variations during the induction of anesthesia, intubation, emergence from anesthesia and possibly during surgical stimulation or bleeding. In this patient population, variations in blood pressure and heart rate can have significant consequences. The prospect of regional anesthesia and analgesia allows the patient to avoid hemodynamic fluctuations, thus minimizing risk.

Patients with cardiac disease may be anticoagulated for a variety of reasons. In these patients, the risks and benefits of the block must take into consideration the possibility of an increased likelihood of bleeding during a nerve block with a resultant hematoma and nerve compression.

Pediatric patients

The pediatric population warrants special considerations when considering the type of anesthetic for surgery. These include anatomic and physiologic differences when compared with adult counterparts. Regional anesthesia offers the advantage of intraoperative and postoperative analgesia for the pediatric population. While still receiving a general anesthesia in most cases, the pediatric patient may benefit from a regional anesthetic as a result of decreased requirements for inhalational agents, leading to improved respiratory status.[51] Improved respiratory status decreases the chance of laryngospasm on emergence. There are additional benefits of comfort for the patient's family, observing a more comfortable and pain-free child in the recovery room. Overall, there is less stress for all involved.[52]

The types of blocks performed on pediatric patients are generally performed with the patient under GA. It is not until the child is older and demonstrating a level of maturity that the block can be performed on the awake patient. When a block is performed on an asleep patient, there is an elevated risk of nerve injury as the patient cannot relay the sensation of paresthesias and pain from the rare event of neural trauma. Overall, regional anesthetic techniques are considered safe with an extremely low incidence of complications.[53]

Ultrasound guidance is strongly recommended when considering regional anesthesia as part of the anesthetic in infants and children. The increased assistance provided in locating sonographic landmarks and nerve targets are of great benefit.[54–56]

Perioperative pain management

For upper extremity surgery, the use of regional anesthesia with local anesthetics is primarily motivated by the desire to avoid general anesthesia. It has resulted in lower postoperative opiate usage and therefore alleviation of opiate-related side effects.[57] This approach has become, in many ways, the standard of care in upper extremity cases.

Peripheral catheters

Peripheral nerve blockade is safe and provides postoperative analgesia through the use of long-acting local anesthetics and/or continuous infusions through peripheral nerve catheters.[58] Outpatient catheters have become very common. Catheters provide longer acting pain relief over single shot techniques and benefit patients who undergo more painful surgical procedures, patients with chronic pain, and patients who are unable to tolerate opioids for various reasons. Peripheral nerve catheters are usually placed preoperatively by the anesthesiologist when the initial nerve block is performed. Alternatively, a catheter may be placed in the postoperative period if the patient experiences severe pain. Continuous catheters do not delay discharge in outpatient surgery as they can be managed at home by the patient.

Clinical tip: use and protocols for ambulatory catheters and pain pumps

For upper extremity procedures, the infraclavicular approach is preferred over the supraclavicular approach because there is less catheter migration at this location, possibly due to the anchoring of the catheter by the pectoralis muscles or the decreased amount of skin movement with activity. Patients are sent home with a catheter and an elastomeric pain pump with an on-demand button function. The pumps are set at a basal rate at 6 mL/hour (on average) with a bolus option of 5 mL every 30 minutes. The pumps are filled to 550 mL and usually last roughly three days, depending on the number of boluses activated by the patient. Patients remove the catheters themselves at home. The patients are instructed on the use and care of the catheter and pump prior to discharge and are sent home with an instruction pamphlet and a 24-hour number to call for any questions or concerns.

Preemptive analgesia

Preemptive analgesia is a pain management technique initiated prior to incision, which continues during the surgical procedure to reduce ongoing changes that occur in the body as a result of surgical incision and stimulation.[59] The rationale is that by preemptively blocking the nociceptive transmission onslaught that occurs with surgical incision, there will be less pain in the postoperative period and thus less need for consumption of opiates with fewer side effects. The duration of treatment includes the entire time that the noxious stimulation of surgery and its inflammatory injuries occur (intraoperative and early postoperative period).[59]

Opiate-related side effects of sedation, nausea, respiratory depression, ileus and urinary retention can impact patient safety and satisfaction, discharge or patient admission, particularly in the outpatient setting, thereby affecting cost issues. Multimodal analgesic regimens have been developed featuring the peripheral nerve block in order to improve perioperative outcomes for minimally invasive procedures.

There has been much controversy surrounding the relevance and effectiveness of preemptive analgesia. Although the benefits have been established to some degree in animal studies, it has had questionable effect in human studies to date.[60] Many physicians practice with the belief that there is some preemptive analgesic effect. Some suggest that there is greater complexity in pain pathways than our understanding, and that studies are too simplistic. However, there is little doubt that excellent pain management in the pre- and postsurgical area contributes to an overall improved pain experience. A meta-analysis demonstrated that analgesia in the preoperative period lowered opiate consumption when the preemptive treatment was epidural analgesia, local infiltration, and systemic non-steroidal anti-inflammatory drugs (NSAIDs).[61] The findings were equivocal with opioids and NMDA receptors alone. Certain studies go further to demonstrate that the preemptive analgesia associated with ketamine or a cox-2 analgesic gives additional benefit pre-incision.

One such study looked at patients about to undergo upper limb surgery under axillary brachial plexus blockade.[62] The study examined the addition of a long-acting NSAID, ampiroxicam, versus placebo given 3 h prior to surgery. A significant improvement occurred in patients who received the NSAID when compared to those in the placebo group. The treated patients consumed significantly less opiates and therefore were less likely to develop narcotic side effects such as sedation, nausea, constipation, or urinary retention. Nociceptive afferent transmission is known to be sensitive to inflammation and NSAIDs are postulated to have this effect via their anti-inflammatory action. Another study retrospectively reviewed a multimodal, preemptive pathway for patients undergoing major knee or hip surgery featuring peripheral nerve blocks, and found that patients were better able to participate in postoperative rehabilitation, were eligible for hospital discharge sooner, initiated earlier ambulation, experienced lower perioperative pain scores, and experienced reduced postoperative nausea and vomiting when compared with more traditional PCA measures.[63] These findings advocate for the preemptive multimodal analgesic regimen.

Inflammatory neuropathies

Since the 2008 ASRA advisory, new knowledge has emerged regarding postsurgical inflammatory neuropathies.[33] These neuropathies appear to be immune-mediated and precipitated by stressors such as infection or surgery. The clinical presentation may be delayed, usually within the first month after surgery, followed by a period of normal recovery. Patients complain of intense pain that is out of proportion to that expected from surgery, which resolves, and is then followed by weakness. Symptoms are outside of the expected location of the anesthetic block or surgery. The neurologic deficits may be focal, multifocal, or diffuse. Patients presenting with this combination of symptoms should be promptly referred for neurologic consultation, as many neurologists recommend treatment with steroids or immunoglobulin, and most postsurgical inflammatory neuropathies improve with early diagnosis and treatment.

Patients with persistent postsurgical pain may suffer from perioperative nerve injury related to their nerve block or surgical procedure. Patients with persistent pain, pain out of proportion to that expected from surgery, pain limiting function, or signs and symptoms concerning for chronic regional pain syndrome should be referred to a pain specialist. The pain physician plays an important role in providing symptomatic treatment and coordinating patient care, education and therapy.

Chronic postoperative pain

The development of postoperative pain after surgery is due to complex pathways – endocrine, metabolic, and inflammatory – that trigger a prolonged state of excitation of the spinal cord.[64] Various chemicals released during and soon after surgical incision may induce conversion of high threshold nociceptors into low threshold receptors, via a process called peripheral sensitization. This complex process eventually leads to release of cellular mediators in the recuperative period resulting in central sensitization and chronic pain.[65] Chronic pain is, among other factors, linked to patients with severe postoperative pain.[15,66] While the development of chronic pain following surgery has lacked a spotlight in the medical literature, it is a reality that needs to be considered particularly in patients who may be at higher risk of

Table 4.3 Risk factors for severe postoperative pain

Knee and shoulder surgery
Psychosocial vulnerability
Repeat surgery
Intensity of early postoperative pain
Surgical approach with risk of nerve damage

developing chronic pain.[67] Inadequately treated postoperative pain is a major source of patients' dissatisfaction with their overall surgical experience.[68] Severe pain in the postoperative period correlates to a greater likelihood of developing chronic pain.[69] There are a number of risk factors[70] for developing severe postoperative pain (Table 4.3).

It is imperative that postoperative pain be treated effectively, possibly with a multimodal approach which considers preemptive analgesia and its potential benefits. It is crucial to identify those patients that have a greater likelihood of developing severe postoperative pain, not only to minimize the likelihood of developing chronic pain, but also to improve the patient's experience in the perioperative period.

Future directions

Wide awake upper extremity surgery

Most upper extremity surgery is performed with the use of a tourniquet, which allows improved visibility offered by a bloodless field. Mitigation of tourniquet discomfort is usually achieved with the use of sedation, regional anesthetic blocks or general anesthesia. An alternative to this traditional approach is the wide awake local anesthesia no tourniquet (WALANT) technique, under which hand surgery is performed only with lidocaine for anesthesia combined with epinephrine for hemostasis.

The use of epinephrine permits adequate hemostasis and visibility; it effectively eliminates the need for a tourniquet in most types of hand surgery. Epinephrine is now considered to be safe for use in the upper extremity, specifically the hand and fingers.[71] There have been no reported cases of digital infarction directly attributable to the use of epinephrine.

There are multiple recognized benefits of wide awake hand surgery. The risks of sedation or general anesthesia can be avoided, particularly in patients with complicated medical histories. Wide awake surgery has been shown to be cost effective as the charges related to the anesthesiologist, preoperative testing and postanesthesia recovery monitoring can be avoided.[72] In the absence of sedation, patients can actively demonstrate intraoperative range of motion during tenolysis and flexor tendon repair surgery. Gapping in tendon repairs can be assessed and corrected immediately. During tendon transfer surgery, patients can activate transfers and demonstrate tensioning; transfers that are too tight or loose can be adjusted prior to skin closure.[73] For these reasons, wide awake surgery can improve results after hand surgery, particularly with respect to tendon repairs and tendon transfers. Wide awake hand surgery is gaining traction and is expected to be increasingly utilized as more surgeons are trained in the technique.

Principles of internal fixation as applied to the hand and wrist

Jason R. Kang, Christopher Cox, and Jeffrey Yao

Access video content for this chapter online at expertconsult.com

SYNOPSIS

- Careful preoperative planning facilitates safe and expeditious surgery.
- Ligamentotaxis relies on the application of linear traction to indirectly reduce fragments via the intact periosteum, ligaments and soft tissues.
- The most appropriate method of fracture fixation depends on a careful assessment of the fracture characteristics and patient-related factors.
- Postoperative care should generally allow for early mobilization if fixation permits.

Introduction

Fracture care was significantly advanced in the twentieth century with the introduction of new techniques and instrumentation for internal and external fixation.[1] Today's capable hand surgeon must be well versed in the spectrum of available techniques of fracture fixation to provide optimum care for the myriad of bony injuries that occur within the purview of a hand surgery practice. Fixation of fractures in the hand is notoriously difficult given the relatively small size of the osseous structures and complexity of the surrounding anatomy.[2] The aim of this chapter is not to review every possible technique of fracture fixation in the hand, but rather, to present basic concepts and general techniques useful in routine fracture care.

Much of the credit for these advances in fracture management should go to the Arbeitsgemeinschaft für Osteosynthesefragen (AO), who devised a set of principles (Table 5.1) that, in its modified form, provides the basic tenets that underlie appropriate fracture care.[3]

Patient selection

Fracture assessment

Any consideration of fracture fixation must begin with a careful, complete history and physical examination. Was the mechanism of injury high or low energy trauma? How much time has elapsed since the fracture and the current presentation? Does the patient require early return to functional activities or are their daily demands limited? Does the patient have multiple injuries, or is this an isolated injury? Are there open wounds or soft tissue damage? Is there angular or rotational displacement? The vast majority of fractures that are non- or minimally displaced are amenable to treatment with immobilization and non-operative methods.

Patient-specific considerations

The treatment of fractures requires a commitment from the patient to observe potential activity restrictions and to participate in appropriate rehabilitation. Failure to comply with immobilization, follow-up care, therapy recommendations, or weight-bearing restrictions may result in compromised outcomes.

Certain host factors can increase susceptibility to fracture and/or surgical wound healing problems. Systemic risk factors for poor healing potential include: diabetes mellitus,[4] an immunocompromised state, advanced age, and smoking. Local risk factors include: skin quality, volume/quality of soft tissues available for closure, type of hardware utilized, and tension across the wound. Failure to recognize and address these factors may result in poor outcomes. Patients with an elevated risk for wound problems should be counseled accordingly and managed with alternative strategies where appropriate. Non-modifiable risk factors should be recognized and taken into consideration during treatment decision-making. Modifiable risk factors should be addressed and optimized before, during, and after fracture treatment.

Preoperative imaging

Proper radiographic assessment requires a minimum of 2 orthogonal views with the X-ray beam centered near the

Table 5.1 AO principles

1. Anatomical fracture reduction
2. Appropriate stability of the fixation construct
3. Preservation of blood supply and soft-tissue attachments to fracture fragments
4. Early and safe mobilization

fracture to minimize distortion. Factors to carefully evaluate include:

1. Location of fracture (articular, metaphyseal, diaphyseal)
2. Pattern (transverse, oblique, spiral)
3. Presence of comminution
4. Displacement
5. Angulation (sagittal, coronal, and axial/rotational planes)
6. Potential deforming forces acting across the fracture site

Occasionally, advanced imaging with computed tomography (CT) scans or magnetic resonance imaging (MRI) may be indicated to further characterize complex fracture patterns or to evaluate for occult injuries to the bones or soft tissue. After careful consideration of the fracture pattern in the context of the injured patient, a decision must be made regarding nonoperative versus operative treatment.

Treatment/surgical technique

Preoperative planning

Once a decision has been made to treat a fracture operatively, the surgeon begins the planning phase. Similar to the "reconstructive ladder" concept for management of soft-tissue defects, the surgeon should, in general, use the simplest method that will reliably produce excellent clinical results. Planning should include every detail of the proposed operation. This includes patient positioning, operating room setup, type of imaging (fluoroscopy) desired, implants needed, surgical approach, fracture fixation constructs, and consideration of backup plans. Time spent planning will save operative time, decrease staff frustration, and ensure that the appropriate tools are present for the safest, most successful and most efficient surgery possible.

Fracture reduction

Fracture reduction may be obtained by closed or open means. For closed reductions, pulling linear traction across the fracture site is usually required. This utilizes the phenomenon of ligamentotaxis,[5,6] whereby intact periosteum, soft tissue attachments, and ligaments help realign bony fragments as they are stretched. For open reductions, the fracture site is exposed and reduction is obtained through a combination of external manipulation and instruments placed within the fracture site. The reduction can be provisionally held with reduction forceps or Kirschner wires. The concept of reducing the number of fragments by temporary or final fixation of fragments to other fragments is critical in achieving a satisfactory reduction in the face of comminution. Forceps or wires used for temporary fixation should be carefully thought out so as to not interfere with the planned definitive fixation.

Reduction hints and tips: reduction forceps

Reduction forceps may be useful to attain and maintain fracture reduction in fixation of larger fragments. One tine of the forceps is introduced firmly onto a fragment and the other tine is used to tease another fragment into the appropriately reduced position. Careful pronation and supination movements while applying the forceps may allow for the restoration of length to difficult fractures. One has to take care not to crush or shatter the fragments with excessive compression of the clamps.

Reduction hints and tips: Kirschner wires (K-wires)

These are discussed in a separate section below in detail. In fracture reduction, K-wires can be used to temporarily secure fractures that are already reduced. Alternatively, they may be applied in a unicortical fashion and utilized as "joysticks" or "handles" to manipulate pieces into the appropriate position. After attaining this position, they are often advanced across the fracture to transition them from a reduction aid into a tool of temporary or definitive fixation.

Reduction hints and tips: Kapandji (intrafocal) pinning[7–11]

This is a special type of application of a K-wire utilized commonly in distal radius fractures. The wire is introduced through the fracture site (intrafocally). The pin is then tilted in the desired direction of the reduction, then advanced through the far cortex. This has particular applicability to the restoration of volar tilt and radial inclination in distal radial fracture. This may be employed as either temporary or definitive fixation.

Reduction hints and tips: temporary/supplemental external fixation

For select, extremely difficult fractures, an external fixator may be utilized to hold traction, neutralize shortening and apply ligamentotaxis to assist with fracture reduction.

Intraoperative imaging

Fluoroscopy provides a valuable adjunct to many fracture fixation surgeries. A complete review of the physics and principles of fluoroscopy is beyond the scope of this chapter, but a few points are worth mentioning. For upper extremity surgery, either an image intensifier or a "mini" fluoroscopic unit may be employed. For the vast majority of hand surgery cases a "mini" fluoro provides adequate visualization with greater mobility and less radiation.[12–15]

Many different operating room setups may be employed, but patient positioning should be confirmed preoperatively to

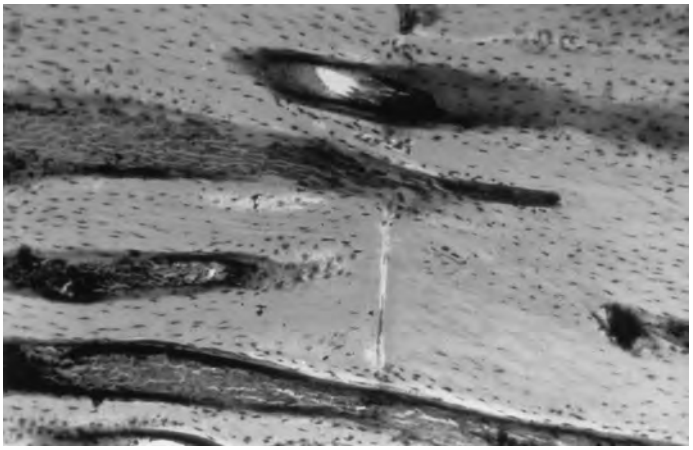

Fig. 5.1 Compressed osteotomy site. Note the migration of osteocytes across the fracture line, an example of contact healing. (Hematoxylin and eosin: magnification ×100.)

allow for adequate fluoroscopic visualization during surgery. We typically position the mini fluoroscopic unit parallel to the bed, oriented from the foot toward the axilla, so that the patient's arm can be adducted off of the hand table to provide unobstructed views.

The region being examined should always be centered on the detector of the fluoroscopic unit to minimize the distortion from the "parallax" effect. Multiple views are helpful to determine fracture reduction or hardware position in all planes. It may also be helpful to orient the beam directly down a placed K-wire or screw to precisely visualize its placement. Specific knowledge of certain anatomic regions may also be helpful. For instance, when imaging the distal radius, inclining the wrist approximately 20–30 degrees from a true lateral can provide better visualization of the cortex of the lunate facet to evaluate for screw penetration into the radiocarpal joint.[16] Live, dynamic fluoroscopy may be useful to examine for stability across a fracture site with controlled motion or to evaluate for intra-articular screw penetration.

Fixation principles

Absolute stability and interfragmentary compression

Absolute stability is employed when fracture fragments are reduced anatomically and secured with rigid fixation. Interfragmentary compression is a critical component of fixation when the surgeon attempts to achieve absolute stability.[17,18] This compression, when combined with anatomic reduction, leads to microscopic interdigitation of fracture ends, thus minimizing the distance required for cells to travel from one side of the fracture to the other. The fracture heals by **primary bone healing** and histologically with "cutting cones" that facilitate direct healing of one fragment to another (Fig. 5.1). Minimal to no fracture callus is observed. This may be achieved via a variety of methods discussed below, including lag screws, compression plates, and tension bands. Interfragmentary compression should be avoided in highly comminuted fractures, as overzealous compression may lead to excessive shortening.

Relative stability

Relative stability is important when treating comminuted fractures where anatomical reduction is not possible or in cases where closed reduction is elected. With relative stability, the primary focus is on restoring the anatomic relationship of the neighboring articular surfaces in length, alignment and rotation. Some micromotion occurs at the fracture site, and, in fact, is conducive to this type of healing (**secondary bone healing)**. Stability, however, must be adequate to maintain alignment and prevent excessive motion at the fracture sites. In contrast to primary bone healing via absolute stability, secondary bone healing occurs via progression through cartilaginous intermediaries and fracture callus is typically observed. Relative stability is typically achieved with external fixation, bridge plating, or intramedullary fixation. This concept, in general, is not commonly applied to articular fractures.

Methods of fixation

Kirschner wires

Kirschner wires (K-wires) are inexpensive and simple, yet versatile tools to assist with fracture fixation. They may be inserted in either a percutaneous or open fashion and appropriate insertion causes minimal tissue trauma. They may be implemented either as provisional or definitive fixation (Fig. 5.2).[19] When used for definitive fixation, relative stability is generally obtained and healing occurs with callus formation. Insertion of K-wires may be either directly across a fracture site or in an intramedullary fashion. The main limitation of K-wires is that they do not allow for interfragmentary compression and may loosen over time, leading to implant migration.

Sizes of Kirschner wires are usually reported either in terms of inches or millimeters. For instance, a 0.062-inch K-wire is the same caliber as a 1.6-mm K-wire. Sizes typically utilized in hand surgery range from 0.035 inches (0.9 mm) to 0.079 inches (2.0 mm), although larger wires may be used for select indications. Most wires are available in either smooth or threaded varieties. Smooth wires allow for easy removal in a clinic setting, but are also more prone to unintended migration. Threaded wires have a tendency to follow prior tracts within bone; advancing them with the drill on reverse somewhat negates this tendency.

Tension band constructs

When bone is subjected to eccentric axial forces, one side of the bone is subjected to compression forces and the opposite side to tensile forces. A tension band,[20–23] either in the form of a wire construct or a plate, aims to convert this eccentric tensile force into compression to assist with fracture compression and healing (Fig. 5.3). This concept is most applicable to simple, transverse fractures in the diaphyseal region and requires an intact cortex (no comminution) on the compression side.

To accomplish this conversion of eccentric forces into compression, the tension band must be placed on the tension surface. Fortunately, in the hand, this is on the dorsal side of the metacarpals and the phalanges, allowing easier surgical access. As the patient actively flexes the fingers, the force of

Fig. 5.2 This 75-year-old had multiple injuries after being run over by a truck. He sustained fractures of all metacarpals. Relative stability through usage of multiple K-wires was elected to minimize further soft-tissue disruption.

flexion on the annular pulleys is transmitted directly to the attached bone, and the vectors of force are through the volar cortex toward one another. Because the tension band fixes the dorsal cortex stably, the effect is to force the volar cortices against each other and, by this process, produce further compression of the fragments, thus attaining absolute stability.

The exact configuration of the wires may vary with the individual fracture, but most commonly consists of a "figure-of-8" construct with dorsally crossed wires (Fig. 5.4). Typically, this is employed by passing the wire either through a drill hole or under a tendinous origin/insertion on each side of the fracture. The wire can then be twisted to reduce and compress the fracture. Depending on the specific situation, one may use a twist on either side of the bone, combine K-wires with the intraosseous wires, or many other techniques.

In the hand, 28-gauge wire is adequate for a tension band in small phalanges; 26-gauge wire serves in larger phalanges and metacarpals. Rotation may be controlled and stability augmented by accurately interdigitating the jagged edges of fracture fragments together (Table 5.2).

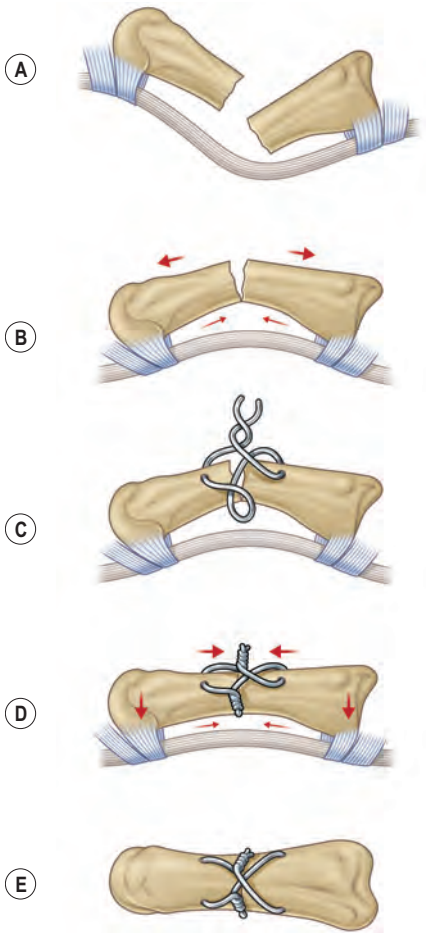

Fig. 5.3 Tension band technique. (**A**) Transverse midshaft proximal phalangeal fracture with volar angulation and displacement. (**B**) Reduction without fixation allows compression of the volar cortex during digital flexion but unacceptable dorsal cortical instability, causing an unacceptable gap. (**C**) A figure-of-eight tension band wire is applied dorsal to the central axis of the proximal phalanx. (**D**) The loops on either side of the tension band are tightened simultaneously to achieve symmetric tension on both sides of the fracture. After the tension band wire is applied, the compressive forces created during digital flexion are evenly distributed across the entire fracture site. The tension band wire absorbs an amount of tension equal to the compression at the fracture site. (**E**) Dorsal view of the tightened tension band wire. Holes may be drilled in the bone, and the ends of the wire loops may be inserted into these holes to minimize soft-tissue irritation. *(After Freeland AE.* Hand Fractures: Repair, Reconstruction and Rehabilitation. *Philadelphia: Churchill Livingstone; 2000:42.)*

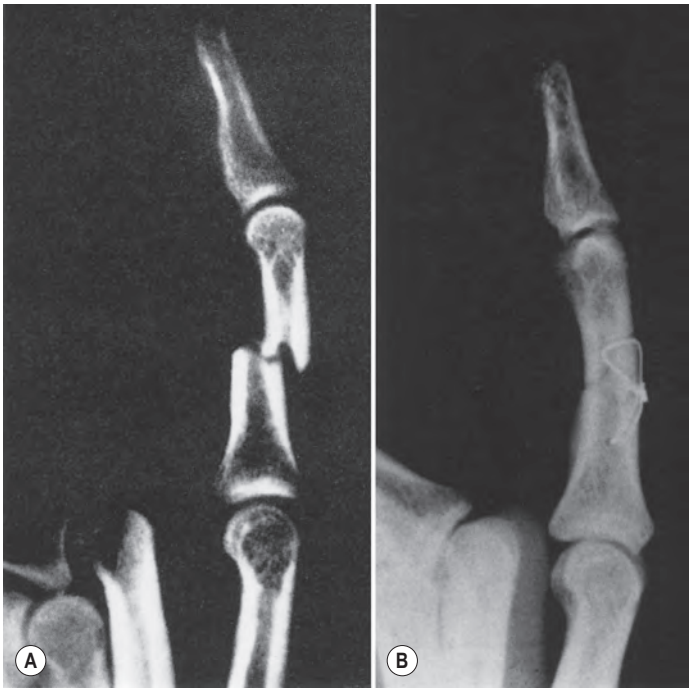

Fig. 5.4 (**A**) A displaced transverse fracture of the mid-diaphysis of the middle phalanx resulting from a glancing blow to the dorsum of the long finger. (**B**) Application of a tension band wire resulting in good interdigitation of the fracture so that it was held securely against rotational forces. *(From Freeland AE, Jabaley ME, Hughes JL.* Stable Fixation of the Hand and Wrist*. New York: Springer-Verlag; 1985:89.)*

A specific form of intraosseous wiring,[24] the 90-90 technique (Fig. 5.5), is useful, especially for arthrodesis, replantation, and transverse fractures. Although not a tension band strictly speaking, it is a rigid enough construct that it will permit immediate motion.

External fixation

External fixation provides a useful, versatile option for fracture stabilization. This typically consists of pins placed on either side of the fracture with the pins connected to each other through an external apparatus. This may be employed as either temporary or definitive fixation. Reduction is achieved through ligamentotaxis.[5,25,26] While this may be used with any fracture, it serves a particular purpose when there is severe fracture comminution (Fig. 5.6) and/or an element of soft tissue loss requiring reconstruction, thus increasing the risk of infection with internal implants. External fixators can typically be inserted through small incisions away from the fracture site and zone of injury, thus avoiding violation of the fracture hematoma. Knowledge of local anatomy together with proper techniques of pin insertion should be used to avoid damage to neurovascular structures. For instance, when placing an external fixator for a distal radius fracture, great care should be used to avoid damage to the radial sensory nerve. Most authors advocate using an open approach and identifying the radial sensory nerve in this instance although others have advocated percutaneous placement of the pins in a more dorsal position.[27]

Two main categories of external fixators exist: non-bridging and bridging. Non-bridging fixators[28] only span the fracture site, while bridging fixators also span a joint. Bridging fixators are more often used with metaphyseal fractures. Bridging fixators may also be combined with limited K-wire or internal fixation for comminuted articular fractures.[11,29] When bridging joints, care must be taken to avoid unwanted overdistraction.[30] Some specialized bridging fixators are hinged to allow mobilization of the spanned joint.[31] Relative stability is achieved with any method of external fixation and healing occurs with abundant callus via secondary bone healing.

Interfragmentary lag screws

Lag screws (Figs. 5.7 & 5.8) provide compression between two fragments to achieve absolute stability. These may be used alone, in combination with another method of fixation, or through a plate. Lag screws are most useful in simple oblique or spiral fractures,[32] but also may be used to piece together comminuted fractures. The utility of lag screws is very limited in the fixation of transverse fractures as proper orientation perpendicular to the fracture is difficult. If the trajectory of the lag screw is not perpendicular to the plane of the fracture, a shear force is introduced.

Key concepts: lagging by technique vs lagging by design

Insertion of a lag screw can be accomplished in two ways. **Lagging by technique** relies on screw placement technique to achieve interfragmentary compression, whereas **lagging by design** applies the design features of the screw to achieve compression.

When placing a lag screw by technique, a proper site of insertion is selected first (see Fig. 5.7 and Video 5.1 ▶). Ideally, lag screws should be positioned perpendicular to the plane of the fracture. Long spiral fractures may be fixed with lag screws

Table 5.2 **Techniques for internal fixation**

	Interosseous wire (gauge)	Kirschner wire (diameter inches)	Interosseous (lag) screw (mm)	Plate (mm)
Distal phalanx	28	0.028/0.035	1.3/1.5	N/A
Middle phalanx	28	0.035	1.3/1.5	1.3/1.5
Proximal phalanx	26/28	0.045	1.5/2.0	1.5/2.0
Metacarpal	26	0.045/0.062	1.5/2.0	2.0
Carpal	24/26	0.045/0.062	1.5/2.0/2.4	2.0/2.4

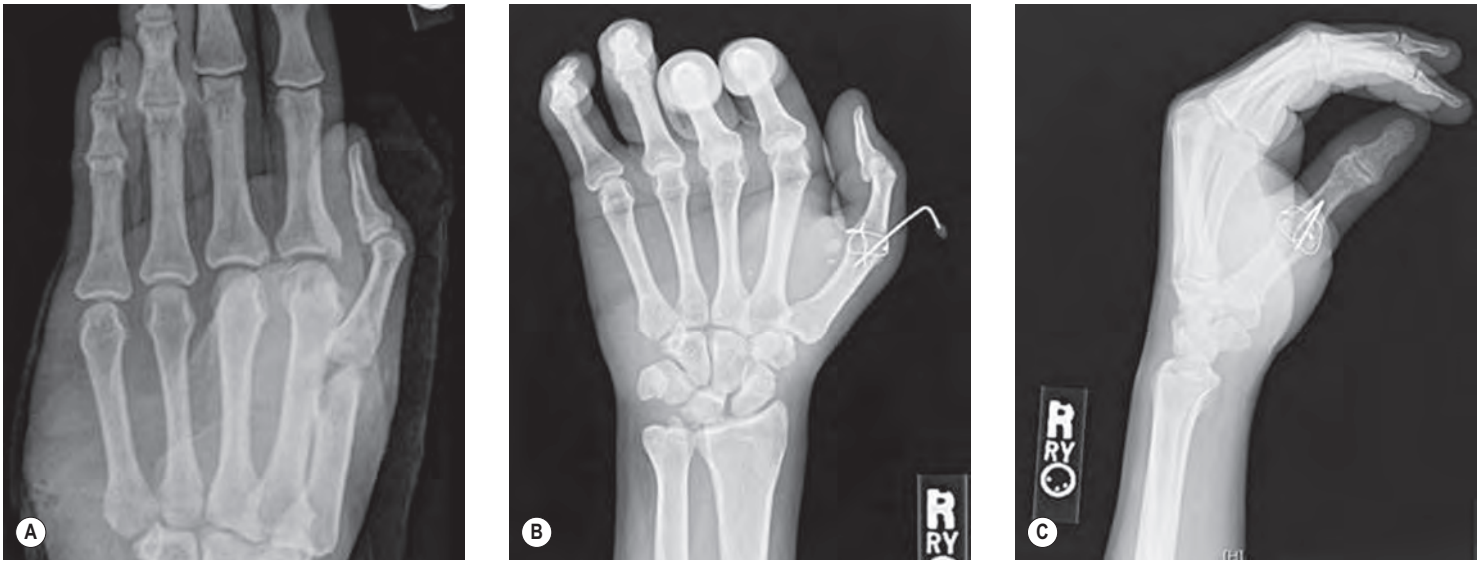

Fig. 5.5 This 37-year-old male had a saw injury to the palm of the hand. In addition to multiple tendon injuries, he sustained a severe injury to the cartilage of the thumb metacarpophalangeal joint. A primary fusion was elected with usage of 90-90 interosseous wires and a supplemental K-wire.

in different planes, but perpendicular to the fracture at each position. Screws placed too close to fracture edges may lead to fracture propagation.

Second, the near cortex is overdrilled with a drill size equivalent to or slightly larger than the outer thread diameter of the planned screw. This allows the screw to "glide" through the near cortex as the screw is tightened.

Next, the far cortex is drilled with a smaller drill size equivalent to the core diameter of the planned screw. Tapping may be done at this stage. However, most modern screws are self-tapping.

Next, the near cortex is countersunk. This increases the contact area of the screw head on the near cortex, thus distributing the forces more evenly and avoiding the high contact pressure that may lead to fracture propagation from the drill site into the fracture site. Countersinking also decreases the prominence of the screw head, decreasing irritation of the overlying soft tissues.

Finally, the screw length is measured with a depth gauge and the appropriate length screw is inserted. Visible compression across the fracture site is frequently observed. Care should be taken to avoid overcompression.

Lagging by design may be achieved by utilizing specially designed implants. Two types of screws commonly employed are partially threaded screws (Fig. 5.9) and headless compression screws. Partially threaded screws have threads at the

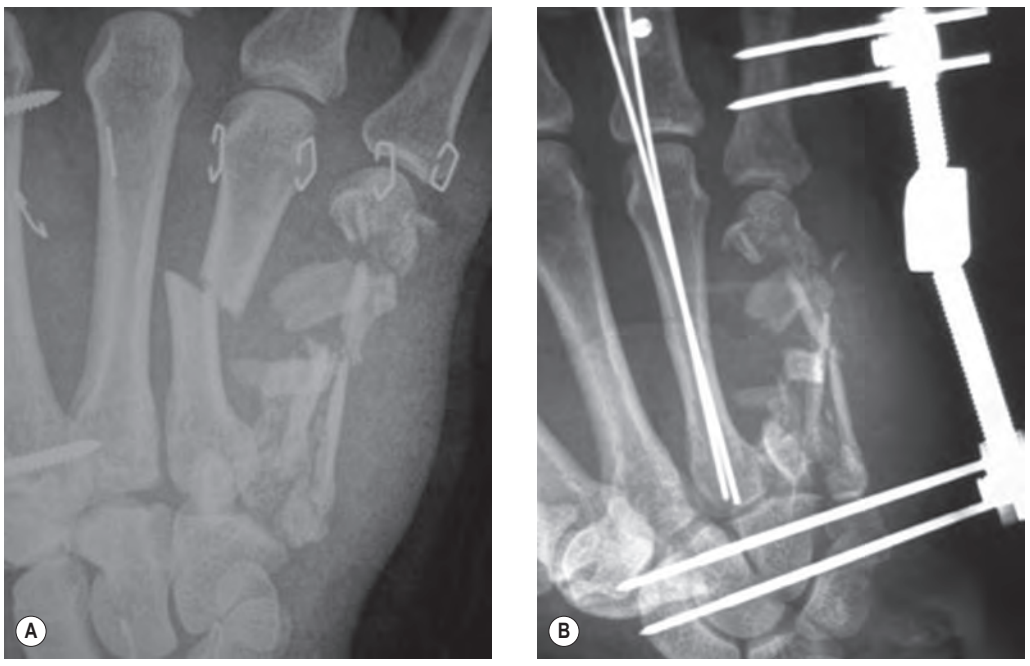

Fig. 5.6 A spanning external fixator has been applied to this highly comminuted 5th metacarpal shaft fracture.

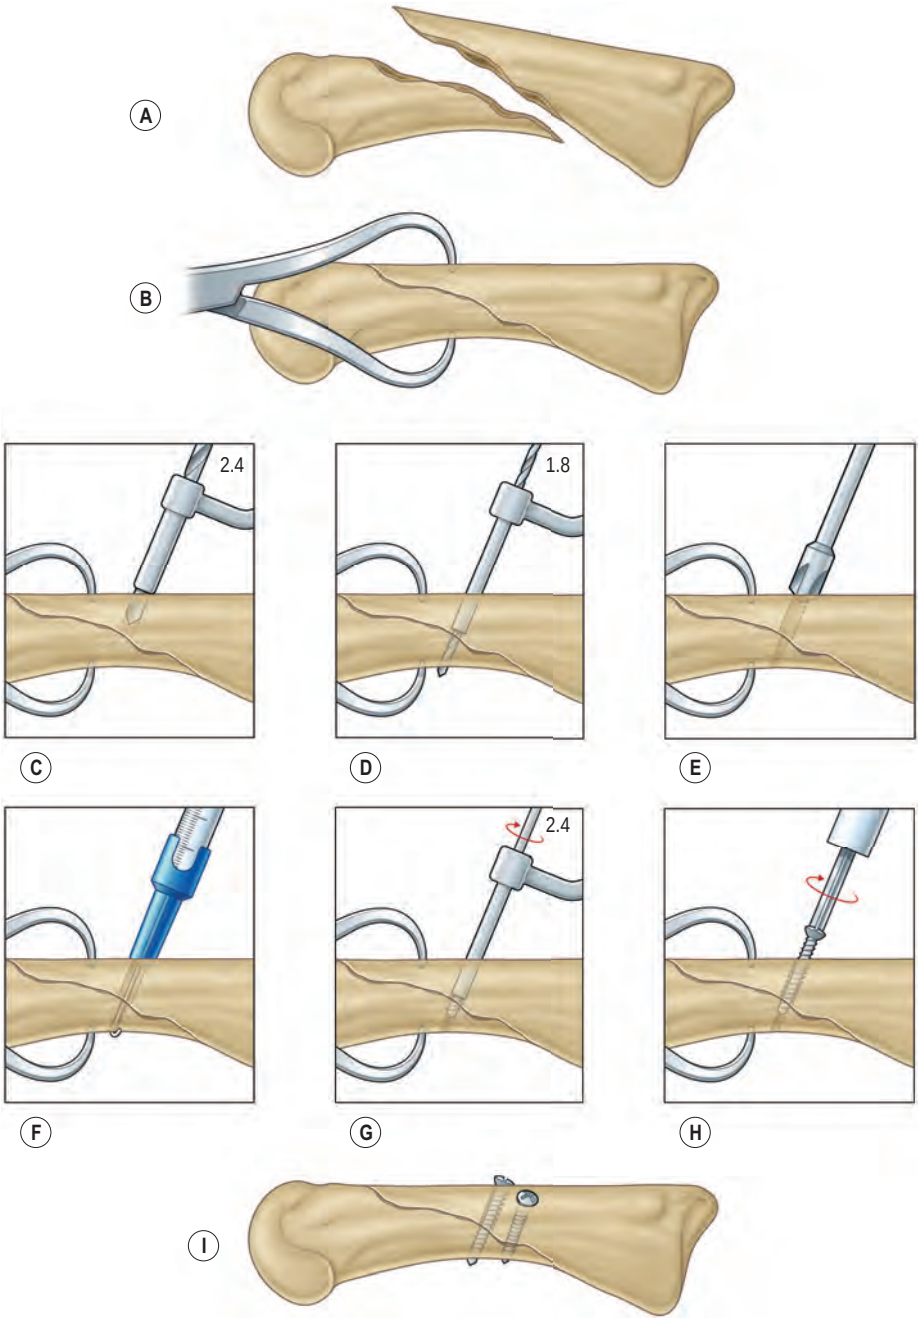

Fig. 5.7 Lag screw technique. A long oblique metacarpal fracture (**A**) is reduced and secured with a pointed reduction forceps. (**B**) A glide hole is drilled perpendicular to the fracture in the near cortex with a 2.4 mm drill bit. A drill guide is used to protect adjacent soft tissue and to prevent skating of the drill bit on the bone. (**C**) The opposite end of this double-ended drill guide inserts into the 2.4 mm gliding hole. It has an internal diameter of 1.8 mm. A concentric 1.8 mm core hole is drilled in the opposite cortex (**D**). A countersink fashions an area in the proximal half of the dorsal cortex to correspond to and seat the screw head (**E**). A depth gauge determines the appropriate screw length (**F**). A 2.4 mm tap threads the core hole of the opposite cortex (**G**). A tap sleeve is used to protect the adjacent soft tissues. (This step may be omitted for self-tapping screws.) A 2.4 mm screw is inserted. As the screw glides through the proximal hole, its head engages the proximal cortex (**H**). A second screw is applied in a manner similar to the first but in a plane perpendicular to the long metacarpal axis, thus satisfying the need for a neutralization screw (**I**). *(Redrawn after Freeland AE.* Hand Fractures: Repair, Reconstruction and Rehabilitation*. Philadelphia: Churchill Livingstone; 2000:42.)*

tip of the screw but no threads below the screw head that allows the screw to glide through the near cortex. They may be placed after drilling bicortically with the core-diameter drill and then placing the screw, which saves time intraoperatively. The utility of partially threaded screws may be limited by the relatively large size of the implant in many regions of the hand and wrist. Another type of compression screw is the headless compression screw (Fig. 5.10 and Video 5.2 ▶). This screw has threads of varying pitches. The threads with greater pitch within one fragment lead to more travel per turn within that fragment compared to the finer pitch threads in the other fragment (Fig. 5.11). Thus, compression is achieved as the screw is advanced (Fig. 5.10 and see Video 5.2 ▶).

Compression plating

Compression plating is a method of obtaining absolute stability and interfragmentary compression through a specific method of plate application. This particular plating method is typically employed for oblique or transverse fractures.

For transverse fractures (Fig. 5.12), the fracture is provisionally reduced and the plate is affixed to one side of the fracture in a neutralization fashion (holes drilled centrally within the screw holes of the plate). Next, a hole is drilled eccentrically (the portion of screw hole farthest away from the fracture) on the opposite side of the fracture. As the screw head engages the plate, it slides down the incline of the screw hole in the plate, thus causing the screw/plate interface to

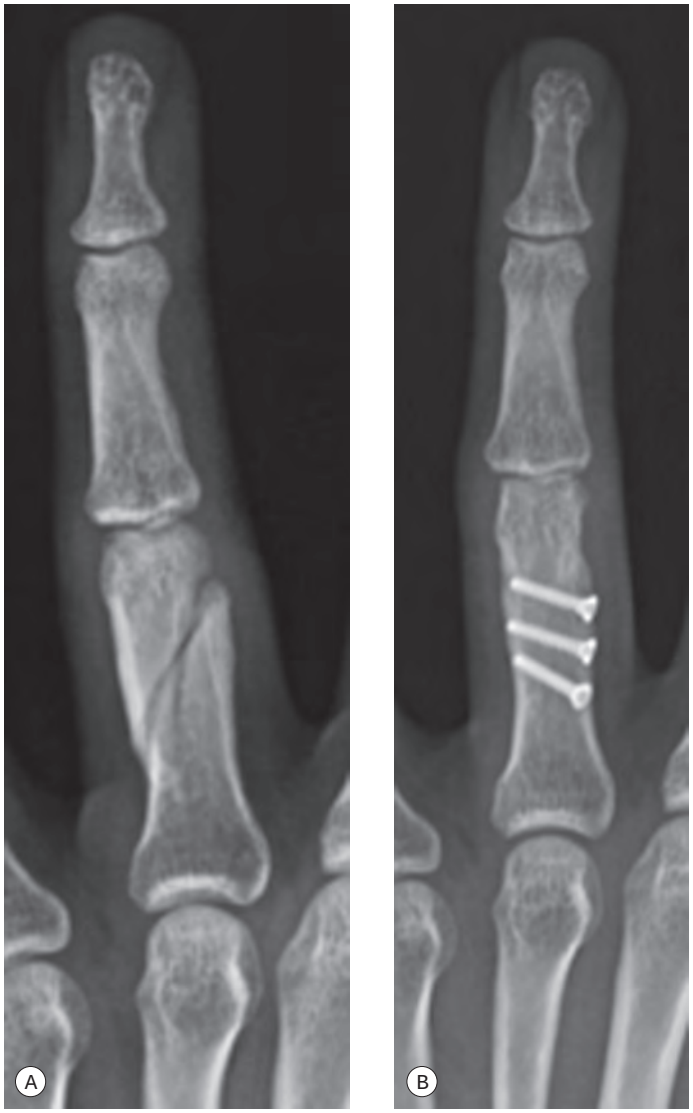

Fig. 5.8 This 34-year-old woman sustained an oblique fracture of the ring finger proximal phalanx. Absolute stability was achieved through usage of multiple lag screws. Note that the screws are placed in different planes, but perpendicular to the fracture at each site.

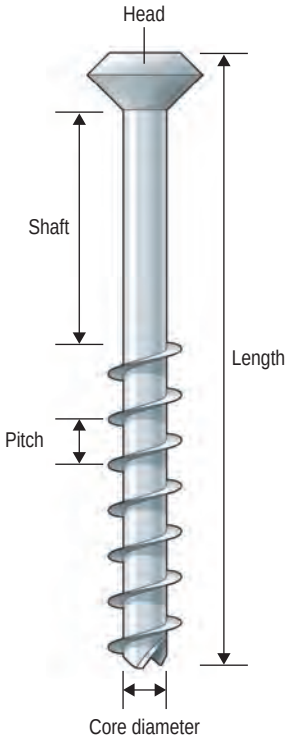

Fig. 5.9 Anatomy of a partially threaded screw.

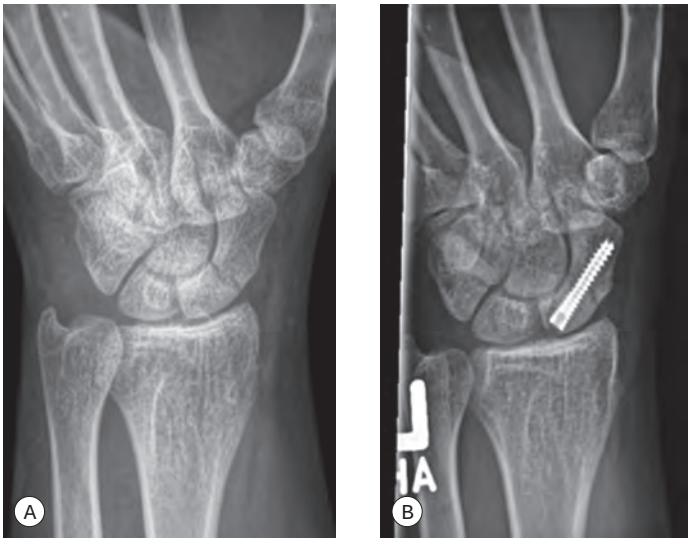

Fig. 5.10 A 20-year-old woman fell onto her wrist and sustained a left scaphoid fracture. A headless compression screw is used for fixation. This device allows for interfragmentary compression while avoiding screw-head prominence when treating intra-articular fractures.

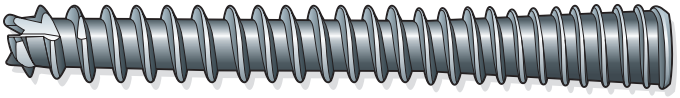

Fig. 5.11 Headless compression screw. Headless compression screws have threads with variable pitch so that the screw advances at a different rate in the proximal and distal bone fragments as the screw is advanced. This achieves compression at the fracture site without the prominence of a screw head at an articular surface.

translate toward the fracture site, leading to interfragmentary compression.

In oblique fractures (Fig. 5.13), the plate should be affixed first to the side of the fracture that allows for an acute angle (or axilla) to be created between the undersurface of the plate and the fragment. This allows for the second fragment to be compressed into the axilla, thus entrapping the fragment and assisting with reduction and compression. If the opposite sequence was done and an obtuse angle was created, further compression would lead to shortening and displacement of the fracture. An angled lag screw through the plate placed perpendicular to the fracture may be added to provide further interfragmentary compression.

Bridge plating

Bridge plating (Fig. 5.14) is a useful method of relative stability for stabilization of comminuted metaphyseal and

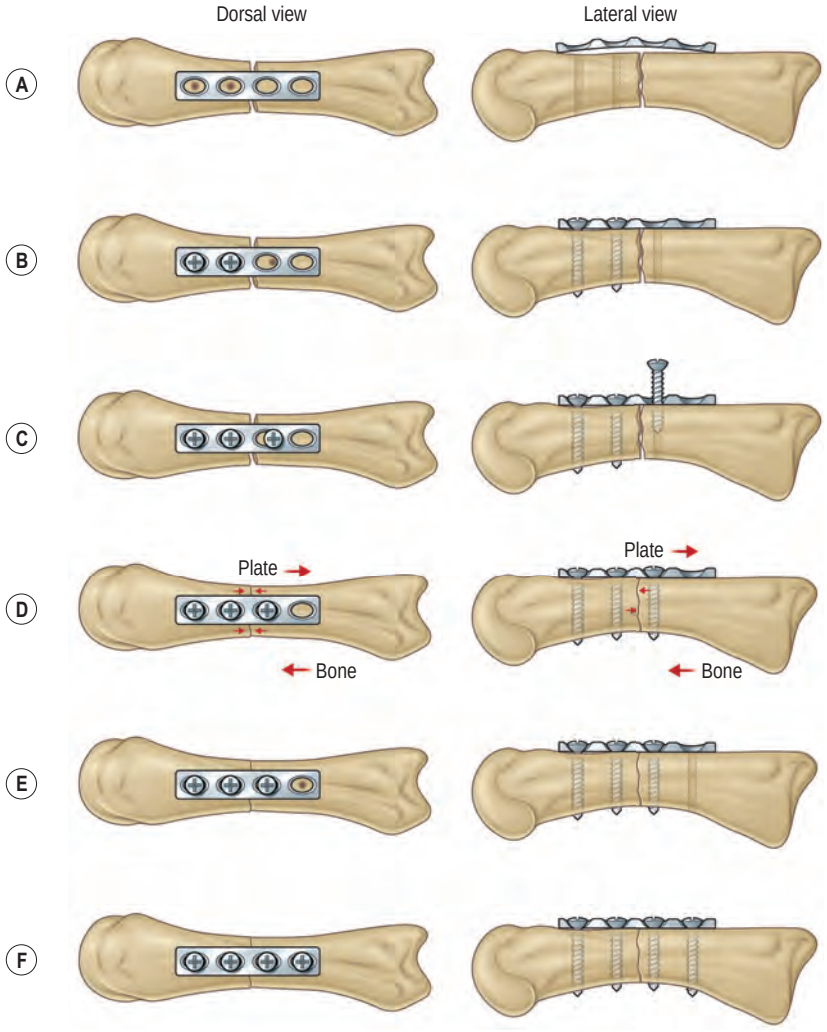

Fig. 5.12 Compression plate. This illustration demonstrates the application of a mini compression plate to a reduced transverse fracture of the mid-metacarpal shaft. The straight miniplate has a graduated bend of about 5 degrees centered at the middle of the plate. (**A**) Two neutral (centered) screws secure the plate to the left (distal) of the fracture. (**B**) A drill hole is placed eccentrically away from the fracture site in the first plate hole to the right of the fracture. (**C**) A screw is inserted in the eccentric drill hole. (**D**) As the screw is tightened and the screw head engages the plate, translation of the plate and bone in opposite directions causes compression at the fracture site. (**E**) After compression is obtained, a neutral drill hole is centered in the remaining plate holes. If further compression is desired a second offset hole may be used instead. (**F**) A neutral screw is inserted, completing the fixation. *(Redrawn from Freeland AE.* Hand Fractures: Repair, Reconstruction and Rehabilitation*. Philadelphia: Churchill Livingstone; 2000:53).*

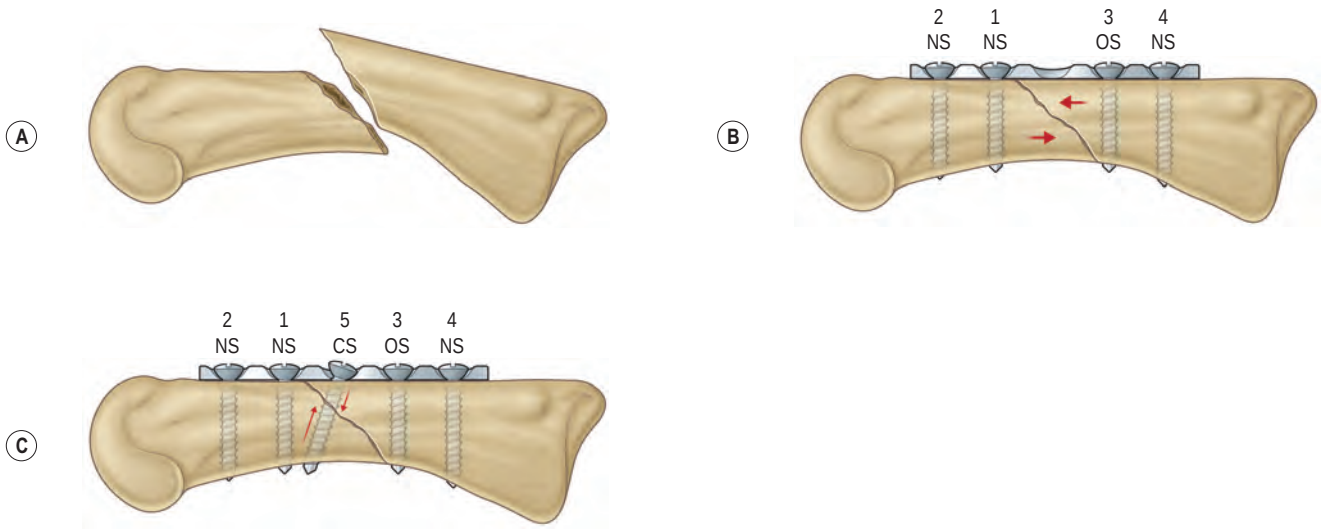

Fig. 5.13 Compression plate – compression screw (CS) within the plate. (**A**) Lateral view of a short oblique mid-diaphyseal metacarpal fracture in the coronal plane. (**B**) The fracture is reduced and a tension band plate is applied, compressing the fracture. It is essential to place the offset mini compression screw (OS) eccentrically away from the triangle of bone that is compressed into the "axilla" of the miniplate. (**C**) A large screw is placed across the fracture site, adding compression and stability. *(Redrawn from Freeland AE.* Hand Fractures: Repair, Reconstruction and Rehabilitation*. Philadelphia: Churchill Livingstone; 2000:55).*

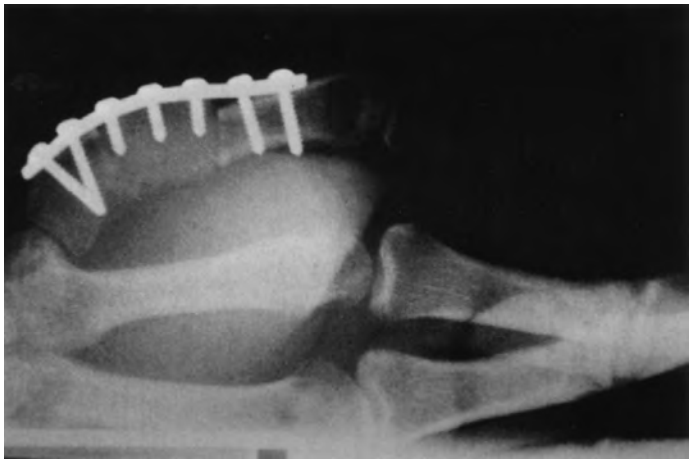

Fig. 5.14 Bridge plate. A complicated fracture in the first metacarpal with comminution and bone loss has been excised and filled with an autogenous graft. This plate provides a modicum of compression and screws through it further stabilize the graft. *(Reproduced with permission from Freeland AE, Jabaley ME, Hughes JL.* Stable Fixation of the Hand and Wrist*. New York: Springer-Verlag; 1986:248.)*

diaphyseal fractures where anatomic reduction is either not possible or would require extensive dissection.[33] Ideally, the fracture site should not be opened with this technique to avoid unnecessary surgical trauma to the surrounding soft tissues and allow for the preservation of vascularity to the comminuted fragments. Bridge plates are used in a similar manner to that of an external fixator. The principal goal is to restore length, alignment, and rotation of the proximal and distal articular surfaces. Healing is indirect via callus formation. Alternatively, if inadequate bone is thought to be present to allow healing, this technique may be supplemented with a staged bone grafting procedure to stimulate healing.

Locked plating

Locking plates allow for the creation of angular stable constructs to share load across a healing fracture (see Video 5.3 ▶). Special threads on the screw heads themselves allow for interdigitation with threads located within the screw hole of the plate. The resultant angular stable construct is no longer reliant on screw thread purchase within bone and may present an advantage in osteoporotic bone or in low-density metaphyseal bone. Failure of this construct is not at the screw/plate interface, but rather would represent catastrophic failure of the entire construct from the bone. Furthermore, because purchase within the far cortex is not mandatory, screws may be used in a unicortical fashion, thus avoiding soft-tissue irritation in the tissues overlying the far side of the fracture.

Locked plates may be applied in a variety of methods, depending on the particular fracture pattern. Compression, if desired, may be achieved through lag screws (either outside or through the plate) or usage of non-locked eccentrically placed compression screws (depending on plate selected).

Postoperative care

Immobilization following fracture fixation may be done for several reasons including: need to protect the soft tissues during initial wound healing, desire to mitigate the possibility of secondary loss of reduction, and as treatment for associated injuries in the polytrauma patient. Immobilization, however, is not without risks. Certain joints, such as the proximal interphalangeal joints of the fingers and the elbow, are notoriously prone to problematic stiffness following immobilization.

Joint immobilization following fracture fixation may result in increased stiffness due to either tendon adhesions or capsular contraction. In the setting of articular fractures, unwanted alterations in cartilage physiology occur with immobilization. Several studies have showed a protective effect of early motion on cartilage following articular injury.[34,35] Furthermore, some degree of micromotion across the fracture site may be beneficial for fracture healing, as illustrated in the examples of bridge plating and external fixation. This micromotion facilitates callous formation through the secondary bone healing pathway.

Where possible, fixation should be stable enough to allow for early postoperative motion without allowing unintended motion across the fracture site. The decision whether to add supplemental splint or cast immobilization following fracture fixation should consider the need for soft-tissue protection, level of stability achieved, and presence of associated injuries.

Summary

The hand surgeon must be familiar with various aspects of proper fracture care and fixation. Decisions regarding optimal treatment rely heavily on careful consideration of patient related factors and on a detailed analysis of fracture morphology. Once operative management is chosen, a myriad of options are available. Comprehensive preoperative planning should be done to shorten operative times and ensure that adequate instrumentation is available. The type of stability desired, planned operative sequence, and desired implants should all be included in the preoperative plan. A thorough understanding of the key concepts underlying proper operative fracture care aids the hand surgeon in optimizing surgical outcomes.

The fingertip, nail plate and nail bed: Anatomy, repair, and reconstruction

Brian Mailey and Michael W. Neumeister

SYNOPSIS

- Fingertip and nail bed injuries are the most common injuries of the hand.
- Large subungual hematomas should be drained to relieve pressure and pain; small and asymptomatic hematomas (<50%) can be observed; trephination of a subungual hematoma is performed to relieve the throbbing pain associated with this injury.
- When the nail plate is intact, not all nail bed lacerations need to be repaired.
- Common secondary nail deformities seen after nail bed injury include nail ridging, splitting, nonadherence, absence, cornified nail bed, hook nails and spikes, or nail cysts.
- Knowledge of the anatomic arterial branching patterns of the fingertip allows creation of flaps to preserve length after distal fingertip amputation injuries, including the volar and lateral V–Y advancement flaps.
- In the appropriate patient, subungual melanoma *in situ* can be safely treated without amputation.
- The purpose of the current chapter is to provide the reader with a comprehensive review of the pathophysiology, diagnosis, and treatment of nail and fingertip injuries and their management.

Introduction

The fingertip serves many functions in our everyday interactions with the world. The sensation provided by the complex unit of the highly specialized immobile, glabrous skin and soft tissue pulp with the rigidity and counter pressure created by the distal phalanx, nail plate and nail bed produces tactile feedback allowing detailed sensation, proprioception, and fine object manipulation. The perionychium consists of the nail bed, nail fold, eponychium, paronychium and hyponychium. Embryologically, these structures develop near the end of the first trimester[1] as a thickened area of epidermis on the dorsal distal phalanx of each finger and toe that proximally invades the underlying dermis to form the nail groove. The deep layer of epidermal cells proliferates to form the nail matrix. Cells within the superficial layer of the nail matrix differentiate into hard keratin, forming the nail. At approximately 14 weeks, proliferation of the deeper layers of the nail matrix pushes the nail distally across the nail bed while firm attachment is maintained between the nail and nail bed.[2] Folds of epidermis lateral and proximal to the developing nail form the nail folds. Nails reach the tips of the fingers and toes at about 32 and 36 weeks of intrauterine life, respectively.[3]

Anatomy

Surface anatomy

The topography of the nail was first described by Zaias in 1963.[4] In this landmark study, fingers and toes of human embryos from 9-weeks to full term were sectioned and examined; and the development of the human nail was detailed. This paper began to clarify terminology of nail structures and embryology with a glossary of various fingernail structures. Later, in 1980, a standardized nomenclature for the anatomy of the nail was proposed by Zook *et al*.[5] to improve communication between physicians regarding nail pathology, injury, and treatment (Fig. 6.1A,B). The entire nail structure, including the nail fold, paronychium, hyponychium, nail bed (germinal and sterile matrices), and nail, is referred to as the perionychium. The paronychium refers to the lateral skin surrounding the nail bed and nail. The skin over the dorsum of the nail fold is referred to as the nail wall. Extension of the nail wall distally onto the dorsum of the nail forms the eponychium. The eponychium is attached to the nail by a cornified material known as the nail vest, or cuticle. The white, convex opacity extending distally from beneath the eponychium is the lunula, which is the distal visible extent of the germinal matrix. The white color remains after removal of the nail and is thought to be secondary to retention of nuclei of the germinal cells to this level in the nail. The mass of

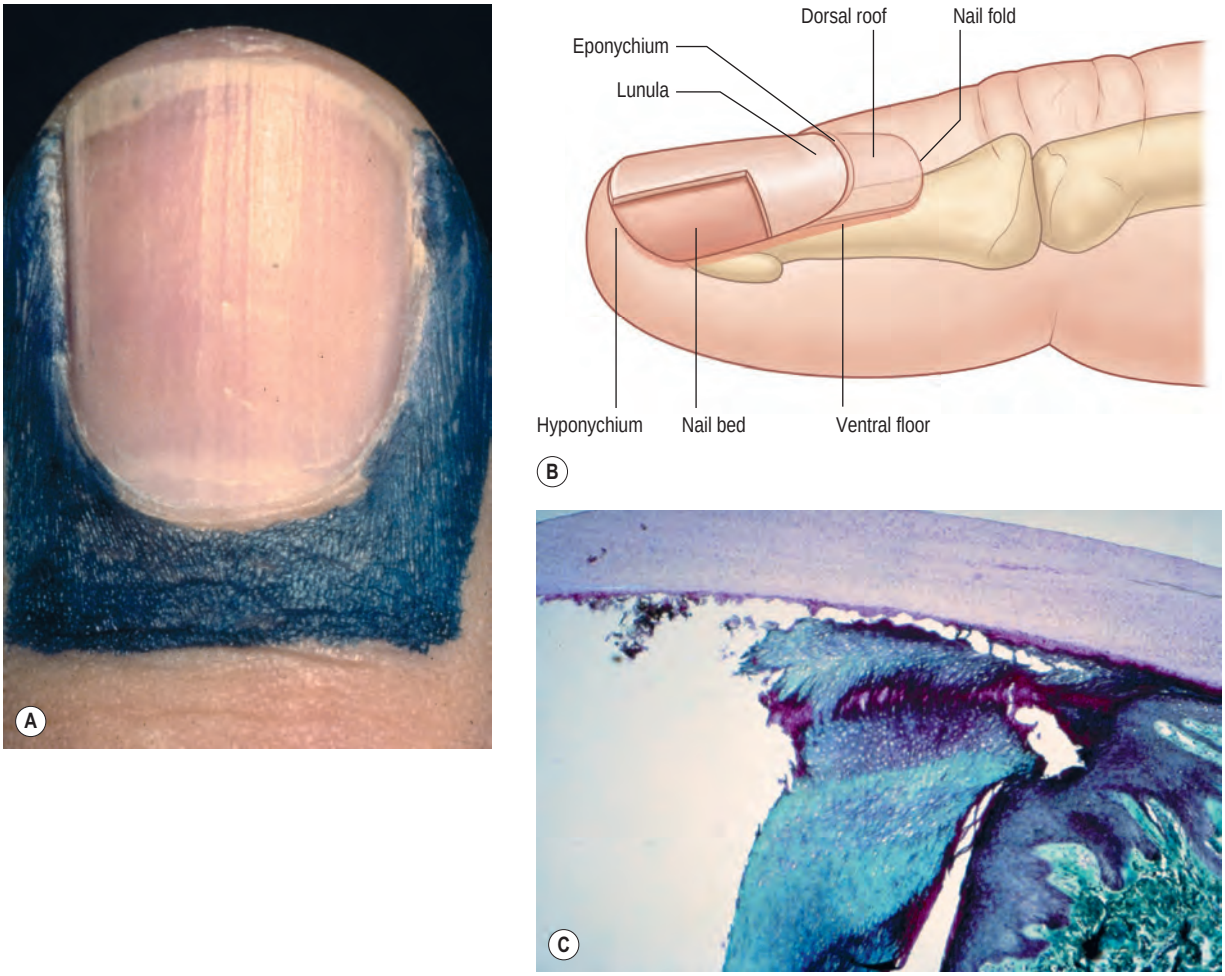

Fig. 6.1 **(A)** The nail, the sterile and germinal matrices, and the surrounding tissue marked in blue compose the perionychium. **(B)** A lateral view of the nail bed showing the ventral floor (germinal matrix), the nail bed (sterile matrix), and the dorsal roof of the nail fold. **(C)** Histologic section of the keratinous plug at the hyponychium. *(© Southern Illinois University School of Medicine.)*

keratin beneath the distal aspect of the nail and at the distal edge of the nail bed is the hyponychium (Fig. 6.1C), which forms from a thickening of stratum intermedium known in the embryo as the distal ridge.

The nail bed consists of the germinal and sterile matrices. The germinal matrix makes up the ventral floor of the proximal nail fold. The sterile matrix consists of the soft tissue immediately beneath the nail distal to the germinal matrix.

Vascularity

The nail unit is supplied by branches of the common volar digital arteries. As described by Flint,[6] the digital arteries form three arterial anastomoses over the dorsal surface of the distal phalanx. A superficial arcade supplies the nail fold, and proximal and distal arcades wrap around the waist of the distal phalanx to supply the sterile matrix and the pulp space. On dissection of 10 amputated digits, Zook *et al*.[5] found two consistent dorsal arterial branches of the digital arteries. The first branch was seen at the base of the nail fold and the second branch at the level of the lunula. Venous drainage of the perionychium coalesces laterally and dorsally, proximal to the nail fold, drains in a random fashion over the dorsum of the digit, and becomes large enough for vessel anastomosis at the level of the distal interphalangeal joint.[7]

Lymphatics roughly parallel the veins and are most numerous at the free edge of the nail (hyponychium). The density of hyponychial lymphatics is greater than in any other dermal area of the body.[8] This explains the low subungual infection rate, considering the heavy exposure of the hyponychial region to pathogenic organisms with use of the nails and fingertips to scratch frequently contaminated areas.

Knowledge of the anatomic arterial branching patterns allows creation of fingertip flaps to preserve length after distal fingertip amputation injuries. These local flaps will be discussed in detail later in the chapter.

Nerve supply

The common volar digital nerves branch dorsally, just distal to the distal interphalangeal joint, to supply the perionychium. Zook *et al*.[5] reported the most common distribution of branching (70%) to be a proximal fascicle into the deep nail bed at the level of the lunula and a distal branch to the hyponychial area. Wilgis and Maxwell[9] reported innervation by three nerve

branches including two dorsal branches, as well as a branch to the pulp.

Physiology

The hard and elastic structure of the nail plate is produced continuously by the nail matrix. The nail is transparent, however appears pink due to the presence of vessels of the underlying nail bed. Keratinization of nail matrix cells occurs along an oblique axis. As a result, the proximal part of nail matrix produces the dorsal portion of the nail plate and, when damaged, gives rise to the development of nail plate surface abnormalities, whereas the distal part of nail matrix produces the ventral portion of the nail plate.[9] The nail plate is firmly attached to the nail bed and it detaches at the hyponychium, where its color becomes white due to the presence of air underneath.

Nail growth continues throughout life. The speed of growth increases with age until 10–14 years, at which point it becomes similar to adults, which averages about 0.1 mm a day,[4,10] and is a rate 4× faster than toenails.[11] The rate of growth changes by season, with growth increased during summer months and by age. Nail growth is twice as rapid before the age of 30 years than after 80 years.[11] Nail growth is also affected by comorbid conditions of the individual, including endocrine, vascular, infectious, and nutritional disorders.[12] The rate of complete nail progression from the nail fold to the free margin has been reported to be between 70 and 140 days.[4] Baden[10] described a 21-day delay in growth after injury, during which time the nail thickens proximally but does not grow distally. Distal growth of a thicker than normal nail proceeds for the next 50 days; followed by growth of a thinner than normal nail for 30 days. Therefore, it is normal for an injury-induced lump to be present on the growing nail. Nail growth is not normal for approximately 100 days after injury. The nail is fixed to underlying tissues by virtue of being a continuous chain of cells from the germinal layer into the nail, each cell attached to the one in front, behind, and beside it.

The nail is produced by cells from three areas of the perionychium: the germinal matrix, the sterile matrix, and the dorsal roof of the nail fold (Fig. 6.2 ◍). The germinal matrix produces the majority of the nail volume (90%) by gradient parakeratosis.[4] The sterile matrix and the dorsal roof of the proximal nail fold produce the remaining nail cells. The sterile matrix adds cells to the volar surface of the nail, accounting for the attachment of the nail to the matrix. The addition of ventral nail during distal growth usually results in a thicker nail distally and compensates for the dorsal wear.[13,14] There are longitudinal ridges in the sterile matrix increasing the surface for attachment and accompany the rich, longitudinally oriented vascularized capillary network. The dorsal roof of the nail fold adds flattened cells to the dorsal surface of the nail, producing the shine of the nail.[15] Loss of the dorsal roof causes a dull-appearing nail. Proximally and laterally, the nail plate is surrounded by the nail folds that are responsible for the protection of the nail matrix.

Fig. 6.2 appears online only.

Function

The function of nails was described in 1724 as "weapons to defend us from trouble … from small creatures, that often make their habitation upon our bodies and to allay the uneasy titillation by scratching".[13] Accordingly, fingernails are used for scratching and in defense. The nail protects the fingertip and contributes to tactile sensation.[16] Counterforce between the nail and the volar skin and pulp aids in delicate and precise touch. Picking up small objects is difficult if the nail is absent. Two-point discrimination will frequently double when the nail is lost. However, incompletely attached or split nails are often painful, especially in individuals who work with their hands and may be worthy of removal in select situations.

Acute injury

Epidemiology

Injury to the fingertip and nail bed is the most common injury of the hand because of its prominent position.[17] The long finger is most commonly injured, followed by the ring, index, small finger and the thumb, with equal frequency bilaterally. The majority of injuries occur between the ages of 4 and 30 years, with 75% occurring in males.[17] Fractures of the distal phalanx are present in 50% of nail bed injuries, and most injuries occur to the middle or distal third of the nail bed.

The mechanism of injury generally constitutes a deforming force, which compresses the nail bed between the nail and the distal phalanx. A subungual hematoma results from injury to the nail bed, causing bleeding beneath the nail. Most commonly injury to the nail bed is a simple laceration (Fig. 6.3A ◍), especially[17] when the object causing the injury is small or sharp. A stellate laceration (Fig. 6.3B) occurs after compression with larger objects causing a bursting injury. Severe crush of the nail bed (Fig. 6.3C) is commonly caused by a wider, greater force of compression. Avulsion injuries (Fig. 6.3D) are the least common.[17]

Fig. 6.3 appears online only.

Subungual hematoma

Subungual hematoma formation causes separation of the nail from the nail bed. The pressure of bleeding in this closed space frequently results in throbbing pain. Hematoma drainage is thus indicated for pain relief.

Treatment

Drainage is performed with a heated (red-hot), sterile paper clip, battery-operated cautery,18-gauge needle,[18] or 2-mm punch biopsy[19,20] or in children, an insulin-syringe needle may be used.[21] The heated object burns a hole through the nail and is cooled by the underlying hematoma. The hole is made large enough to ensure prolonged drainage of the hematoma. A small hematoma will be incorporated into the nail and travel distally with nail growth. The decision to perform trephination is made by the size of hematoma and symptoms; not all hematomas require drainage.

The extent of underlying nail bed injury is difficult to assess with a subungual hematoma. Some advocate the use of ultrasound to detect nail bed injuries.[22] If there is minimal disruption of the nail bed, normal nail growth is expected. However, if a significant disruption of the nail bed is present, there is higher risk of nail deformity if the nail bed is not repaired.

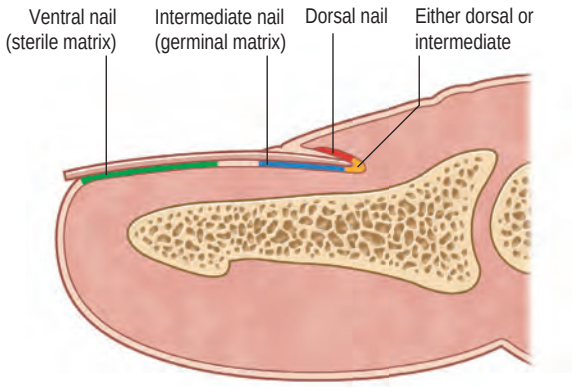

Fig. 6.2 Components of the nail are produced in three areas. *(© Southern Illinois University School of Medicine.)*

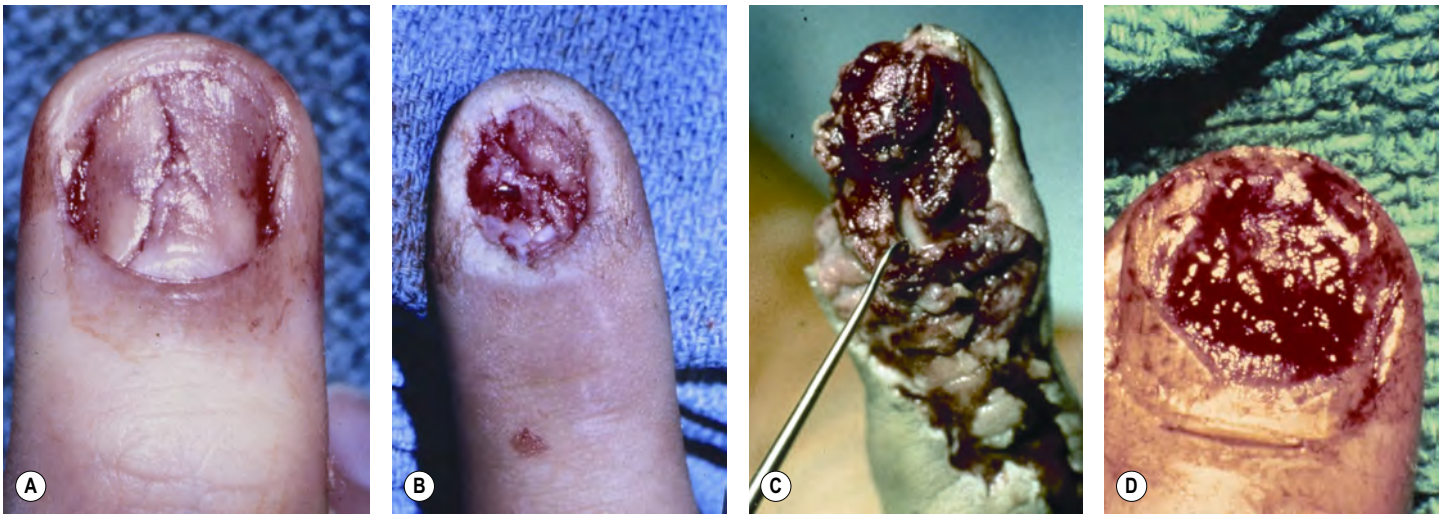

Fig. 6.3 Of nail bed injuries: **(A)** 36% are classified as simple lacerations; **(B)** 27% as stellate lacerations; **(C)** 22% as crushing injuries of the nail bed; **(D)** 15% as avulsions of the germinal or sterile matrix. *(© Southern Illinois University School of Medicine.)*

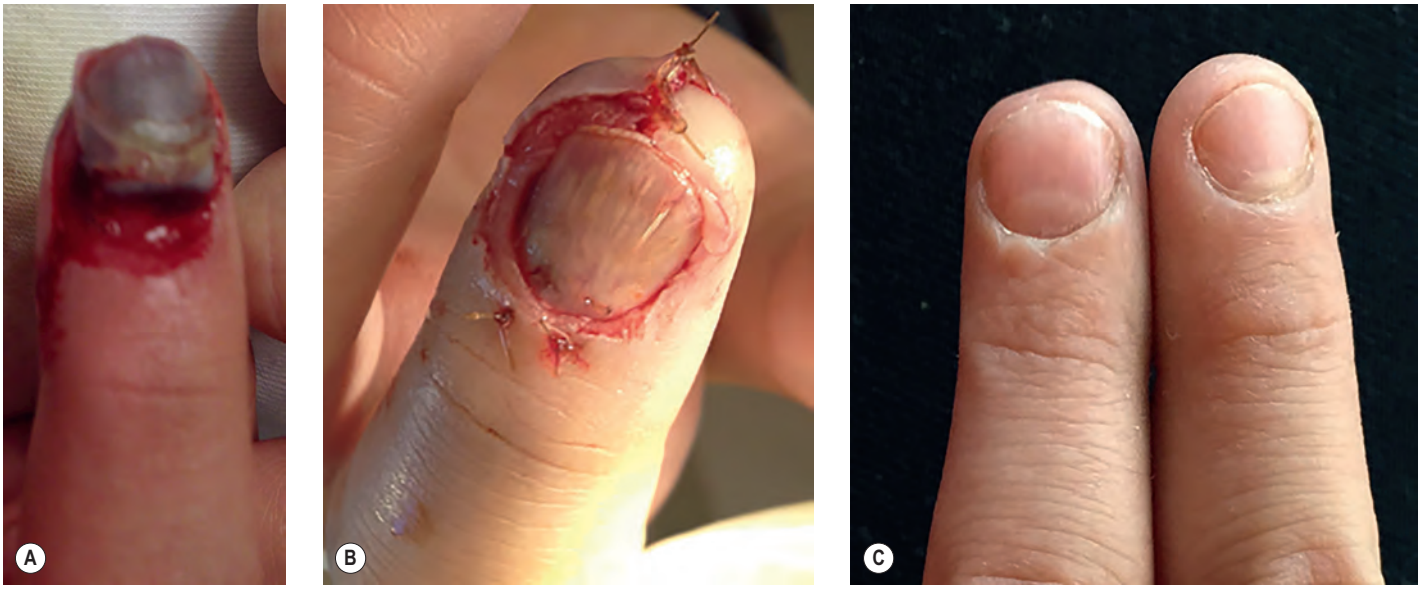

Fig. 6.4 11-year-old male crushed his left index finger in a fence and suffered **(A)** an avulsion injury of the nail plate with a stellate laceration of the nail bed in the sterile matrix with an intact germinal matrix. **(B)** The nail was taken off with a Freer elevator, the nail bed and hyponychium were repaired and the nail plate replaced. **(C)** 4 months after injury and repair (left index finger) compared to the uninjured right index fingernail.

Therefore, whether a subungual hematoma should be drained with the nail left intact or the nail removed and the nail bed repaired is debatable. In the past, removal of the nail for inspection of the nail bed with repair, as needed, was advocated for hematomas undermining more than 25% of the nail. Simon and Wolgin[23] examined the nail beds of 47 patients presenting to the emergency department with a subungual hematoma and found that a hematoma >50% had a 60% incidence of laceration requiring repair. Repair of the nail bed was advocated with a hematoma >50% and an associated distal phalanx fracture. At the University of Pittsburgh, a 2-year prospective, observational study was designed to examine the outcome of 48 patients with subungual hematomas treated with drainage alone. No complications of nail deformity were found with this treatment, regardless of the size of hematoma or presence of fracture.[24] Roser and Gellman[25] compared three treatment groups in a prospective study of 52 children with subungual hematomas. A total of 26 fingers were treated with nail removal and repair of the nail bed. Drainage only was performed in 11 fingers, and 16 of 27 fingers were observed. No notable difference in outcome was found between the groups, regardless of hematoma size. It was concluded that nail removal and nail bed exploration are not justified in children with subungual hematoma with an intact nail and nail margin. A systemic review in 2012 evaluated four articles comparing nail bed repair with simple decompression and concluded the outcome of nail cosmesis did not differ by the mode of treatment.[26] Leaving the nail in place is recommended for most subungual hematomas with an intact nail. Exceptions may include children or patients with concern for an optimally aesthetic nail. If the nail is broken or the edge disrupted, removal of the nail and exploration of the nail bed are advised (Fig. 6.4). The acutely painful subungual hematoma should be decompressed, whether done by trephination or nail removal.

Hints and tips

Nail bed repair

The nail bed handles like wet tissue paper; each suture should be thrown with two bites. Be conservative with the placement of sutures. The goal is simple – re-approximation. Tension on the nail bed suture line will lead to excessive scarring.

Lacerations

Avulsion of the nail, or nonadherence of the nail to the nail bed, is an indication for nail removal. Any loose nail should be trimmed and only enough of the nail that allows adequate exposure and repair of the nail bed laceration should be removed. Complete removal of the nail is not always necessary. With middle to distal nail bed injuries, it may be possible to leave the proximal nail undisturbed within the nail fold.

Treatment

Exploration of the nail bed is performed with digital block, anesthesia, and tourniquet (e.g., a half-inch Penrose drain or cut-out from a sterile glove). The nail plate is gently removed from the nail bed with a small periosteal elevator or iris scissors. Careful removal of the nail is important to avoid further injury to the nail bed. Once removed, the nail is scraped to remove residual soft tissue, then soaked in povidone-iodine (Betadine) solution. The nail bed is examined with loupe magnification. It is better to leave ragged edges and allow the replaced nail to mold the edges than to debride and cause tension on closure. Careful undermining of the edges may assist in reducing tension on closure. A double-armed 7-0 chromic suture on an ophthalmic needle is recommended.

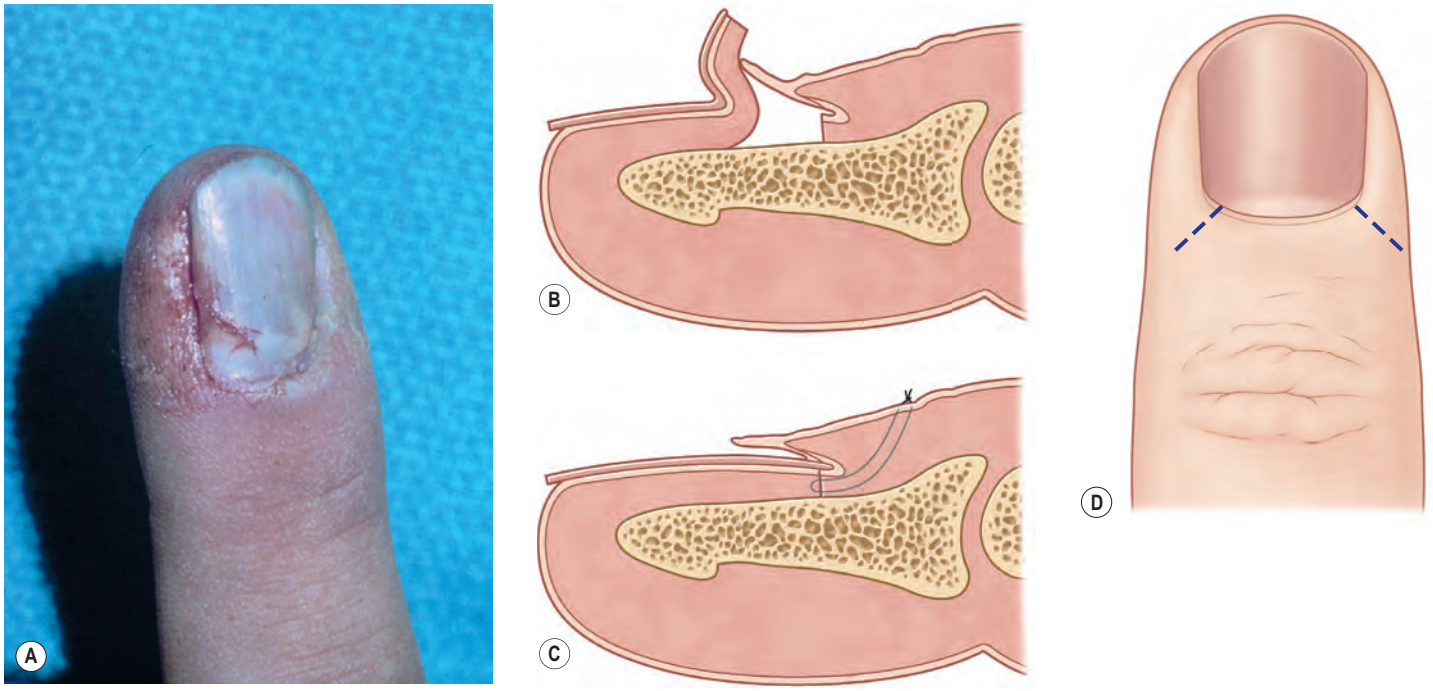

Fig. 6.5 **(A)** When the proximal nail is flipped out of the nail fold and is lying on top of it, one must remove the nail and explore the nail bed. **(B)** There is almost always a nail bed laceration with stripping of the germinal matrix up with the nail or a Salter fracture of the distal phalanx. **(C)** The laceration must be replaced and repaired. **(D)** Radial incisions are made in the eponychium to access the nail fold. It is almost impossible to replace the nail in the nail fold without its total removal and then sliding it back. *(© Southern Illinois University School of Medicine.)*

The suture is cut in half to provide a second stitch because the small needle is commonly bent during the repair.

Re-approximation of the more complex stellate laceration and crush injury is more difficult. In these types of injuries, it may appear to be missing fragments. However, they are often present, attached to the undersurface of the nail. Small fragments should be gently removed with a periosteal elevator and used as a nail bed graft. A split- or full-thickness nail bed graft up to 1 cm in diameter will usually survive, even when it is placed directly on the distal phalanx cortex.[6] Blood supply to the graft is established by inosculation and vascular ingrowth from the periphery.

The scenario with nail bed fragments attached to the nail commonly occurs in avulsion type of injuries. To avoid further insult to the nail bed, leaving the large nail bed fragment on the nail is recommended. The edges of the nail are trimmed a few millimeters to expose the nail bed for suturing into the defect.

Avulsion of the bed often occurs at the level of the germinal matrix and proximal nail fold, leaving a distally based nail bed flap of germinal or sterile matrix (Fig. 6.5A). The nail bed remains attached to the nail, avulsing the germinal matrix off the bone and out of the nail fold (Fig. 6.5B). The nail and germinal matrix must be separated and the germinal matrix replaced and sutured back into the nail fold (Fig. 6.5C). The nail fold is exposed with unilateral or bilateral incisions perpendicular to the lateral corners of the eponychium. The incisions should be made at a 90° angle to the eponychium to prevent a notch deformity (Fig. 6.5D). If the laceration occurs at the junction of the ventral and dorsal roof of the nail fold, suture approximation may not be possible. In this case, a horizontal mattress stitch is placed through the proximal end of the avulsed nail bed and brought out through the nail wall. This will secure the nail bed within the nail fold. The eponychial incisions are then re-approximated with 5-0 or 6-0 nylon after nail bed repair.

Loss of small areas of nail bed may be replaced with split-thickness nail bed grafts from adjacent uninjured nail bed, harvested carefully with a No. 15 scalpel blade (Fig. 6.6A,B). A split-thickness nail bed graft may be harvested from an adjacent noninjured finger (risky) or an amputated finger. A split toenail bed graft may also be used acutely and avoids the possible deformity of an adjacent nail (Fig. 6.6C–H).[27] With exception of the great toe, the nail bed from the other toes are not large enough to supply enough graft for an entire finger nail bed.

On completion of the nail bed repair, the nail is removed from the povidone-iodine solution and a hole made in the nail away from the site of injury. The hole allows drainage of the subungual space after reinsertion of the nail into the nail fold. The nail is placed within the nail fold to mold the edges of the repair, to act as a splint for tuft or phalangeal fractures, to prevent formation of synechiae between the nail fold and the injured nail bed, and to protect the tender fingertip. The nail is held in place with a 5-0 nylon suture placed distally through the nail and hyponychial region. On rare occasions with severe injury to the fingertip, a mattress suture may be placed proximally through the nail fold. If the nail is not available or is in small fragments, a piece of silicone sheeting (reinforced 0.020-inch-thickness silastic) may be shaped to fit beneath the nail fold and secured proximally through the nail fold (Fig. 6.7 ◍). Unlike the nail, the silastic sheet is soft and easily slips from beneath the nail fold if it is secured only distally. Non-adherent gauze may also be placed within the nail fold if no nail or silicone sheet is available.

Fig. 6.7 appears online only.

Fig. 6.7 An example of a stitch in the silicone sheeting to hold it in place. *(© Southern Illinois University School of Medicine.)*

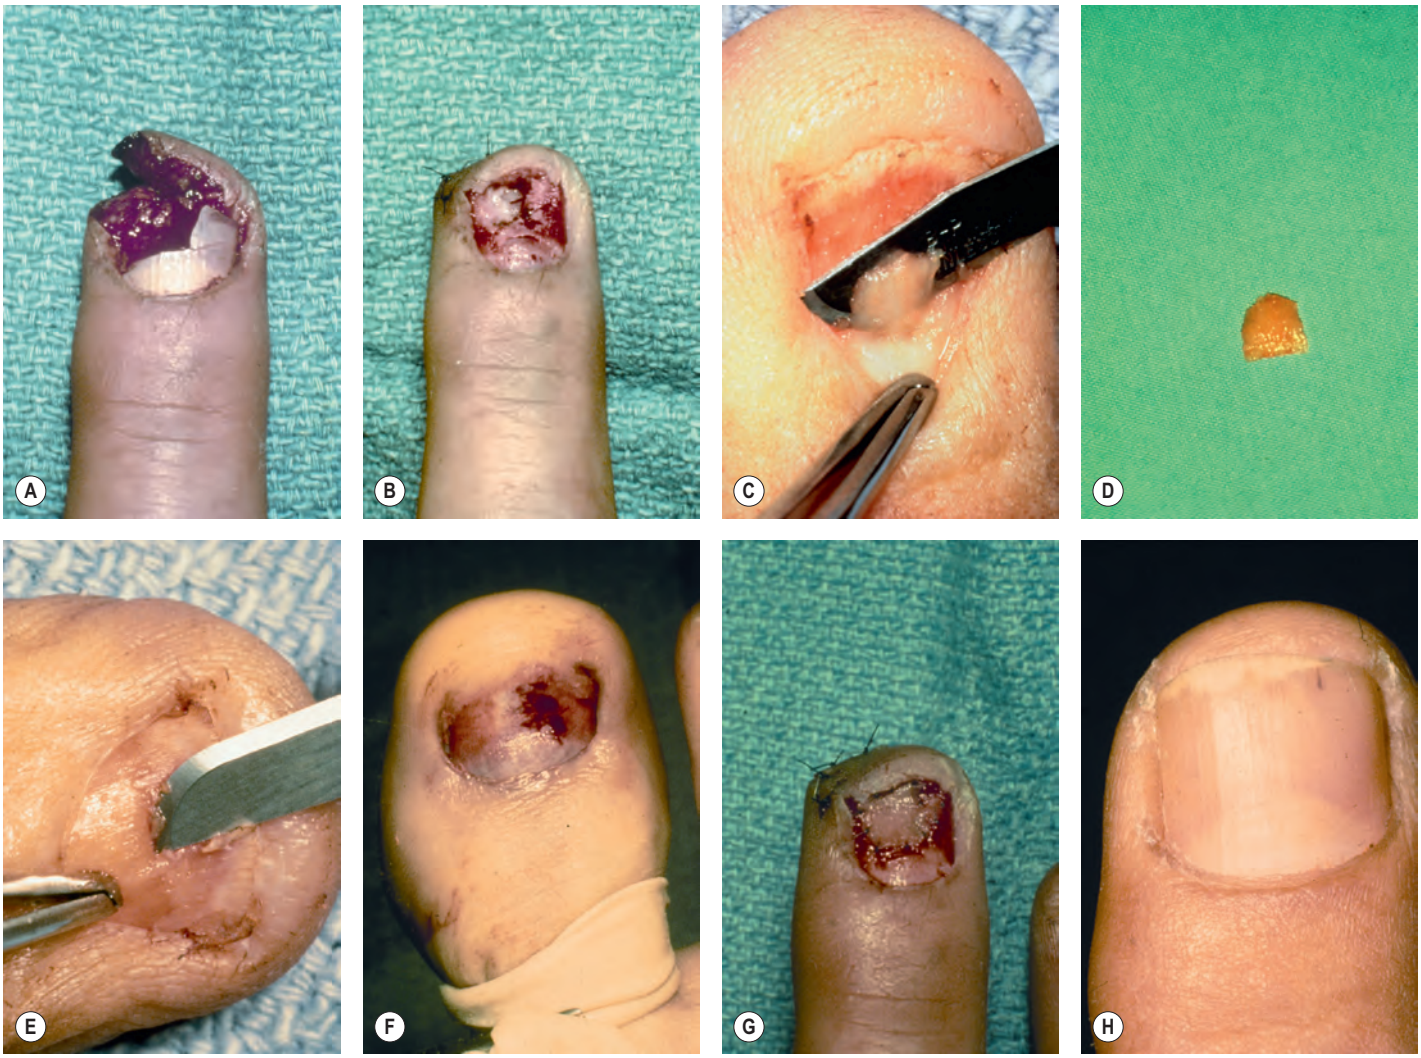

Fig. 6.6 **(A)** A crushing injury to the tip of the finger with laceration of the surrounding skin. **(B)** After the skin is sutured, an area of cortex is seen. **(C)** A split-thickness sterile matrix graft is removed from an adjoining area on the finger or toe. Back-and-forth sawing with a scalpel blade will remove a small fragment of nail bed, which is slightly curved after the nail has been removed. The white line of the sharp edge of the blade should always be able to be seen so that the graft is not taken too thick with a resultant deformity. **(D)** The fragment of nail bed taken. **(E)** If a larger piece of nail bed graft is needed, it may be taken from proximal to distal; the tip of the knife blade is used to dissect up the split-thickness layer of nail bed. **(F)** The large toe after removal of the split-thickness nail bed graft. **(G)** A split-thickness nail bed graft is sutured into place over the periosteum without any manipulation of the cortex. **(H)** One year later, good regrowth of the nail and adherence are shown. *(© Southern Illinois University School of Medicine.)*

Hints and tips

Nail plate replacement

Trim the nail plate of sharp contours. Place the nail plate under the eponychial fold for a distance of 2–3 mm. An absorbable suture can be used to hold the nail plate in place as an alternative to nylon. This will avoid painful suture removal.

Postoperative care

The fingertip is dressed with nonadherent gauze, 2-inch roll gauze, and a four-prong splint to protect the repair. At 3–7 days after repair, the holding suture is removed, especially if it is in the proximal nail fold position. The authors have observed stitch track formation in the nail fold if the stitch is left in place longer than 7–10 days. If not disturbed, the nail will frequently adhere to the nail bed for 1–3 months as the new nail forms beneath. Fingertip tenderness is usually less with the nail replaced.

Distal phalanx fractures

Initial evaluation

Distal phalanx fractures are found in approximately 50% of nail bed injuries and result in a higher incidence of secondary nail deformities.[17] Therefore, multiple-view radiographs of the distal phalanx are recommended. A Seymour fracture presents in children with the appearance of an elongated nail. The fracture occurs through the physis with interposed soft tissue, usually consisting of nail bed matrix but can include other tissues, like eponychial fold.

Treatment

Treatment of nondisplaced distal fractures consists of nail bed repair and replacement of the nail. The nail acts as an excellent splint for the fracture. Small, displaced tuft fractures and most stable distal fractures can be reduced with reapproximation of the nail bed and replacement of the nail. Larger displaced fractures or unstable fractures require longitudinal or cross K-wire fixation. Care must be taken to put the pin in the medullary cavity of the bone. K-wires traversing the nail bed can cause a painful ridging deformity.

Secondary procedures

Reconstruction

The painful non-adherent, split, or hooked nail, may hinder work productivity in the laborer. For others, nail deformities, such as nail ridges, grooves, or absence of the nail may create self-consciousness or an unsightly appearance. Goals for reconstruction should be based on concerns and wishes of the individual patient. Surgical measures often improve function and appearance but often do not produce a normal nail. The best chance for restoring a normal nail is at time of the initial repair.

Most nail deformities are secondary to scarring of the nail bed with subsequent disruption of nail growth. Similar to other scars, it is recommended to wait at least 8–12 months after injury before consideration of reconstruction. With scar remodeling, small nail deformities may resolve significantly or completely. Common secondary nail deformities seen after nail bed injury include nail ridging, splitting, non-adherence, absence, cornified nail bed, hook and spikes, or cysts.

Nail ridge

Nail ridges are secondary to an irregularly healed distal phalanx fracture or scar within the nail bed. Nail ridges may also occur secondary to a K-wire placed between the sterile matrix and the periosteum on reduction of a phalanx fracture (Fig. 6.8). Longitudinal irregularities result in longitudinal ridges or grooves. Transverse irregularities beneath the nail bed result in corresponding transverse grooves or ridges or distal nonadherence. Correction of this deformity requires excision of the scar or irregular bone edge to form a flat, smooth nail bed surface.[6,16] A defect that cannot be reapproximated primarily requires use of a nail bed graft.

Fig. 6.8 appears online only.

Transverse nail ridges may develop secondary to hypoxia from ischemic injury or tourniquet hemostasis. The ridges resolve with correction of the inciting factor and subsequent new nail growth.

Split nail

A split nail is often secondary to longitudinal scarring of the germinal or sterile matrix. Unlike the germinal and sterile matrices, the scar does not produce nail cells, resulting in splitting of the nail. Scar within the germinal matrix can split the nail from its most proximal aspect. Scar within the sterile matrix disrupts the progressive addition of nail cells to the volar nail, leading to detachment of the nail plate (Fig. 6.9). Other causes of split nails include bone spurs beneath the nail bed, eponychial pterygium resulting from failure of the dorsal roof matrix to detach from the nail, and scar formation between the dorsal roof and ventral floor of the nail fold. Although longitudinal splits are most common, a horizontal split has been reported; it caused a diagonal scar in the matrix and formation of a portion of the nail on each side (Fig. 6.10). The nail was produced within both folds, forming a horizontally split nail.

Figs. 6.9 and 6.10 appear online only.

Treatment

Scar must be minimized to allow normal nail production. Scar within the sterile matrix can occasionally be treated with excision and primary closure. The excised defect is frequently too wide to be approximated without tension and requires repair with a split-thickness sterile nail bed graft from the same digit or a toe. In germinal matrix injuries, Johnson[28] recommended releasing incisions in the lateral paronychial folds with bilateral central advancement of the germinal matrix, but our experience with this technique has been disappointing in traumatic deformities. Replacement of germinal matrix with sterile matrix will not be successful because sterile matrix grafts do not produce a nail. Split-thickness germinal matrix grafts also do not produce hard nail growth. The germinal matrix defect requires repair with a full-thickness germinal matrix nail bed graft.[27,29] The second-toe germinal matrix is a good option with its similar shape and size; the large toe is a second choice (Fig. 6.11). The patient is warned that use of the toenail germinal matrix will eliminate hard nail growth on the toe. This second-toe nail defect is frequently more acceptable to patients than a defect of the great toenail. In the case of an existing bone spur, the nail bed is lifted free and the spur is removed with rongeurs to produce a flat surface, and the nail bed is replaced.

Pterygium

Splitting of the nail may also be caused by a pterygium. A pterygium of the eponychium results from adherence of the eponychium or dorsal roof of the nail fold to the nail plate or nail bed during healing. A web between the eponychium and nail bed will result in splitting of the nail as it grows distally from the nail fold (Fig. 6.12).

Fig. 6.12 appears online only.

Treatment

Simple pterygia are amenable to warm water soaks until the eponychium can be bluntly separated from the nail. Sharp dissection of the eponychium from the dorsal nail is performed if blunt dissection is unsuccessful. Separation between the dorsal roof and nail is then maintained with nonadherent gauze or a silastic sheet. This allows epithelialization of the undersurface of the nail fold. If adherence persists between the dorsal roof and the ventral floor (matrix) of the nail fold, it must be divided surgically. Once the nail fold has been redesigned, maintenance of the separation must be achieved with nail, silicone sheet, or gauze until healing occurs. If a large raw surface is present after freeing, a split-thickness sterile matrix graft can be placed on the raw surface of the dorsal roof. If the scar has completely replaced the normal germinal matrix, a full-thickness germinal matrix graft is necessary.

Nonadherence (onycholysis)

Nonadherence of the nail is the most common post-traumatic nail deformity. This occurs secondary to nail bed scarring and is often found immediately distal to transverse or diagonally oriented nail bed scars or bone irregularities. The scar interrupts the progressive addition of nail cells from the sterile matrix to the volar nail plate, causing detachment of the nail. The nail is unable to reattach to the nail bed distally.[30]

Distal nonadherence may lead to problems with subungual hygiene, an unstable nail when picking up small objects, pain from repeated avulsions when catching the nail on objects, or may simply be an aesthetic concern.

Treatment

Nonadherence secondary to a nail bed scar is corrected with scar excision and primary closure or closure with a split-thickness sterile matrix graft from the adjacent nail bed or toenail bed.[30–32]

Malalignment of distal phalanx fractures may cause nonadherence. Prevention begins with accurate alignment of the fracture at initial repair. Secondary deformities caused by bone exostosis, bone angulation, or nonunion will require revision. The exostosis should be removed to form a flat surface for the sterile matrix and subsequent nail adherence. Bone angulation may require osteotomy of the distal phalanx to re-form a flat surface.

Nail absence (anonychia)

Any process, including trauma, infection, and burn, which destroys the nail matrix will lead to an absent nail. Frequently, small nail remnants will remain that can cause other secondary deformities. Nail absence is also rarely seen as a congenital deformity known as anonychia.

Treatment

Free partial and composite nonvascularized nail grafts have been described by McCash[33] and Lille *et al*.[34] for reconstruction of absent nails. Both germinal and sterile matrices are needed for total reconstruction of a nail bed. Zook recommended a full-thickness second-toe germinal and sterile matrix graft to approximate the width of the fingernail. To match the length of the fingernail, a split-thickness sterile matrix graft from another toe is placed distal to the free composite graft. The large toenail is used for thumbnail reconstruction. Results can be unpredictable and at times unsuccessful secondary to nontake or shrinkage of the graft. Patients should be informed of the risk of toenail deformity and a possible suboptimal outcome.

The most reliable and normal-appearing nail is constructed with a free vascularized dorsal tip of the toe.[35–38] This procedure can be technically difficult, requiring microsurgical expertise, and produces scarring of the foot from harvest of the vascular pedicle.

Skin grafts, as opposed to nail bed grafts, have been used with some success to mimic the nail. This method has been advocated for treatment of traumatic nail absence and congenital nail absence in which multiple digits are involved (Fig. 6.13). The scar is excised from the fingertip in the shape of a larger than normal nail (10% larger), and replaced with a similarly shaped split- or full-thickness skin graft. Full-thickness grafts can be placed proximally and distally to simulate a white lunula and hyponychia, respectively. An artificial nail can then be fixed to the healed skin with glue, but patients may have difficulties maintaining the nail in place with glue alone. To aid in nail adherence, Bunke and Gonzales[39] reconstructed the proximal fold using a prosthesis wrapped in split-thickness skin graft and buried it under the dorsal finger skin. Artificial nails were then secured beneath the new fold. Unfortunately, the fold was only temporary and slowly disappeared with time. Baruchin *et al*.[40] described an osseointegrated anchorage device to secure the artificial nail.

Cornified nail bed

With ablation of the germinal matrix, nail production ceases. However, an intact sterile matrix will continue to produce

Fig. 6.13 A nail-shaped split-thickness skin graft is placed on the dorsum of the finger to mimic a nail. *(© Southern Illinois University School of Medicine.)*

varying amounts of keratinous material, resulting in a cornified nail bed.

Treatment

Treatment for a cornified nail bed includes excision of the sterile matrix and replacement with a split-thickness skin graft. Overproduction of keratinous material from the sterile matrix can also occur beneath a nail from chronic repetitive partial avulsion, allowing build-up beneath the distal nail, leading to nonadherence. Treatment includes removal of the nail to a point just proximal to this area of overproduction. The keratinous material is scraped from the nail bed with a scalpel blade. The nail is then able to adhere to the nail bed during distal growth. The process may need to be repeated if overproduction on the exposed nail bed occurs more quickly than nail growth (Fig. 6.14 ◍). Sterile matrix grafts may be necessary if scraping is unsuccessful (Fig. 6.15 ◍).

Figs. 6.14 and 6.15 appear online only.

Nail spikes and cysts

On elimination of the nail bed or amputation of the distal phalanx, care must be taken to excise the germinal matrix completely. Any residual matrix allows continued production of nail cells. These cells produced within a closed space form nail cysts and the cells that are able to grow distally form nail spikes.

Treatment

Treatment consists of complete surgical removal of the cyst or spike along with the residual matrix. These deformities are seen more commonly after revision amputations performed in the emergency department.

Hooked nail

The hooked nail is a nail that hooks volarly during distal growth. This deformity is commonly seen after tight closure of tip amputations. On closure, the nail bed is pulled around the tip of the finger. Healing of a distal amputation site by secondary intention may also pull the nail bed volarly over the tip. Because the growing nail follows the direction of the nail bed, the nail grows in a hooked fashion, curving around the fingertip.

Treatment

This deformity can be avoided during repair of the acute injury by following two rules. The nail bed should never be pulled over the tip of the distal phalanx. If bone support beneath the nail bed is missing, it must be replaced or the nail bed shortened to match the length of the remaining distal phalanx.

Correction of the hooked nail secondary to the distal nail being pulled over the tip comprises release of contracted soft tissue, return of the nail bed to its normal position, and replacement of fingertip soft tissue. A full-thickness skin graft, V–Y advancement flap, cross-finger flap, or proximal thenar crease flap can be used to augment the tip and reposition the nail bed on the dorsum of the distal phalanx.[41] When bony support is missing, the options are either to shorten the nail bed or add bony support to maintain length. Non-vascularized bone grafts have been placed distally with successful initial support of the nail bed. However, they often resorb with time, and the correction is lost.[6] Osteotomy and distraction of the distal phalanx with placement of a bone graft between the distracted segments has been proposed to decrease the incidence of graft resorption but may be technically difficult.

Bubak *et al*.[42] described a repair of a hooked nail deformity using a composite second-toe graft for tip support. A fish-mouth incision is made in the hyponychium and carried proximally on the lateral aspects of the digit until the nail bed is released. An elliptical, transverse wedge of skin and pulp is excised from the second toe and placed beneath the released nail bed. Good results were reported with a 2-year follow-up.

Free vascularized second-toe tip (bone, soft tissue, and nail bed) transfer has been presented as a more permanent yet more complex option.[36]

Eponychial deformities

Eponychial deformities occur as sequelae after trauma, burns, tumor, infection or any process causing direct destruction of the nail fold tissue. As the tissues heal, scar contractures create the final deformity. Loss of eponychium causes more of an aesthetic defect than a functional one. Notching or loss of the eponychium exposes more of the proximal nail and results in loss of nail shine. Despite this change in appearance, there is no effect on nail growth.

Treatment

The three-dimensional structure of the nail fold makes reconstruction difficult. Multiple local rotation flaps have been

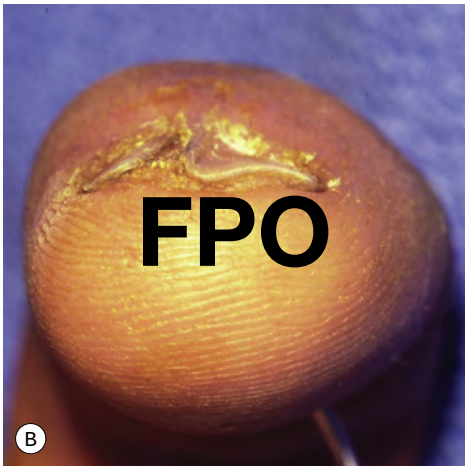

Fig. 6.14 **(A)** Nonadherence of nail to the sterile matrix thought to be due to an episode of pulling the nail free from the nail bed traumatically and then repeated attempts to clean under the nail. The area of nonadherence is marked on the nail. **(B)** That area of nail is removed, showing the hyperkeratinous sterile matrix. described. Reconstruction of a nail fold with both inner and outer surfaces has been described with use of rotation flaps lined with split-thickness skin grafts.[16] Hayes[43] used distally based ulnar finger flaps for creation of the nail fold without reconstruction of the inner surface. Kasai and Ogawa[44] modified Hayes' technique of distally based ulnar finger flaps by using the local tissue to reconstruct the inner surface. The scarred eponychial tissue is incised proximally and turned over distally to form the nail roof. An ulnar, dorsal flap is then raised on a distal base and placed on top of the new roof to form the new eponychium, with split-thickness skin grafting of the donor site. Achauer and Welk[45] described a one-stage reconstruction of the burn-scarred eponychium with dorsal transposition of bilateral proximally based lateral digit flaps.

A composite eponychial graft of skin and dorsal roof from the first or second toe to the eponychial defect is recommended. This eponychial graft has been found to improve appearance and restore the shine to the nail (Fig. 6.16).

The eponychial flap is a technique used for fingertip injuries when the eponychium is intact. This flap lengthens the appearance of the visible nail. It was first presented in 1998 by Bakhach[46] and is indicated for fingertip injuries with a resultant small stump of intact nail and nail bed. The procedure consists of incising the dorsal eponychium with two radial incisions, elevating the dorsal eponychium as a flap and suturing it down in a more proximal location. This can be done at the time of acute injury or as a later reconstructive procedure.[47]

Hyponychial defects

The keratinous plug of the hyponychium may hypertrophy secondary to acute or chronic trauma to the distal nail and hyponychium. When this occurs, it may protrude beyond the nail and cause pain when it is bent or pressed with use of the finger. It may also produce an unsightly protrusion from under the nail (Fig. 6.17 ◍). Loss of the hyponychium results in lack of support of the nail and a hook nail deformity. To prevent hygiene and cosmetic issues, patients must keep their nails trimmed. Alternatively, further shortening of the digit or nail bed ablation would be required.

Fig. 6.17 appears online only.

Treatment

Treatment for the hypertrophic hyponychium requires determination of the inciting activity, which is often something that causes acute or chronic irritation. Initial management consists of avoidance of process producing the pathology. If irritation cannot be avoided or if symptoms persist despite avoidance, excision of the hypertrophic hyponychium and coverage with a split-thickness sterile matrix graft have resulted in a high incidence of symptom relief. The split-thickness sterile matrix graft is carried out in the same manner as with replacement for avulsion of a portion of the sterile matrix or scar excision.

Pigmented lesions

The differential diagnosis for pigmentation of the nail bed is complex; it includes subungual hematoma, foreign body, onychomycosis nigricans, junctional nevi, pyogenic granuloma, paronychia, vascular lesion, melanonychia striata, melanoma *in situ*, and malignant melanoma.[48] Although most pigmented lesions of the nail are benign, they should be evaluated carefully to rule out malignancy.

Patient presentation

The history of the pigmentation is generally the most valuable aspect to making the diagnosis. Trauma may cause bands of pigment, especially in darkly pigmented individuals. Development of pigment in adults, even without a known history of trauma, is often secondary to a subungual hematoma, but the differential diagnosis of malignant melanoma must be considered. These suspicious areas can be monitored by scratching the nail at the proximal and distal edges of the pigment with a scalpel blade or 18-gauge needle (Fig. 6.18).

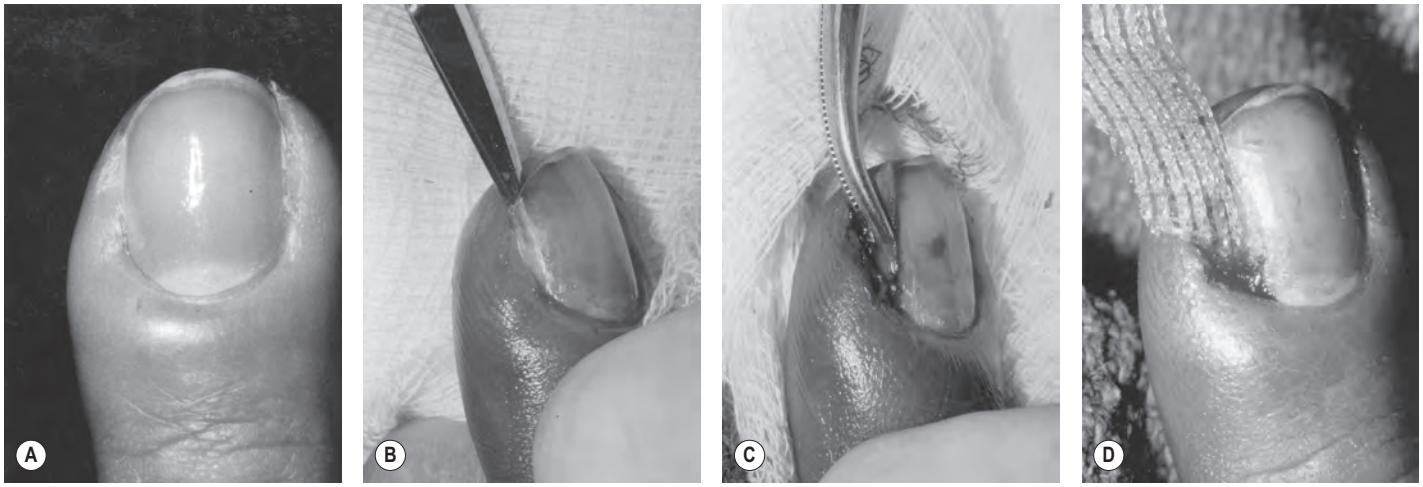

Fig. 6.18 **(A)** A swollen, inflamed paronychium known as a paronychia. **(B)** The side of the nail, which is undermined by the infection, is separated from the nail bed and the lateral aspect of the dorsal roof of the nail fold. **(C)** This fragment of nail is removed, giving adequate drainage to the infection. **(D)** A piece of water-soluble gauze is placed as a drain. *(© Southern Illinois University School of Medicine.)*

Distal migration of pigmentation over 3–4 weeks, together with the scratch marks suggests a hematoma. However, if the scratch marks move distally, away from the pigment, this suggests foreign body, nevus, or melanoma. The evaluation of nail clippings can also provide some diagnostic value.[49] To do this, a sample at least 4 mm in length is required and can be used to diagnose a number of conditions, including melanonychia, subungual hematoma, onychomycosis and others.[49]

Melanonychia striata is defined as any linear tan–brown–black pigment of the nail bed that is carried into the nail as growth occurs. This pigmentation is caused by focal increase in the number or function of melanocytes. Melanonychia striata is common in individuals with darkly pigmented skin but uncommon in those with fair skin (Fig. 6.19).

Subungual nevi produce pigmentation within the nail bed and the ventral nail (Fig. 6.20). These pigmented nevus cells are derived from neural crest cells and are frequently present at birth or shortly thereafter. The nail is frequently pigmented with elevation and ridging (Fig. 6.21).

Fleegler and Zeinowicz[50] recommended nail bed biopsy of dark streaks present at or shortly after birth because of the danger of malignant degeneration at puberty. Melanocytic hyperplasia without atypia can be observed. However, complete excision with reconstruction of the nail bed is advised if atypical cells are found.

Subungual melanoma

Nail melanoma is an infrequent cause of brown–black nail color compared to other melanocytic and nonmelanocytic pigmentations. More common causes of nail discoloration are subungual hematoma, exogenous pigmentations and melanonychia, which are all benign. In a review of 100 patients seen at a dermatology clinic for nail discoloration, 25 required additional evaluation, but only one had a melanocytic pigmentation that required a surgical evaluation.[51] Most lesions can be diagnosed by history alone. The first determination is to decide if the pigment is due to melanin within the nail. This step can help exclude exogenous pigmentations, fungal melanonychia and subungual hematoma. Examining the other digits can reveal racial melanonychia, effects of systemic drugs or pregnancy, endocrine disorders and frictional melanonychia. Next, the appearance of the nail itself can provide diagnostic information, including trauma, psoriasis and nail tumors (onychopapilloma, onychomatricoma, Bowen's disease). Nail clippings can also be used to assist in the diagnosis. Finally, if the diagnosis has not be determined then removal of the nail plate and a histopathologic evaluation of tissue is required.[51]

Subungual melanoma represents only 1–2% of all cutaneous melanoma and usually affects the thumb or big toe.[52] An

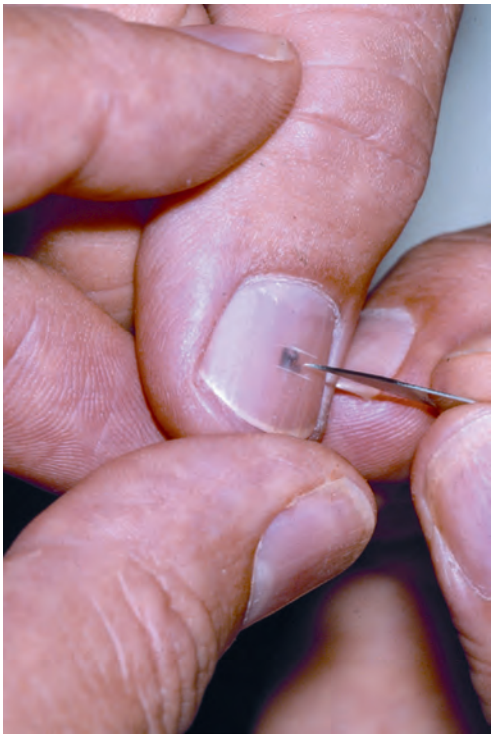

Fig. 6.19 Scratching of the nail proximal and distal to the pigment to determine whether the pigment is in the nail or in the nail bed. *(© Southern Illinois University School of Medicine.)*

important clinical clue to subungual melanoma is characterized by extension of brown or black pigment from the nail bed, matrix and nail plate to the adjacent cuticle and proximal or lateral nail folds; this is known as Hutchinson's nail sign. There are two stages to melanoma growth. The first stage is superficial, radial growth under the nail plate, followed by a vertical growth. At this stage, the lesion begins to develop a more dramatic change in appearance.

Treatment

The historic standard treatment recommendation for subungual melanoma has been *en bloc* partial or complete digit amputation. This strategy was considered the safest means of obtaining clear margins, preventing recurrence and metastasis. This rationale, however, was not based on clear scientific evidence, but rather the principles of wide excision for what was thought to be an aggressive malignancy. Current evidence suggests this disease is not more aggressive than their more common cutaneous counterpart of similar depth.[53,54] The original evidence to support these recommendations came from Das Gupta *et al.* in 1965.[55] They presented 34 patients with subungual melanoma treated with amputation at different levels. Three patients who underwent a less aggressive form of amputation recurred and subsequently died from their disease. On the basis of these findings, it was determined that local amputation was not an adequate resection. However, it should be noted that they did not present the depth of these lesions and half of the patients in the study were being treated for recurrent melanoma or already had regional lymph node metastases at time of treatment. Therefore, the conclusions derived from Hutchinson's and Das Gupta's findings regarding aggressive amputation are not appropriately supported by their evidence.

Today, interphalangeal joint amputations are the most commonly performed treatments for this disease. However, digit sparing procedures in appropriately selected cases have also been successfully performed. The precedent for digit sparing came from a study in 1992 by Park *et al.*[56] In this manuscript, the authors treated subungual melanoma *in situ* without amputation. This was followed by a number of series in the literature presenting similar experiences with variable results, but not infrequent recurrence. Today, it seems wide excision can be an option for patients with melanoma *in situ.* However, they should be followed closely for signs or disease recurrence. For a complete discussion and further in-depth review of available literature, a manuscript presented by Cochran *et al.* in the August 2014 issue of *Plastic and Reconstructive Surgery* is available for the reader.[57]

Pincer nail

Pincer nail deformity is described as lateral hooking or excessive transverse curvature of the nail plate, unilaterally or bilaterally (Fig. 6.22). The progressive tubing of the nail eventually pinches off the nail bed and hyponychium, resulting in an unaesthetic, painful nail. Pincer nail is most commonly seen in middle-aged to elderly women. The cause of the pincer nail is not known.

Treatment

Previous treatments have included resection of a wedge of the phalanx to flatten the nail edges and release of the nail bed with a medial longitudinal nail bed incision and split-thickness skin graft coverage of the resultant triangular defect.[58] They have been largely unsuccessful. Brown *et al.*[59] have advocated the use of dermal graft strips between the lateral nail bed and

Fig. 6.22 **(A)** Unilateral pincer nail deformity. **(B)** The perionychium is freed from the bone, and a graft of dermis or dermal substitute is placed into the tunnel to flatten the nail bed. **(C)** One year after correction. *(© Southern Illinois University School of Medicine.)*

the distal phalanx periosteum for elevation of the lateral borders of the nail bed. The nail is removed, and incisions are made at the tip of the digit to allow freeing and elevation of the paronychial folds from the periosteum. The dermal grafts are placed within this space to maintain the elevation and to flatten the nail bed. Our preferred technique is a modification of this, using human acellular dermal matrix in place of autologous dermal strips. We have achieved equally good correction of pincer nail without the addition of an additional donor defect.

In more severe cases, the pain from a pincer nail deformity may be severe enough to warrant surgical ablation of the nail bed, especially if other forms of reconstruction are unsuccessful.

Reconstruction of fingertip injuries

Reconstructing defects on the fingers requires thorough knowledge of a variety of coverage options. Treatment possibilities range from simple, including an occlusive dressing to allow healing by secondary intention, to extremely complex, including free pulp transfer. As the surgeon considers each possibility to obtain definitive closure, one must also integrate the priorities of function, contour, stability, and the anticipation for further reconstructive surgery. The reconstructive decision is based on characteristics of the defect, including size, shape, location and availability of donor sites. Age, occupation and individual attributes of the patient ultimately play the largest role in appropriate selection of the reconstructive plan. The final decision is made by the patient, however the surgeon may affect this choice. A recent survey sent out to American Association for Hand Surgery members revealed US and private practice physicians were less likely to perform replantations than academic or international centers.[60] For soft-tissue fingertip injuries, local flaps were preferred over secondary intention or skin grafts more commonly in surgeons with a plastic surgery background or with more than 30 years of experience.[60] Younger surgeons were also more likely to perform skeletal shortening than those with more than 5 years' experience.[60]

The Allen classification[61] is commonly used to describe the level of fingertip injury, as thought of in a transverse amputation. Type 1 injuries involve the pulp only. A type 2 injury also involves the nailbed. Concomitant distal phalangeal fractures with associated pulp and nail represents a type 3 injury and the type 4 injury occurs more proximal with involvement at the level of the lunula.

Reconstructive principles

The principles of wound management in the traumatized digit or hand are the same basic guidelines that apply to the rest of the body and include irrigation, debridement, and

restoration of vascularity. Stabilization of fractures and repair of specialized tissues such as nerve and tendon become the second priority, followed by the definitive soft-tissue coverage. The skin of the hand and the fingers varies from palmar to dorsal sides. The palmar aspect is covered with glabrous skin notable for its limited sheer, high friction coefficient and papillary ridges, which create the characteristic fingerprint. Numerous fibrous septae compartmentalize subcutaneous tissue of the palm with fibers from the underlying dermis to the musculoskeletal structures below. The midaxial line of each digit is formed by connecting the lateral volar finger crease at the distal interphalangeal joint (DIP), proximal interphalangeal joint (PIP) and metacarpal phalangeal (MCP) joint. It is at this line that the transition from the glabrous to non-glabrous skin of the hand occurs. The midaxial line corresponds to the midline of the phalanx. Whereas the true midlateral line of the finger corresponds to the location of the neurovascular bundle. The dorsal skin is relatively soft, pliable, and thin. It is devoid of the fibrous septae observed in the volar skin.[13] The importance of understanding the difference of glabrous and non-glabrous skin comes to light when one observes one of the dictums of reconstructive surgeons to replace "like with like". Local flaps that include glabrous skin should be considered first for glabrous defects. The relative limited and inelastic quality of glabrous skin on the body prevents reconstruction of large glabrous defects with similar tissue. In such cases, alternative strategies must be employed, including using spare parts in a multi-digit injury, use of multiple grafts for a single defect, allow wounds with non-vital structures exposed to heal by secondary intention or coverage with non-glabrous skin. Dorsal skin more closely resembles skin on the anterior trunk and defects of the dorsal hand and fingers can readily be closed with other similar quality skin.

Flap selection

A multitude of available flaps can produce good outcomes for both the recipient and donor site. Each flap has inherent advantages and drawbacks. Ultimately, flap selection is dependent upon variables such as size, shape, location of the defect, and the characteristics of the tissue lost. The hand surgeon must select the most ideal flap to restore as many of the native skin characteristics present prior to the defect, and to provide the quickest means of wound closure. Efficient wound closure becomes a higher priority to prevent finger stiffness and maximize hand function.

Fingertip injuries should be thoroughly irrigated and debrided of foreign material and nonviable tissue before closure is attempted. If the entire defect cannot be closed primarily, the wound can be partially closed and the remainder allowed to heal by secondary intention. Suture selection varies by surgeon preference. If possible, the wound should be closed with a chromic or other resorbable suture. Nylon sutures in the fingertip are not usually necessary; they are uncomfortable to remove in the early follow-up periods. The wound is covered with a non-stick dressing like Xeroform or other minimal adherence dressing. Daily dressing changes permits rapid wound healing. Early motion is encouraged to prevent stiffness at the DIP or PIP joints. Larger wounds can heal by secondary intention if bone, tendon or neurovascular structures are not exposed. Wounds up to 2–3 cm may be allowed to heal by re-epithelialization, but both surgeon and patient must be aware that closure may take 4–6 weeks (Fig. 6.23). Previously, authors advocated that defects >1 cm should be closed with local flaps.[62] However, secondary intention offers many advantages over flap closure, including improved contour, sensation, and lack of donor site morbidity.[63]

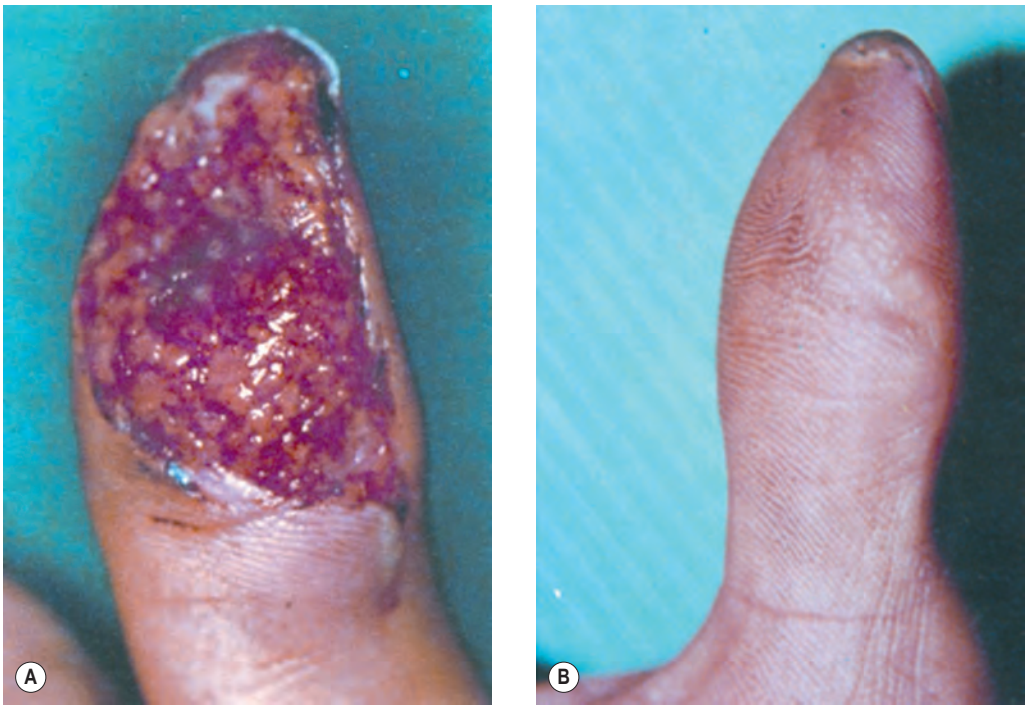

Fig. 6.23 **(A)** Large soft tissue defect of the volar aspect of the thumb allowed to heal by secondary intent. **(B)** 4-year follow-up of healed thumb showing good contour.

Skin grafting

Patient selection

When the extent of the defect is limited to skin, a split- or full-thickness skin graft may be used for coverage of a well-vascularized bed. Graft contraction is expected. Although re-innervation is poor with split-thickness grafts, protective sensation may be possible if full-thickness grafts are used.[62,64] Dermal substitutes (Integra, Intera LifeSciences Co., Plainsboro, NJ) over tendons can provide an interface that accepts a skin graft and prevents scar adhesion formation that prevents motion (Fig. 6.24). Distal fingertip amputations often comprise skin, subcutaneous fat and a portion of the nail bed. The amputated part may be replaced as a composite graft after defatting, called a cap graft.[65] The overall success rate of composite grafts is poor in the adult population and better in children <10 years of age. A recent review of pediatric patients treated with cap grafts revealed a relatively poor rate of complete take (7.7%).[66] The majority of patients had a partial take (38.5%) and 33% had total loss of the graft. Despite this seemingly poor overall success of composite grafts, only 10% of patients went on to require a secondary procedure.[66] It can be concluded that a composite graft placed on a fingertip that does not revascularize should be left as a biologic dressing to allow healing from below the eschar. This often leads to an adequately contoured fingertip. These injuries do, however, take many weeks to months to completely heal and in the adult laborer needing to return to work, a revision amputation may be a preferred method for treatment of these types of injuries.

An evaluation by Allen level concluded that cap grafts are most successful for Zone I and II sharp or blunt-cut injuries, but Zone III or IV injuries regardless of mechanism should be treated by another method (e.g., revision amputation, local flap, micro-anastomosis, etc.).[67]

Treatment: Local flaps

Volar V–Y advancement (Atasoy, Kleinert)

Fingertip defects less than one centimeter and oriented in a dorsal oblique or transverse fashion may be closed with a volar V–Y advancement flap.[64] Originally described by Atasoy *et al.* in 1970, this flap is oriented as a triangle and closed in a V–Y fashion. The base of the triangle sits at the wound edge and the apex at the DIP crease (Fig. 6.25).[68,69] This skin is incised down through the dermis and then scissor dissection is used to release fibrous septae that anchor glabrous skin to the deeper musculoskeletal structures.[64] The most distal corners of the flap must be freed by 2–3 mm in order to allow adequate release of the flap distally. Similarly, the apex of the flap at the DIP joint must be released significantly to permit distal migration of the flap.[70] The flap is elevated with its neurovascular pedicles on either side of the flap in the plane of flexor tendon sheath; 0.75–1 cm of length can be obtained with a volar V–Y advancement flap. Functional and cosmetic results are extremely good as this flap remains one of the most important tools in treatment of fingertip injury closure.[62,64,68,69]

Lateral V–Y advancement flaps (Kutler)

Transverse and lateral oblique defects can be covered with sensate vascularized skin using V-Y advancement flaps on the lateral aspect of the digits (Fig. 6.26).[64] Often bilateral flaps are required to get sufficient closure of the of the fingertip defect. The lateral V–Y flaps are elevated in a similar fashion as to the volar V–Y flap; however, they are based laterally and medially instead of volar. Unlike the Atasoy counterpart, this flap's advancement has limited mobility and can only reliably close defects of 0.5 cm, but no more than 1 cm. The flap is elevated in the plane of the deeper musculoskeletal structures.[70]

Visor flap

Described by Neumeister *et al.*, the visor flap is indicated for closure of transverse distal fingertip amputations with exposed bone.[70,71] This flap utilizes skin on the dorsal aspect of the finger to preserve length and close defects on the most distal aspect of the finger amputation site. The visor flap is a bipedicled rectangular-shaped flap from the dorsal aspect of the finger. It is raised at the level of the paratenon immediately proximal to the defect (Fig. 6.27). The width of the flap is approximately that of the fingertip defect. The flap is sensate and vascularized by branches of the volar lateral and medial digital arteries and nerves, respectively.[71] Back cuts in the dorsal aspect of the skin may be required for transposition of the flap. The donor site requires a skin graft. If dog ears are present, they are left in place and should flatten over a period of months. The visor flap provides acceptable sensation, good cosmetic appearance and preservation of length of the digit without violating adjacent normal digits or creating volar scars.

Homodigital flaps

Reverse homodigital flap

The reverse homodigital flap, originally described by Lai *et al.*,[72] takes advantage of the dual vascularity of the digit, as the finger can remain viable on a single digital artery. The other artery can provide blood supply for an axial flap that can be based proximally or distally (Fig. 6.28). The digital nerve remains *in situ* to preserve sensation to the finger, however small nerve branches can be used for coaptation to improve sensation of the transferred flap. These arterial perforator flaps involve small perforators arising from the digital artery. The skin island can be isolated on the perforator while the remaining aspect of the artery provides length to the pedicle, ultimately creating an arc of rotation of up to 180° (Fig. 6.29A–D ◍).[73,74] The donor site may be closed with a skin graft if primary closure is not possible. Distally based homodigital flaps take advantage of the communication with the contralateral digital artery.[75] These flaps may be somewhat precarious as they require retrograde venous flow and may have limited communication with the contralateral vessels. This reverse homodigital flap can also be taken as an adipofascial flap.[76] This technique can provide a slightly broader and larger flap and reduces donor site morbidity.[76]

Fig. 6.29 appears online only.

Alternative modifications described islandize a dorsal–lateral skin paddle on a volar perforating branch from the digital vessel. This digital artery perforator propeller flap is innervated and can be used to reconstruct lateral oblique fingertip defects and prevent further skeletal shortening.[77]

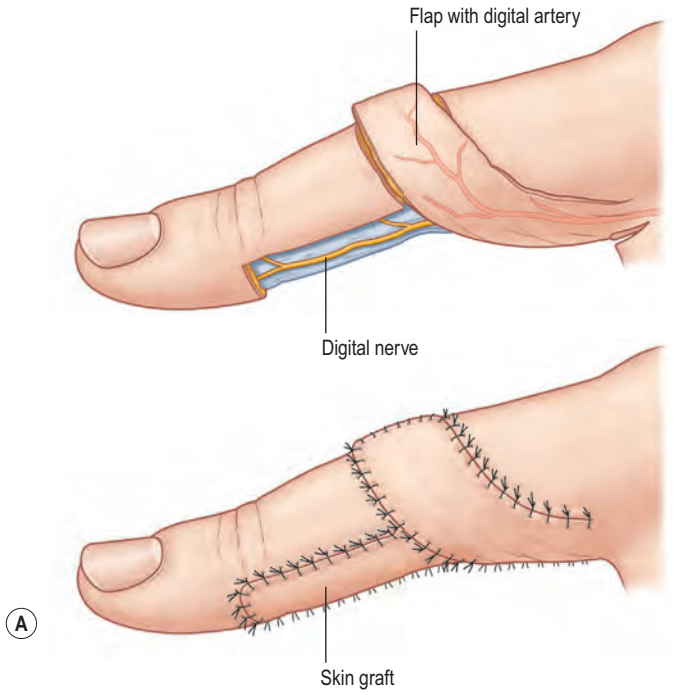

Fig. 6.29 **(A)** Homodigital flaps are based on the nondominant digital artery to the fingers and used to transpose either in a retrograde or an antegrade fashion. **(B)** Exposed PIP joint necessitates closure, the homodigital flap is elevated, care is taken to incorporate the digital artery proper into the flap. **(C,D)** The flap is transposed and the donor site closed with a full-thickness skin graft. The flap can be elevated without transecting the skin paddle proximally. This improves the venous outflow of the flap. **(E)** Healed flap, dorsal aspect of finger.

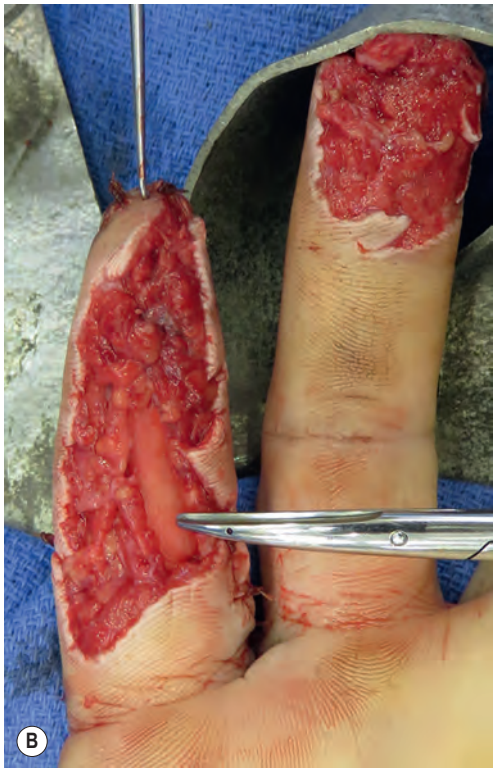

Fig. 6.24 54-year-old male suffered occupational avulsion injury as an elevator repairman. **(A)** The neurovascular bundles were intact, but there was exposed flexor tendon sheath. **(B)** The wound was debrided and Integra (indicated by the scissor tips) was placed over the tendon sheath and **(C)** immediately covered with a full-thickness skin graft from the volar forearm. **(D)** Some areas of purplish discoloration are seen during the immediate postoperative period. **(E)** At 4 weeks postoperative, he healed completely and with good motion.

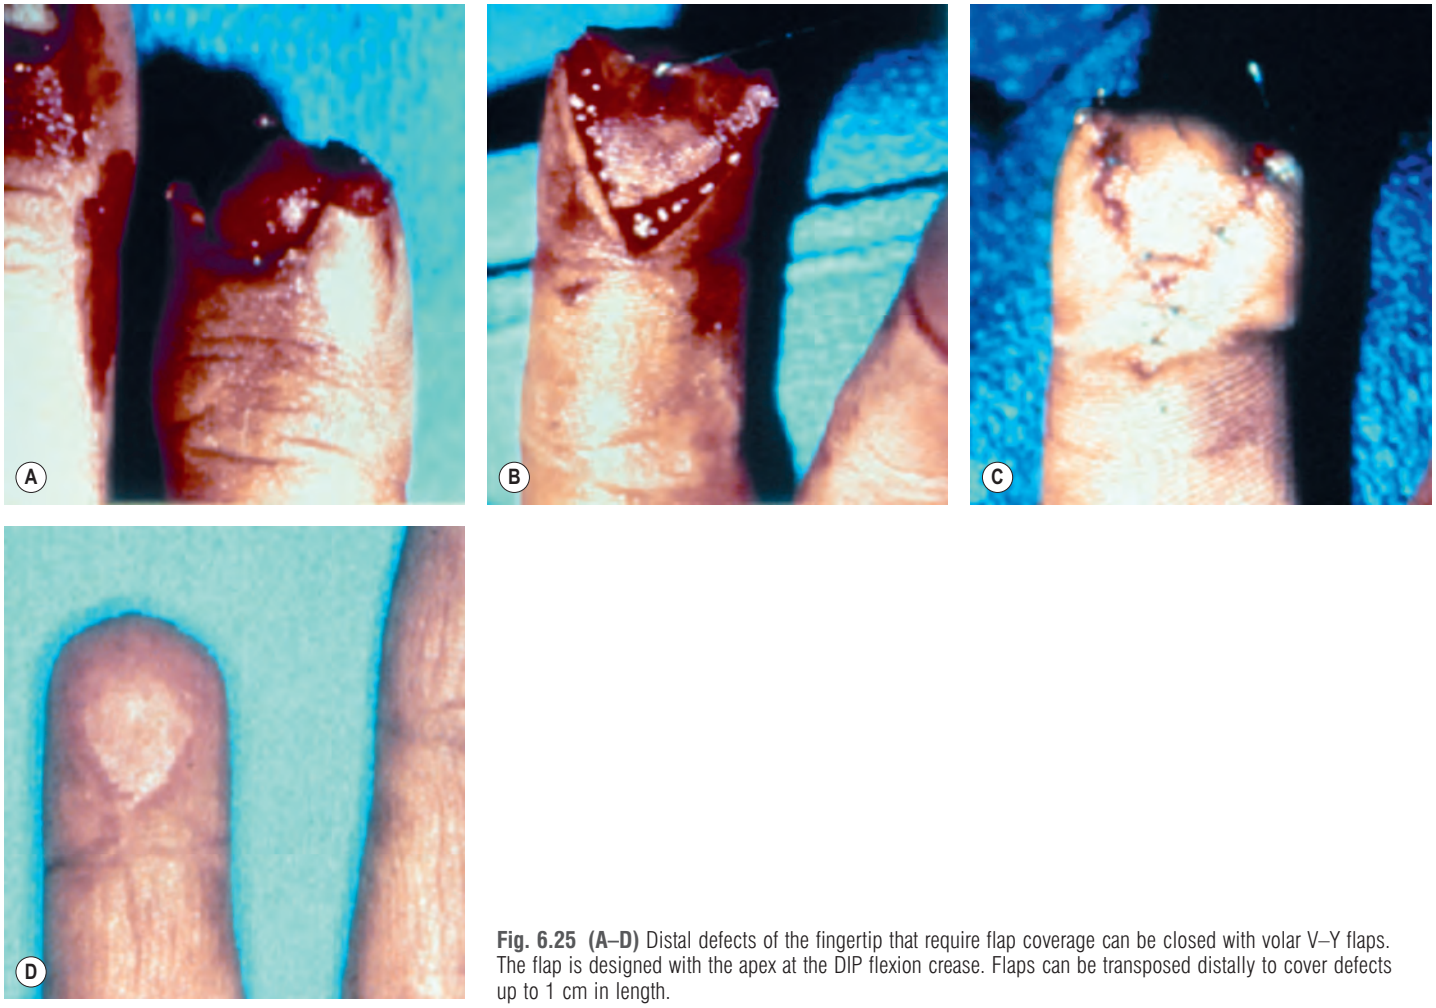

Fig. 6.25 (A–D) Distal defects of the fingertip that require flap coverage can be closed with volar V–Y flaps. The flap is designed with the apex at the DIP flexion crease. Flaps can be transposed distally to cover defects up to 1 cm in length.

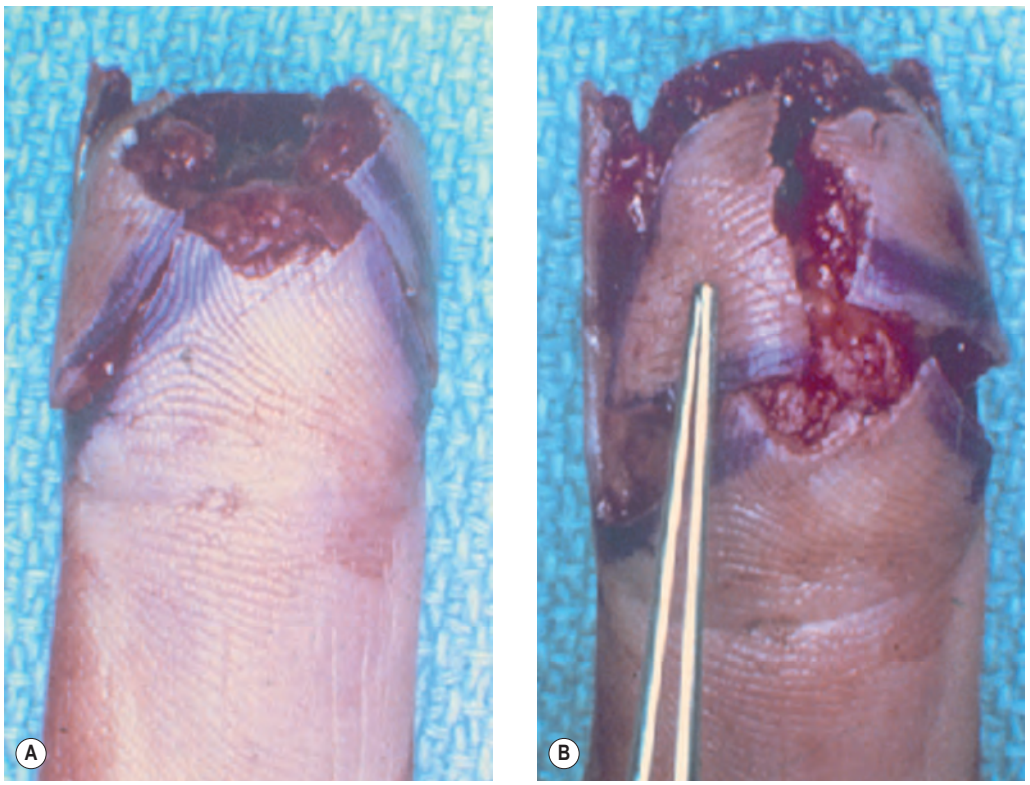

Fig. 6.26 Distal fingertip injuries are sometime more amenable to laterally V–Y flaps. The limited length gained is more limited reaching only up to 0.75 cm.

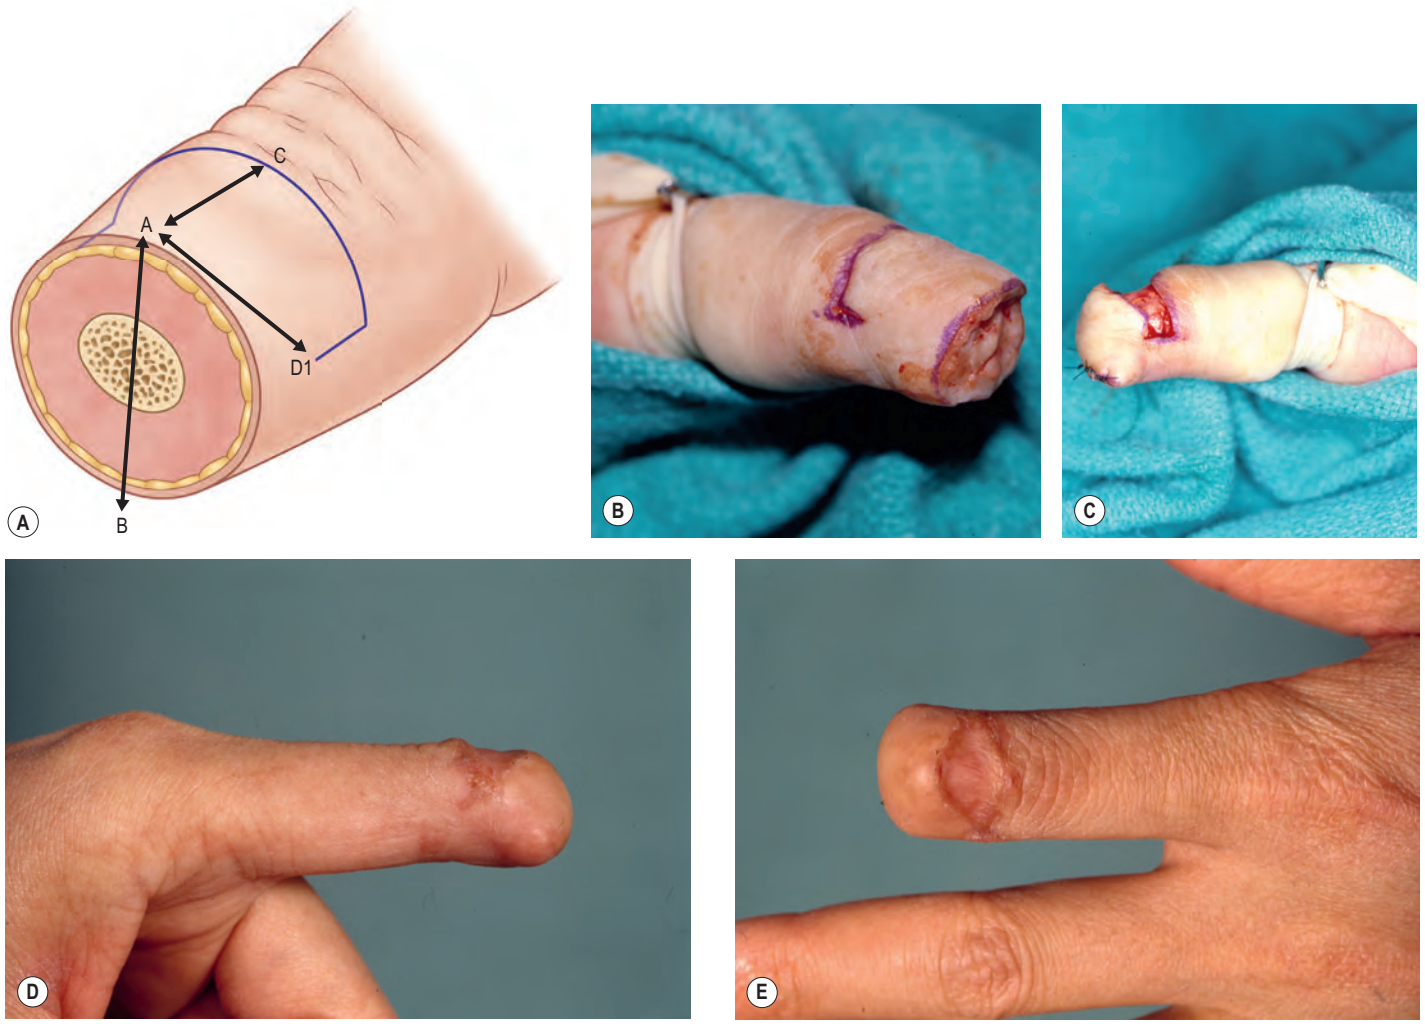

Fig. 6.27 **(A)** The visor flap is designed over the dorsum of the digit. The height of the defect (A to B) is equal to the height of the flap (A to C). The proximal incision is carried down to the midaxial line on either side of the dorsum of the finger. A back cut to D1 can be made but only through the dermis in order to protect the neurovascular structures supplying the flap. **(B)** Clinical picture of the design of the visor flap. **(C)** The flap was transposed over the distal aspect of the amputated stump. The donor defect is closed with a split thickness skin graft or a full thickness graft. **(D,E)** Lateral and AP view of the visor flap after it is transposed and healed.

Moberg flap

The homodigital volar advancement flap, also known as a Moberg flap, can be used to reconstruct defects on the thumb (Fig. 6.30A–C). A volar oblique injury to the tip of the thumb is the classic indication for this flap. However, this flap's uses have expanded to include a wider range of defects. The unique dorsal and volar blood supplies to the thumb allow creation of a volar skin paddle with both neurovascular bundles. Flap elevation is performed in a plane just volar to the tendon sheath. The flap can be completely islandized on the neurovascular structures, with a variety of proximal incisions used to close the defect in the palm, including a V–Y design (Fig. 6.30D) or transverse incisions at the base with excision of Burow's triangles. The Dellon modification of the flap allows closure of defects up to 3 cm. This requires dissection of the flap into the palm past the base of the thumb.

Heterodigital flaps

The cross-finger flap

The cross-finger flap utilizes skin from the dorsal aspect of the adjacent finger as part of a two-stage technique. The inner cross-finger flap is most applicable for volar defects of the distal aspect of an adjacent finger. The flap is normally taken from the dorsal radial surface over the middle phalanx of the adjacent digits.[62,64,70,77] The flap is designed slightly larger than the defect to ensure complete coverage. Vascularity of the flap arises from the digital artery and vena comitantes that send branches dorsally beyond the PIP joint. The flap is elevated superficial to the extensor paratenon and flipped over like a page in a book to cover the volar defect of the adjacent finger (Fig. 6.31). The base of the flap remains intact with the donor finger while the donor defect on the dorsal aspect of the middle phalanx is covered with a full-thickness or

Fig. 6.28 **(A)** Dorsal defects of the fingers with exposed bone or flap closure. **(B)** A homodigital island flap is designed involving the nondominant side of the right ring finger. **(C)** The healed flap over the dorsal aspect of the fingers. The flap was based on the ulnar digital artery.

split-thickness skin graft. The flap is sutured in with chromic sutures and the fingers are immobilized for 2–3 weeks. The flap is then divided and inset. The dorsal cutaneous branches of the digital nerve can be incorporated into the flap and coapted to the recipient digital nerve to improve re-innervation potential.[70]

The reverse cross-finger flap is utilized to cover dorsal defects of the adjacent digit. In the reverse cross-finger flap, the dorsal skin is elevated but left with an intact base at the lateral border away from the defect. The subcutaneous tissue is then elevated at the level of the paratenon and turned over 180° like a page of a book to cover the dorsal defect of the involved finger (Fig. 6.32). The elevated full-thickness skin flap on the opposite side of the donor finger is then replaced in its original position.[62] A skin graft is still required at the recipient site to cover the adipofascial flap that overlies the dorsal defect. Both cross-finger and reverse cross-finger flaps provide tissue with reliable blood supply to defects measuring up to 3 cm in size. Following division and insetting of the flaps, mobilization and aggressive therapy may be warranted to prevent stiffness or contractures.

Thenar crease flap

Smaller fingertip defects with exposed bone may be closed with a thenar crease flap. The flap itself is designed based on the radial aspect of the palmar thenar crease. It is most often utilized for the index and long fingers because of their proximity to the thumb.[62,64] The thenar crease flap is designed in a two-stage fashion. At the initial phase, the flap can be elevated measuring up to 1½×1 cm (Fig. 6.33). Care must be taken not to injure the neurovascular bundles that lie immediately beneath the fasciocutaneous thenar crease flap. The injured finger must be flexed at the PIP and often the DIP joint in order to allow flap inset with chromic sutures and the donor site closed primarily (Fig. 6.34 ◍). After 2 weeks, the flap is divided.[78] Sensation is reported to be better than skin grafting to the affected digit or with cross-finger flaps.[79] Care must be taken when utilizing this flap in the elderly, as permanent stiffness or PIP joint contractures may arise. Aggressive therapy is required following the flap division and inset.

Fig. 6.34 appears online only.

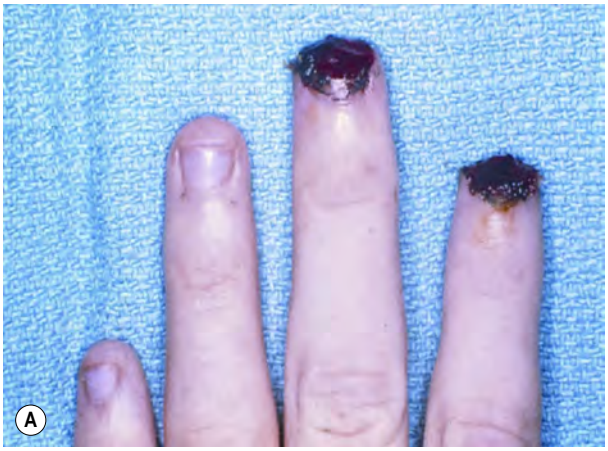

Fig. 6.34 **(A)** Distal fingertips with exposed bone of the index and long fingers in a 23-year-old female. **(B)** A thenar crease flap is elevated based on the radial aspect of the MP joint of the thumb. The index finger is flexed at the PIP joint and the flap is inset onto the defect of the fingertip. A heterodigital flap is elevated on the index finger and transposed to cover the tip of the long finger. **(C)** Flaps are divided and definitively inset after 2–3 weeks per time to provide appropriate coverage for the distal fingertips of the index and long fingers.

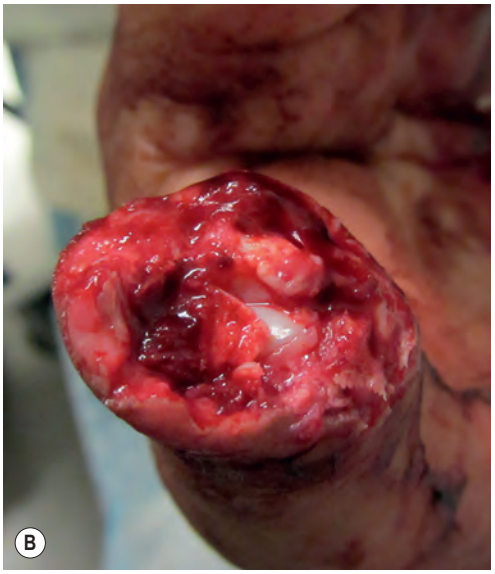

Fig. 6.30 52-year-old male suffered **(A)** volar oblique injury to his left thumb during an industrial accident with **(B)** exposed bone. **(C)** A Moberg volar advancement flap was performed to prevent skeletal shortening. Many modifications have been made to increase the flap advancement including **(D)** the V–Y proximal incision (different patient pictured). This technique islandizes the flap on the volar neurovascular bundles.

Fig. 6.31 **(A)** Mutilated fingertip with exposed bone requiring soft-tissue coverage. **(B)** Cross-finger flap from the adjacent digit is used to cover the volar defect of the index finger. The flap is elevated at the level of the paratenon and the donor site is then closed with a full-thickness skin graft. **(C)** 2–3 weeks later the flap is divided and inset. **(D)** Long-term outcome after soft-tissue healing and nail regrowth.

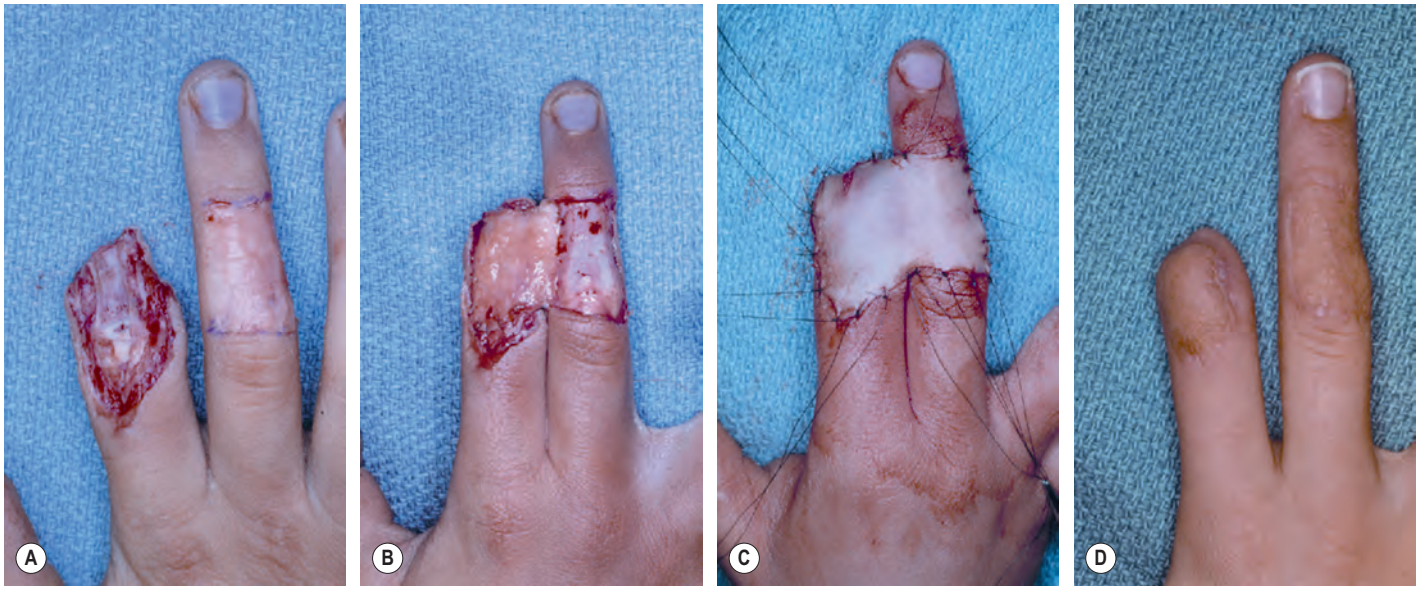

Fig. 6.32 **(A)** A finger injury with tip amputation and soft-tissue avulsion from the dorsal aspect of the index finger with exposed tendon. A reverse cross finger flap is designed. The dorsal skin of the long finger is de-epithelialized. **(B)** The flap is elevated at the level of the paratenon and transposed like a page in a book over the dorsal aspect of the index finger. **(C)** Both digits are covered with a full-thickness skin graft and the flaps are then divided and are inset 2–3 weeks later. **(D,E)** Final outcome of the reverse cross-finger flap and donor site is shown.

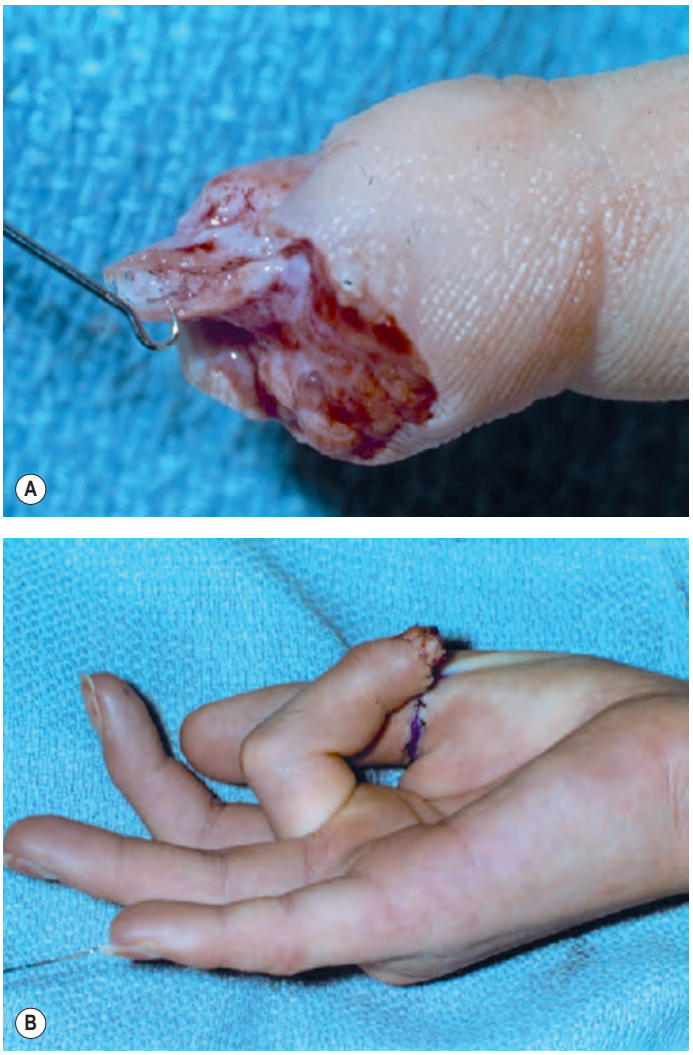

Fig. 6.33 (A) The long finger has a distal amputation with exposed bone. To preserve length, the defect will be closed with a thenar crease flap. **(B)** The flap was designed with approximately 1 cm width and based radially. The recipient finger was flexed at the PIP joint for flap inset.

Littler neurovascular island flap

This neurovascular island flap utilizes the donor skin from the ulnar aspect of the long or ring finger to provide sensate vascularized tissue to a given recipient site (Fig. 6.35 ◍).[64] However, donor site compromise may be significant resulting in stiff fingers with contractures making this flap less desirable than others for fingertip or thumb pulp reconstruction. Arteriograms and digital Allen's tests have been advocated prior to performing this flap to confirm an adequate co-dominant arterial supply to the donor and adjacent finger because the dissection of the flap requires extension beyond the bifurcation of the common digital artery. The contralateral branch will need to be ligated and divided. Dividing this contralateral branch in a finger that does not have another means of circulation can result in significant digital ischemia. Therefore, before ligating and dividing the contralateral branch, a temporary clip should be applied, the tourniquet released, and the viability of the finger verified.[80]

Fig. 6.35 appears online only.

The flap may be tunneled through a subcutaneous plane to the defect on the volar aspect of the thumb or, alternatively, through a zig-zag Brunner type incision to allow easy transposition of the flap without fear of compression or compromise to the pedicle. The donor site is closed with a split-thickness skin graft. Creating chevron incisions lateral to the DIP and PIP creases is important to prevent contractures at these joints following healing of the skin graft. Protective sensation has been observed with two-point discrimination averaging 6–7 mm.[68] Although there is a potential for cortical relearning or plasticity, most patients perceive the sensation as that of the donor site and not the recipient site. Cortical relearning may only be present in 25–40% of individuals.[64,81]

Dorsal metacarpal artery flaps

Foucher described the first dorsal metacarpal artery flap for reconstruction of thumb defects involving the volar thumb pulp (Fig. 6.36A ◍). This is also known as a kite flap because of its distinct appearance of a distal skin paddle pedicled on a tail of neurovascular structures. This flap utilizes the skin and subcutaneous tissue of the proximal phalanx of the index finger and is based on the neurovascular bundle that rests within or under the fascia of the first dorsal interosseous muscle (Fig. 6.36B–F).[82] The first dorsal metacarpal artery supplies vascularity in the vena comitantes and some superficial veins supply the venous outflow of the flow. Branches of the superficial radial nerve provide sensibility to this flap. The flap is elevated at the plane above the paratenon so that the donor site can accept the skin graft for closure. The rest of the pedicle is dissected and the flap can either be transposed through a tunnel or through a zig-zag incision into the volar thumb defect.[70] Although this flap provides protective sensation, cortical relearning is required. The morbidity from harvesting tissue from an undamaged digit must also be considered.

Fig. 6.36 appears online only.

A reverse dorsal metacarpal artery flap based on perforators from the palmar digital arteries (Fig. 6.37 ◍) can be used as an adipofascial flap or with a skin paddle.[70] These perforators arise between the metacarpophalangeal joints and at the neck of each metacarpal. This flap is a reverse-flow island flap where the skin paddle is taken from the dorsum of the hand closer to the wrist. It is elevated off the fascia of the interosseous muscles and transposed to resurface distal finger defects. In order to get adequate pedicle length to cover the distal finger, the pedicle should be dissected down into the web space. This flap is not typically used for distal fingertips but for dorsal defects of the finger as the dissection is somewhat tedious between the digits.

Fig. 6.37 appears online only.

Hints and tips

Reverse dorsal metacarpal artery flap

To gain pedicle length, continue the dissection between the proximal phalanges on either side. The pedicle is easily mobilized to reach the volar or dorsal fingertip area.

Fig. 6.35 **(A)** The Littler neurovascular island flap utilizes the skin subcutaneous tissue and neurovascular bundle from the nondominant side of the long or ring fingers. The dissection is carried down into the palm and the flap is transposed to the defect on the thumb. **(B)** This flap was elevated on the neurovascular bundle involving the nondominant side of the long finger. **(C)** The donor defect closed with a full-thickness graft and then the flap transposed onto the dorsum of the thumb. **(D)** The healed defect on the thumb with the neurovascular island flap well inset. The donor finger that may result in a contracture if the flap is harvested in a more volar aspect of the finger.

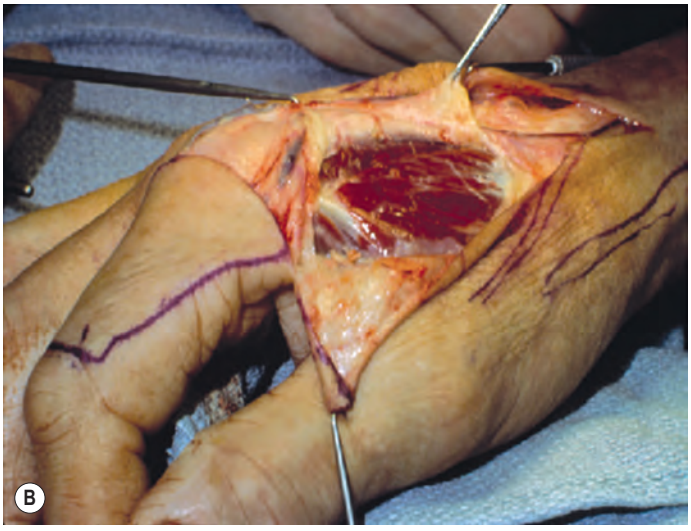

Fig. 6.36 **(A)** Significant defect of the volar pulp of the thumb with exposed bone and tendon. **(B)** First dorsal metacarpal artery flap is designed over the dorsal aspect of the index finger. The first dorsal metacarpal artery lies within the fascia of the first dorsal interosseous muscle. **(C)** The pedicle is elevated with the fascia and care is taken to keep the superficial veins to allow appropriate drainage of the flap. **(D)** Final appearance of the defect on the thumb as well as the donor site.

Fig. 6.37 **(A)** Dorsal defects of the finger with a designed reversed dorsal metacarpal artery flap. **(B)** The flap is based between the metacarpal heads as perforators from the palmar side communicate with the dorsal metacarpal arteries. The venous drainage is retrograde. **(C)** The flap is tunneled and inset into place to the dorsal aspect of the finger. This flap can be carried out to the distal aspect of the finger if further dissection is carried down within the web space.

Conclusions

The choice of treatment for fingertip injuries relies heavily on the patient's primary outcome goal, namely speed to recovery *vs.* skeletal preservation. Revision amputation returns a laborer to work faster and minimizes chances for complications, including wound breakdown, joint stiffness and flap failure. Women or patients interested in preservation of anatomic normalcy may prefer a potentially longer and possibly multi-stage procedure to return the fingertip as closely as possible to its normal state. The classic flaps described for reconstructing the fingertip, including the Moberg, Atasoy, Foucher and others, remain excellent viable options. Additional developments have included use of adipofascial reverse-flow turnover flaps, use of volar perforating branches from the digital arteries to design custom homodigital flaps and otherwise considered randomly based flaps (i.e. keystone design). These allow creation of variable skin paddle designs to cover defects and speed healing. Additional modalities include use of negative-pressure dressings and neodermis (e.g., Integra) to promote granulation and prevent tendon desiccation.

Recent experiences have demonstrated that many simple nail bed injuries with an intact nail plate can be observed with a comparable or potentially superior long-term aesthetic outcome. More complex injuries or extensive subungual hematomas still require repair and drainage, however; if possible the proximal nail plate can be left *in situ*. A good understanding of fingertip anatomy and treatment options remains important, as these types of injuries continue to be some of the most commonly seen presenting complaints in emergency and urgent care settings. Avoiding complications and preventing delayed return of function remains the continued challenge for practitioners treating these injuries.

Future directions

Managing joint stiffness, hyperesthesia and nerve injuries remain the most difficult and unpredictable issues to resolve after fingertip injuries. The mainstays of treatment include early range-of-motion therapy to improve gliding and prevent internal scarring from limiting motion. For patients with hypersensitivity of the fingertip, desensitization therapy, smoking cessation, and neurologic medications including gabalin and pregabalin along with the tincture of time are the best methods currently available. The use of neuromodulators, including botulinum toxin, may prove to have an added benefit for these patients. Use of vitamin C has proven useful for preventing complex regional pain syndrome (CRPS) after repair of distal radius fractures and may have a benefit for preventing CRPS in fingertip injuries, too. Regaining full sensation in transected nerves in the digit also remains an incompletely solved issue. The current gold standard in order of preference includes a tension-free primary repair, followed by autograft, allograft and lastly a nerve conduit. However, evidence in the literature can be found to support a wide range of reconstructive strategies. Future directions will need to be directed towards solving the ongoing unsolved problem of restoring normal nervous function after injury, preventing hypersensitivity of the injured fingertip and restoring normal range of motion.

Hand fractures and joint injuries

Joseph S. Khouri and Warren C. Hammert

Access video and video lecture content for this chapter online at expertconsult.com

SYNOPSIS

- Diagnosis of hand fractures and joint injuries requires history, examination, and adequate imaging studies.
- Treatment decisions are based on fracture geometry, stability, and individual patient needs.
- Non-operative principles include reduction, maintenance of reduction through casting or splinting, followed by protected motion.
- Operative treatment includes closed reduction with or without percutaneous pinning, external fixation, and open reduction and internal fixation.
- Rehabilitation is an important aspect of caring for patients with hand fractures and joint injuries and involves splinting and restoring motion.
- Secondary procedures may be considered when the desired outcome is not achieved. These include correction of malunion, tenolysis, and capsulotomy.

Introduction

Phalangeal and metacarpal fractures are estimated to account for 16.2 and 12.5 fractures per 10000 persons, respectively.[1] Appropriate diagnosis and treatment can minimize deformity and maximize function. Although many of these fractures can be managed non-operatively, appropriate follow-up is crucial for a good outcome. These injuries can result in time away from work and activities and can be complicated by stiffness and weakness. The goal of the treating physician should be to minimize deformity and maximize function. The decision to operate depends on multiple factors, including stability, location, geometry, configuration, and associated injuries, but ultimately is chosen when the anticipated outcome is better than non-operative management.[2]

The goal of treatment of fractures in the hand is to reduce and stabilize the fracture, maintain the reduction and begin rehabilitation to restore function. The treating physician must take into account the vocation and avocation of the injured patient, as this may affect the treatment.

Anatomy

The metacarpals and proximal and middle phalanges are anatomically divided into the head, neck, shaft, and base. The distal phalanx is divided into the tuft, shaft, and base. The carpometacarpal (CMC) joints of the index and middle fingers have little mobility, while the ring and small fingers have some motion to allow for grasp and power grip. The metacarpophalangeal (MCP) joints are stabilized by the volar plate and the collateral ligaments: the proper collateral ligaments are thicker and run between the head of the metacarpal and the base of the proximal phalanx, while the accessory collateral ligaments are thinner and have a more vertical direction, running from the metacarpal head to the volar plate. The cam shape of the metacarpal head contributes to the tightening of the collateral ligaments when the joint is flexed, stabilizing the joint and decreasing abduction and adduction, whereas in extension, the collateral ligaments are lax and allow some radial–ulnar motion. The thick intermetacarpal ligaments stabilize the second through fifth metacarpals distally, often providing stability with fractures of the metacarpal shaft. The MCP joint articulations of the thumb are hinged, allowing flexion and extension whereas MCP joints of the index through little fingers are condyloid in nature and allow flexion/extension, abduction/adduction, and circumduction.[3]

The proximal phalanx acts as an intercalated segment, with tendons running on all sides, but nothing inserting on this bone. The collateral ligaments of the proximal interphalangeal (PIP) joint contain a proper and accessory component, with insertions into the base of the middle phalanx and the volar plate, respectively. They function to provide lateral stability. The head is bicondylar in shape (as opposed to the cam shape of the metacarpal head) and the collateral ligaments of the PIP joint are tightest with the joint in extension. The middle phalanx has insertions of the extensor mechanism (central slip) and flexor tendon (flexor digitorum superficialis – FDS). The distal interphalangeal (DIP) joint is anatomically similar to the PIP joint and the distal phalanx contains the insertion

of the terminal portion of the extensor mechanism and the flexor digitorum profundus (FDP).

The volar plates of the MCP joints differ from the IP joints in that the MCP joint volar plate has more of an accordion-like structure, allowing for the volar plate to be compressed with flexion and expanded with extension. The volar plates of the IP joints have stout proximal extensions known as checkrein ligaments. When contracted, these can contribute to PIP flexion contractures.

The thumb has a greater degree of motion at the CMC joint, allowing for opposition to the fingers. The CMC joint of the thumb is classified as a saddle joint allowing flexion/extension, abduction/adduction as well as circumduction. The shape of the metacarpal head (radial condyle has greater dorsal–volar dimension) allows for pronation of the thumb to assist with opposition.

Classification of fractures and dislocations

Fractures of the phalanges and metacarpals may occur through the joints (articular) or along the shaft (extra-articular). Articular fractures are more common in the PIP and DIP joints than the MCP joints. They may occur through the head or the base. Fractures through the head of the phalanges are classified as unicondylar or bicondylar and can occur in the sagittal and/or coronal plane. Fractures through the shaft can occur as transverse, oblique, or spiral planes. In addition, fractures can be classified as comminuted when there are multiple fragments.

The angular deformity of the fracture is dependent upon the forces acting on the distal bones. The deformity is classified according to the position of the distal fracture segment relative to the proximal segment. Metacarpal fractures most commonly have an apex dorsal angulation while fractures of the proximal phalanx tend to have apex volar angulation secondary to the pull of the interosseous muscles. Fractures of the middle phalanx have a variable deformity, depending on the location of the fracture. Those proximal to the insertion of the FDS have dorsal angulation due to flexion of the distal portion of the bone from the FDS, while fractures distal to the FDS insertion have apex volar angulation due to flexion of the proximal fragment (Fig. 7.1).

For a dislocation to occur, the stabilizing structures (collateral ligaments, volar plate, dorsal capsule) must be

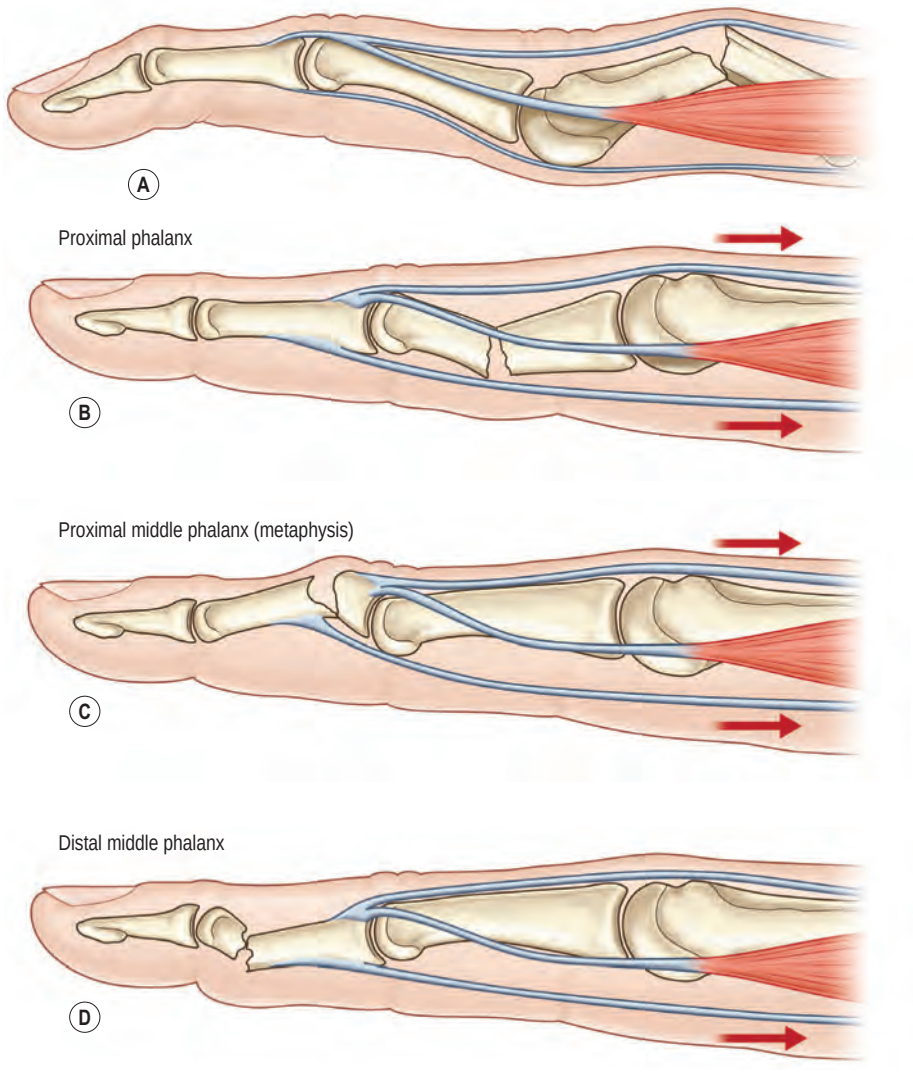

Fig. 7.1 Angular deformity associated with fractures of the metacarpal and phalanges. **(A)** Metacarpal fractures typically have apex dorsal angulation secondary to the location of the interosseous muscles, while the proximal phalanx fractures **(B)** have an apex volar angulation. The angulation of middle phalanx fractures is dependent on the location of the fracture, relative to the insertion of the FDS tendon: fractures proximal to the insertion **(C)** will have apex dorsal angulation while those distal **(D)** will have apex volar angulation.

disrupted. Dislocations are similarly described by the location of the distal bone and are classified as dorsal, volar, radial, or ulnar.

Fracture dislocations commonly occur at the PIP joints of the fingers, and the base of the thumb and ring/small metacarpals. PIP joint and ulnar sided CMC joint fracture dislocations are most commonly dorsal. Thumb CMC joint fracture dislocations are referred as Bennett or Rolando, depending on the configuration and size of the fractured segments.

Fracture stabilization/fixation and return to function

The goal of fracture treatment in the hand is to reduce the fracture and maintain the reduction while restoring motion. Prolonged immobilization will lead to stiffness and should be avoided. Open reduction requires exposure of the fracture sites and stripping of the periosteum. This will induce scaring that impedes motion, so when open reduction is performed, it is important that fixation be stable enough to allow early motion.

For non-displaced fractures, often protection with buddy straps and active motion without resistance is adequate. For displaced or unstable fractures, reduction and fixation is necessary. Rigid internal fixation with plates and/or screws can provide an anatomic reduction, and the fractures can heal by primary bone healing, but this is not always necessary for hand fractures. This can be particularly problematic for proximal and middle phalanx fractures as there are tendons on all sides that must glide for full motion. The presence of plates and screws in this area will produce scarring and often require removal to maximize motion and ultimately function.

Functionally stable fixation implies the fracture is stable enough to begin motion. This can often be accomplished by closed reduction with percutaneous Kirschner wire (K-wire) insertion. The K-wires can be removed, leaving no internal hardware and minimizing additional scarring.

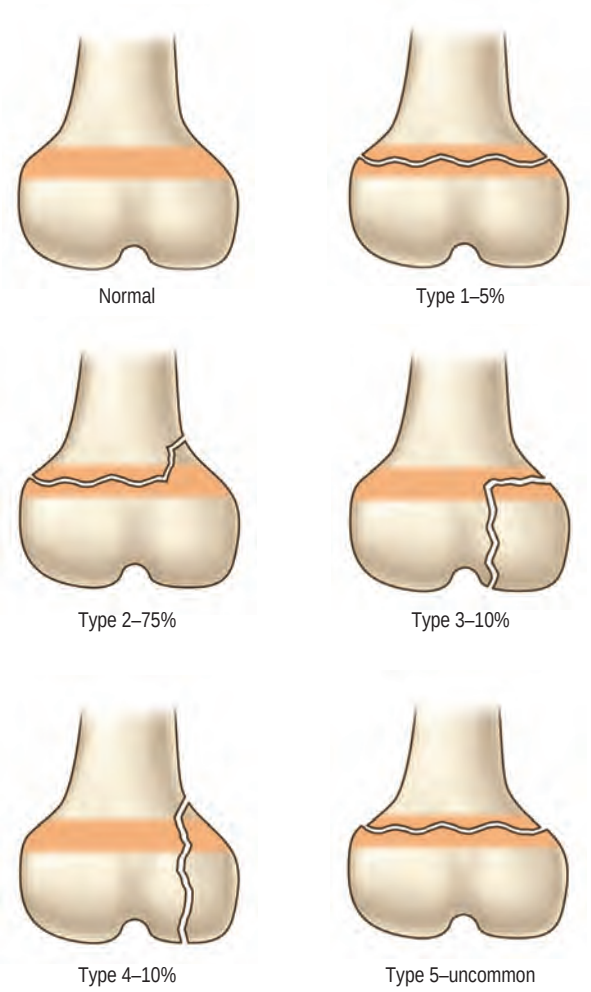

Fig. 7.2 Classification of Salter–Harris fractures. Type 1 is through the physis. Type 2 extends from the physis toward the shaft. Type 3 extends from the physis toward the joint. Type 4 starts in the shaft and extends through the physis and into the joint. Type 5 is a crush injury of the physis.

Pediatric fractures

Pediatric fractures, or fractures in patients with open growth plates require special attention. The physes are located in the metacarpal neck regions in the index, long, ring, and small fingers and at the metacarpal base in the thumb. The physes of the phalanges are located at the base. Growth plate fractures are described by the Salter–Harris classification (Fig. 7.2 and Table 7.1), with type II being the most common. An extra-articular fracture of the proximal phalanx is the most common pediatric fracture of the proximal phalanx. This is a Salter–Harris type II fracture with angulation distal to the physis. The physeal fracture is secondary to the proximal attachment of the collateral ligament.

General principles include early reduction and stabilization. An initial reduction attempt should be completed for displaced fractures, but remanipulating a fracture involving the growth plate should be minimized as this can lead to physeal arrest and premature closure of the growth plate. Generally, the use of plates and screws is avoided and hardware is removed when the fracture is healed. Stabilization of fractures can be accomplished with smooth K-wires and if necessary to cross the physis, effort should be made to minimize the number of passes and thus further injury to the growth plate.

Open fractures

Open fractures of the distal phalanx are treated with irrigation and debridement. If the circulation is intact and the patient is

Table 7.1 Classification of Salter–Harris fractures

Type 1	Fracture is confined to the physis, often with normal radiographs
Type 2	Fracture starts in the physis and extends through the shaft (away from the joint)
Type 3	Fracture starts in the physis and extends into the joint
Type 4	Fracture starts in the shaft and extends through the physis and into the joint
Type 5	The physis is crushed, and there may be sheering through the physis

immunocompetent, antibiotics are not necessary. Fractures of other bones in the hand are treated with antibiotics in addition to irrigation and debridement. Cephalosporins are generally used and with crush injuries or heavy contamination, an aminoglycoside is added. Bite wounds (human or animal) should have penicillin added to cover anaerobes (*Eikenella* in human bites) and *Pasteurella* in animal bites (see Chapter 16, Infections of the hand).

Bone gaps

In high-energy injuries such as gunshot wounds, the hand surgeon may be faced with a bone defect. These defects are divided into non-critical (less than 6–8 cm) and critical (greater than 6–8 cm). In a non-critical bone deficit of the hand, reconstruction with autologous bone graft allows rigid fixation to promote optimal healing.[4] Free vascularized bone flaps are necessary when treating critical bone gap (greater than 6–8 cm), but require microsurgical expertise. Osteoconductive substrates such as calcium phosphate cement and demineralized bone are contraindicated in infected or potentially infected wounds; they also require a previously stabilized defect, as they will add no structural support.[5]

Diagnosis

The diagnosis of hand injuries begins with a history, including hand dominance and occupation as well as the mechanism of injury. The appearance of the hand should be evaluated with the fingers extended as well as flexed. The alignment of the digits may appear normal in extension, but the patient should be asked to flex the fingers as a rotational deformity may become apparent, even with limited flexion (Fig. 7.3).

Specific areas of edema, ecchymosis or tenderness are noted as well as any wounds that may be present. While general screening radiographs of the hand may be beneficial for initial evaluation, specific X-rays provide better detail and should be used once the diagnosis is made (radiographs of the injured finger are preferred over radiographs of the hand for phalangeal fractures). Three views of the injured part are required to adequately evaluate a fracture in the hand.

Fig. 7.3 Clinical example of malrotation of the middle finger secondary to a metacarpal fracture.

Occasionally, additional studies will be necessary for diagnosis or to further define the injury. For example, a collateral ligament injury at the metacarpophalangeal (MCP) of the thumb may not be apparent with plain radiographs, but will become apparent with stress views when the joint space is increased. Magnetic resonance imaging (MRI) can also be used to evaluate collateral ligament injuries and determine if a Stener lesion is present, guiding treatment. Computerized tomography (CT) scans can be used to determine bony alignment/fracture configuration and may be helpful in some joint injuries.

Treatment: fingers

Once the diagnosis of a fracture has been made, a decision must be made regarding the best treatment. Options include protection with early motion, immobilization alone or reduction by closed or open techniques. The goal should be to reduce the fracture, maintain the reduction and return the patient to function with early motion, while minimizing stiffness.

Phalangeal fractures and dislocations

Fractures of the *distal phalanx* are among the most common fractures encountered.[6] They can involve the tuft, shaft, or base, often extending into the articular surface of the DIP joint. Tuft fractures are often associated with nail bed injuries and repair of the nail bed often reduces and stabilizes the fracture. Shaft fractures are often stable and patients may function well after healing with a fibrous union. For those cases where the fibrous union is symptomatic, correction of the non-union/fibrous union can be performed.

DIP joint

Bony mallet fractures involve the dorsal aspect of the base of the distal phalanx. The dorsal aspect contains the terminal extensor tendon and the goal of treatment should be to allow healing of a congruent joint without an extension lag. Most of these can be treated with a splint, maintaining the alignment of the joint.[7,8] These fractures tend to have palpable and sometimes visible prominence along the dorsal aspect of the finger following healing, even when the radiographic alignment is anatomical, but this typically does not adversely affect their function. Fractures with volar subluxation of the distal phalanx should be reduced and often require pinning of the joint to maintain the reduction.[9] Several techniques have been described, but all involve reduction of the joint surface.[10–12] Attempted screw placement into the fragment is difficult, even when the fragment appears large on radiograph, and often results in fragmentation of the dorsal bone. Surgical treatment of stable fractures without subluxation is generally reserved for patients who cannot wear the splint continuously during the healing process, as complications such as pin breakage, pin tract infections and subsequent osteomyelitis can occur, and the risks must be carefully considered.

DIP joint dislocations are typically in a dorsal direction (distal phalanx is dorsal to the middle phalanx) (Fig. 7.4). Acute dislocations can often be managed by closed reduction.

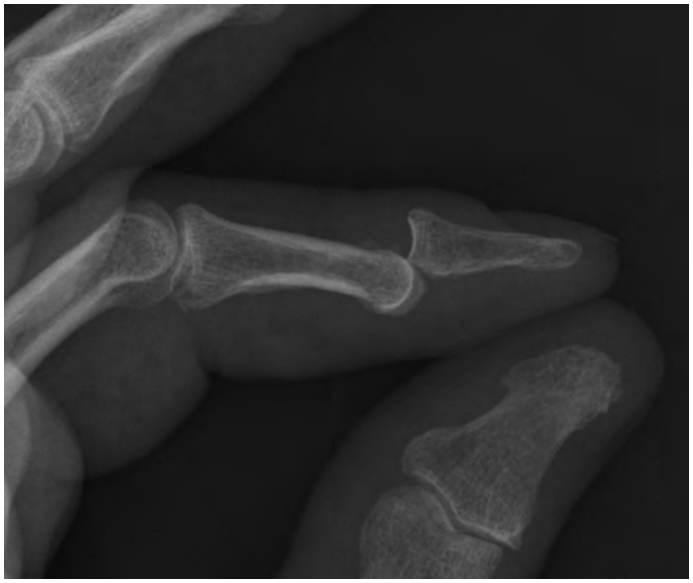

Fig. 7.4 Radiograph of DIP dorsal dislocation of index finger.

Flexing the wrist and MCP joints to take the tension off the flexor tendons, and applying distal pressure to the base of the distal phalanx will often reduce the joint. If this is unsuccessful, it is often due to tissue interposed in the joint – most commonly the volar plate – and an open reduction is necessary.[13] This can be completed through a volar zig-zag incision or midlateral incisions. The joint is exposed and any intervening tissue is removed, taking care to avoid damaging the articular cartilage, and the joint is reduced. Late presentation of DIP joint dislocations will usually require open reduction, using the same technique. Following reduction, these injuries are typically stable and immediate motion can be started using a dorsal blocking splint.

Fractures involving the proximal aspect of the DIP joint can occur as isolated middle phalanx articular fractures, involving one or both condyles and may extend proximally into the shaft (diaphysis). Stable fractures can be managed with protective splinting and followed closely with radiographs. If alignment is maintained, buddy taping and range-of-motion (ROM) exercises can begin around 3 weeks and can be continued for an additional 3 weeks or until radiographic healing is present. Unstable or displaced fractures should be reduced and stabilized either with K-wires or screws.

Middle phalanx shaft fractures

Treatment of middle phalanx shaft fractures depends on stability and fracture pattern (transverse versus oblique/spiral). Stable, non-displaced fractures can be managed with a short period of immobilization (typically 2–3 weeks) followed by protected motion with buddy taping. They should be followed closely, checking for displacement and clinical signs of malrotation. This should be checked with the fingers in flexion. Any evidence of malrotation is an indication for reduction and stabilization.

Oblique fractures tend to be unstable, even following closed reduction, and often result in shortening, which is poorly tolerated by the extensor mechanism. Spiral fractures shorten and rotate. Therefore, these fractures are usually best treated with stabilization. Stiffness is common following these injuries, making postoperative rehabilitation important to optimize the outcome. Plate and screw fixation can provide good stability and allow early motion, but hardware tends to irritate extensor tendons, often resulting in adhesions, necessitating removal and tenolysis to improve tendon gliding. Lag screws are better tolerated than plates, but still require soft tissue dissection, which can result in adhesions and limit postoperative motion. K-wire fixation can often be accomplished with minimal soft-tissue stripping and can easily be removed following healing, but the fixation is not rigid, so the rehabilitation program cannot be as aggressive. These fractures take a longer to heal due to the higher ratio of cortical to cancellous bone (in comparison to the proximal phalanx and metacarpal), but are usually stable enough to remove the K-wires between 4 and 6 weeks. Radiographic healing may take up to 4 months. A removable splint for protection and protected motion with buddy strapping is instituted to maximize motion.

PIP joint injuries

Injuries around the PIP joint are challenging to treat and good outcomes can be difficult to obtain. Stiffness is common and causes difficulty with gripping and grasping activities, as well as fine dexterity. The small size of the articular fracture fragments can make it difficult to maintain reduction. The goal in treating injuries of the PIP joint is to create a congruent joint and begin a rehabilitation program aimed at restoring motion.

The PIP joint functions as a hinge joint with approximately 100° of motion in the sagittal plane (flexion/extension) and minimal motion in the coronal or axial planes. The base of the middle phalanx is a biconcave surface with a central ridge. The volar lateral aspects of the bone are the sites of insertion of the proper collateral ligaments. The volar plate is a fibrocartilaginous structure, which provides additional stability to the joint. It has thicker fibers that insert laterally and thinner fibers, which insert centrally, to the base of the middle phalanx and proximal extensions (checkrein ligaments), which attach to the periosteum on the proximal phalanx. The volar base of the middle phalanx and its curvature play an important role in stability, preventing dorsal subluxation of the middle phalanx.

The head of the proximal phalanx contains two condyles, separated by a groove or sulcus. There is a slight difference on the size of each condyle, allowing the fingers to converge in flexion. The index and middle have a slightly larger radial condyle while the small finger has a slightly larger ulnar condyle.

Injuries involving the PIP joint can involve fracture of the base of the middle phalanx, the head of the proximal phalanx, a pure dislocation, or any combination of these. Fractures involving the base of the middle phalanx include dorsal base fractures (involving the insertion of the central slip of the extensor mechanism), the volar base, resulting dorsal subluxation of the middle phalanx, avulsion of the collateral ligaments, or pilon type of fracture involving the dorsal and volar margins, with a depressed central articular fragment (Fig. 7.5). Fractures involving the proximal phalanx head can involve one or both condyles and can occur with or without proximal extension.

Pure dislocations result from hyperextension and an axial load. They are often dorsal dislocations and are managed

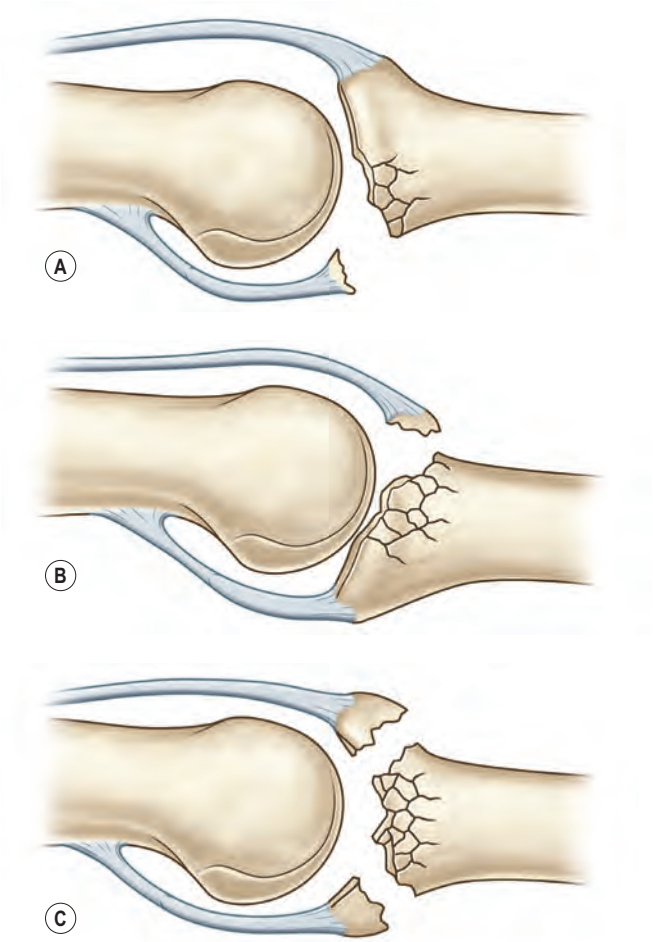

Fig. 7.5 Classification of PIP joint fracture dislocations. **(A)** Volar base fracture resulting in dorsal subluxation of the middle phalanx. **(B)** Dorsal base fracture resulting in volar subluxation of the middle phalanx. **(C)** Pilon type fracture with dorsal and volar base fractures and comminuted, depressed central articular surface.

similar to the DIP joint, with an initial trial of closed reduction (with the wrist and fingers flexed and distal pressure on the base of the middle phalanx). When successful, a dorsal blocking splint and early active flexion can produce good results. When reduction cannot be completed by closed means, open reduction is indicated, either through a volar or midlateral approach.[14]

Volar dislocations are less common, but can lead to late deformities if not recognized and treated.[15] The central slip is often injured and can result in late boutonniere deformities. Following reduction, splinting the PIP joint in extension and active flexion of the DIP joint will allow gliding of the lateral bands. Active flexion can be started following three weeks, as further immobilization of the PIP joint may result in permanent stiffness. Irreducible dislocations are due to an interposed central slip or collateral ligament and require open reduction through a dorsal approach, allowing direct inspection of the central slip.

Middle phalanx base articular fractures

Fracture dislocations of the PIP joint result from an axial load in a dorsal direction or longitudinal direction when the finger

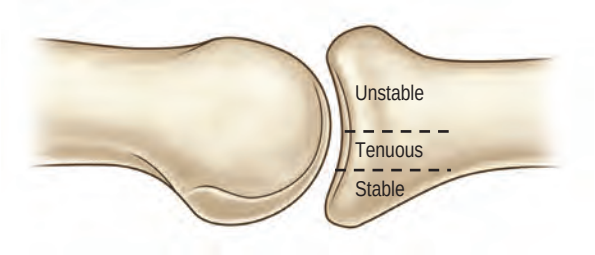

Fig. 7.6 Stability of PIP fracture dislocations. Fractures involving <30% of the articular surface are typically stable. Those involving 30–50% are tenuous and those involving >50% are unstable and have resultant dorsal subluxation.

is slightly flexed. These injuries are classified according to the amount of the articular surface involved. Fractures involving <30% of the articular surface of the base of the middle phalanx are typically stable and can be managed non-operatively. Fractures involving 30–50% of the articular surface are tenuous and often are unstable. Fractures involving >50% are unstable and result in dorsal subluxation of the middle phalanx (Fig. 7.6).[16]

Lateral radiographs should be carefully evaluated for the "V sign", indicative of dorsal subluxation (Fig. 7.7). The two condyles of the proximal phalanx should be superimposed and the base of the middle phalanx should be collinear with the head of the proximal phalanx. There should be a smooth curvature of the joint surface, with a consistent space between the proximal and middle phalanx. If there is convergence of the joint space creating a dorsal "V", the patient may be able to flex the digit at the PIP joint, but this occurs through a hinge process rather than rotation, and the joint surface will degenerate.

Treatment is directed at recreating a congruent joint surface and restoring motion. Stable fractures and those which are classified as tenuous but maintain stable reduction and a congruent joint with no more than 30° of flexion can be managed non-operatively with a dorsal extension block splint. Active flexion is initiated and extension is allowed short of the point of subluxation. These patients should be followed closely to ensure that subluxation of the joint does not develop. Unstable fractures, or those which a congruent joint

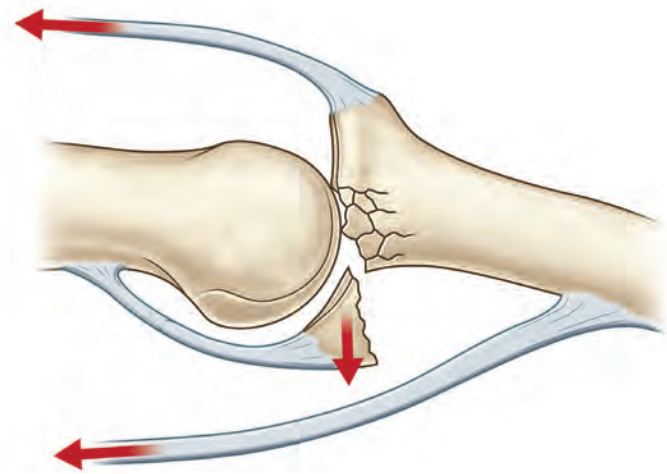

Fig. 7.7 The lateral "V" sign indicating dorsal subluxation of the middle phalanx and associated hinging with flexion.

cannot be established with <30° of flexion, require operative treatment.

A variety of techniques have been described, including extension block pinning,[17,18] open reduction and internal fixation,[17] volar plate arthroplasty,[18,19] replacement arthroplasty,[20,21] and external fixation. All of these techniques have case reports or small series illustrating good outcomes, but there are no prospective studies indicating one technique is better than others for a particular injury.[22–24]

Hints and tips

- Fluoroscopy can be helpful to determine stability of PIP dorsal fracture dislocations.
- The patient can actively flex and extend the digit and the point of subluxation can be determined.
- If this is <30°, an extension blocking splint with active flexion can be used.
- If this is >30°, operative treatment is indicated.

External fixation

A variety of devices have been described for management of PIP joint fracture dislocations.[22–25] The common principle is to produce distraction across the joint, allowing alignment to be maintained through ligamentotaxis. In addition, some devices provide a volar directed force on the middle phalanx to assist in maintaining alignment. They all allow immediate PIP joint motion. Careful attention should be paid to the fragments along the volar base of the middle phalanx as dorsal subluxation can recur if these do not heal in proper position (the volar lip of the base of the middle phalanx is a restraint to dorsal subluxation, so healing of the fracture fragments must recreate the normal curvature).

External fixation systems can be fabricated from K-wires with or without the use of rubber bands, or commercially available devices can be used. Fig. 7.8 illustrates an example of a PIP joint fracture dislocation in the small finger managed with an external fixator fabricated from K-wires.

Technique of external fixation

A 0.045-inch K-wire is inserted through the head of the proximal phalanx, perpendicular to the joint surface (Fig. 7.8). A second 0.045-inch K-wire is inserted through the distal shaft of the middle phalanx, parallel to the DIP joint surface. The proximal wire is bent distally along the radial and ulnar aspects, paralleling the digit. Distal to the second wire, a dorsal proximal bend is created, followed by a dorsal distal bend. The bends should be at the same level on both the radial and ulnar sides. This creates a groove in the proximal wire for the distal wire to be positioned, allowing slight distraction across the joint, which will aid the reduction via ligamentotaxis. Increasing or decreasing the first bend on the proximal wire can adjust the distraction across the joint. This can be performed under local anesthesia and immediate motion is initiated. The fixator is left in place for approximately six weeks and rehabilitation focuses on motion of the PIP and DIP joints. The joint surface will remodel over time.

Internal fixation

Internal fixation of middle phalanx base fractures can be demanding, but good results can be obtained. Postoperative rehabilitation is critical to a good outcome, so the patient must be compliant or the result can be a good radiograph with a stiff non-functional finger. Larger fragments can often be stabilized with small screws, reconstructing the volar base of the middle phalanx (Fig. 7.9). Dorsal fragments can be stabilized with screws or K-wires to reinsert the central slip. Comminution at the base of the middle phalanx creates a greater challenge and the surgeon should be prepared for this as often what appears as a large piece on X-ray is found to be multiple smaller pieces. If the articular surface can be reduced, a cerclage wire may be used to hold the bone fragments in place (Fig. 7.10).[26] his may provide adequate stability to allow early motion.

If the remaining fragments are too small to stabilize, they can be excised and the joint surface is reconstructed. The two most common methods to accomplish this are by advancing the volar plate (volar plate arthroplasty) or replacement of the volar base of the middle phalanx. This can be accomplished by using a portion of the hamate (hemi-hamate graft/replacement arthroplasty, HHRA).

The volar plate arthroplasty was described by Eaton and Malerich in 1980[19] and involves excision of the collateral ligaments, removing the comminuted portion of bone along the volar aspect of the base of the middle phalanx, creating a trough parallel to the dorsal surface of the middle phalanx, and advancing the volar plate to resurface the joint. The volar plate is attached to the bone, either through drill holes or with a permanent suture at the lateral aspect. The joint is temporarily pinned in slight flexion. At 3 weeks, the pin is removed and motion is begun.[18] The volar plate serves to prevent dorsal subluxation of the middle phalanx. The results with this technique can be unpredictable as stiffness and recurrent dorsal subluxation can occur. Long-term follow-up of Dr. Eaton's patients have been published with good results,[27] but there are few recent reports of this procedure.

More recently, the hemi-hamate replacement arthroplasty has been described (Hastings *et al.*, ASSH annual meeting, 1999) and subsequently published. The dorsal distal portion of the hamate has similar anatomy to the volar base of the middle phalanx. Osseous cuts must be precise and the curvature of the volar base of the middle phalanx must be reproduced or persistent dorsal subluxation will occur. This can be rigidly fixed and early motion can be instituted. Published series have shown promising results.[21,28]

Technique of HHRA (Video 7.2)

The finger is approached from the volar aspect with a Bruner incision from the palmodigital crease to the DIP flexion crease (Fig. 7.11). Skin flaps are elevated and retracted. The digital neurovascular bundles are freed so they are not under tension when the joint is exposed. A radial or ulnar based flap of the flexor sheath is created between the A2 and A4 pulleys. The collateral ligaments are released from the middle phalanx, leaving a small stump for later repair, and the volar plate is released from fragments at the base of the middle phalanx. The neurovascular bundles are inspected to make sure they will not tether as the joint is exposed. The flexor tendons are

Fig. 7.10 Postoperative radiograph of cerclage wire (and K-wire) used to repair middle phalanx base articular fracture. Radiographically, the wire does not appear secure dorsally because this is secured around the articular cartilage (not seen on radiograph) and cannot be placed further distally due to the central slip insertion.

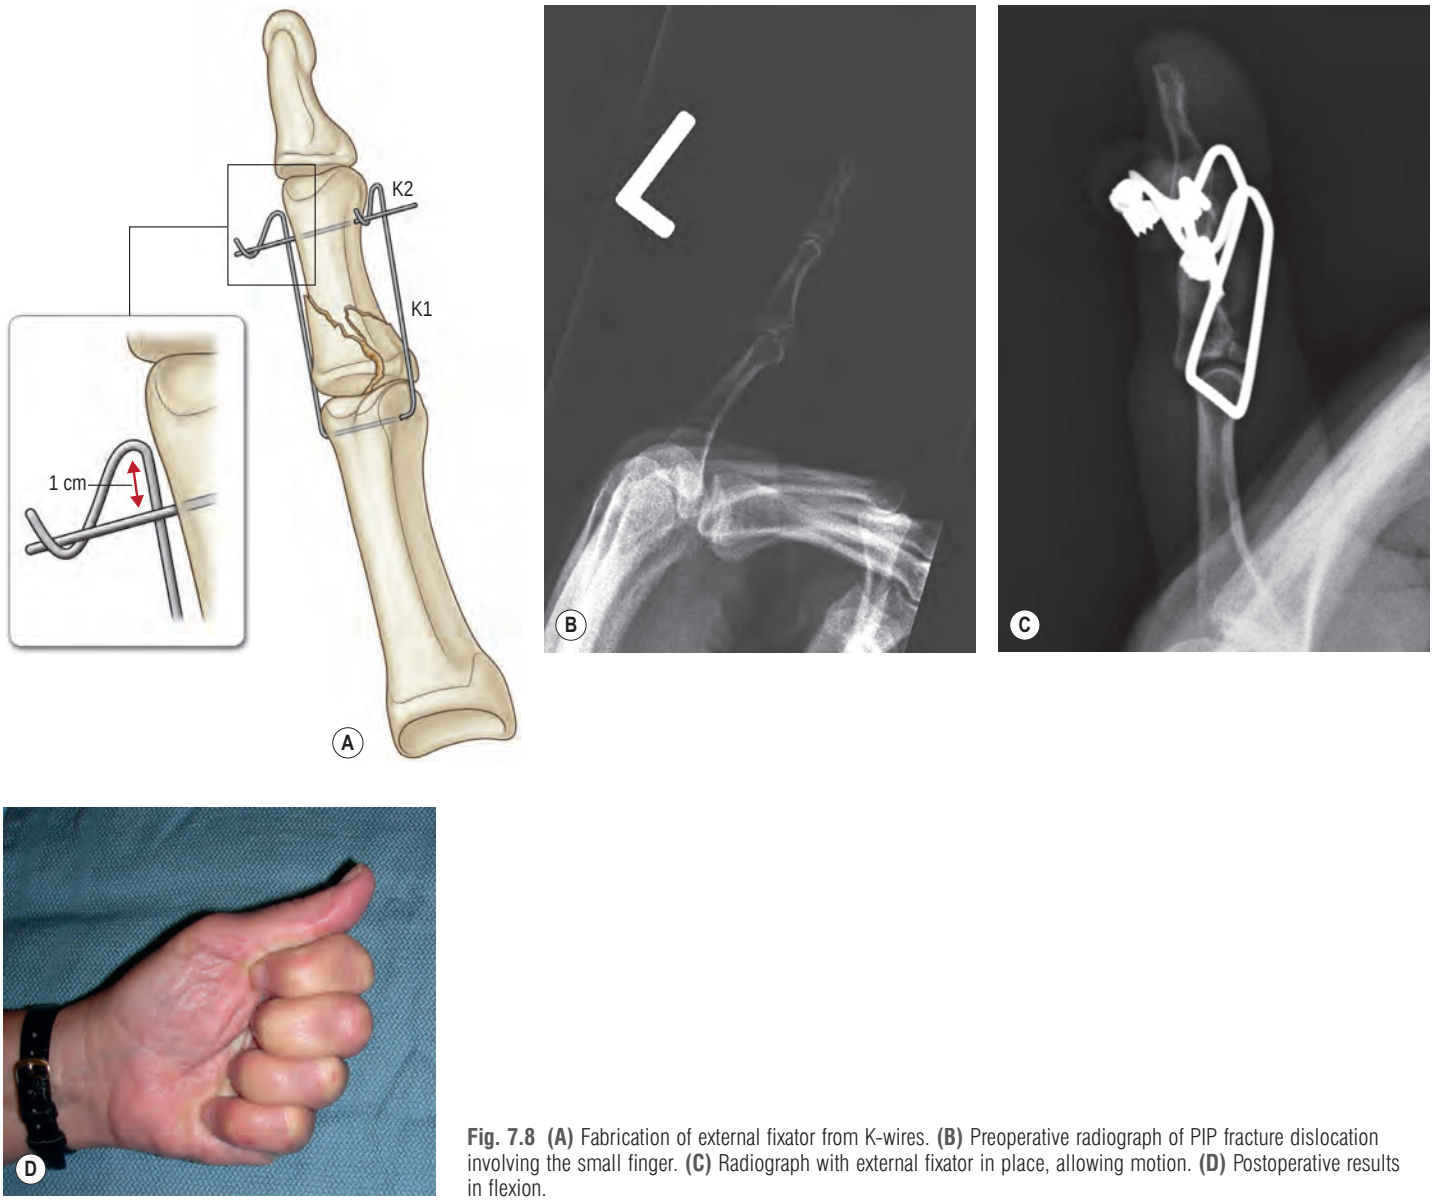

Fig. 7.8 **(A)** Fabrication of external fixator from K-wires. **(B)** Preoperative radiograph of PIP fracture dislocation involving the small finger. **(C)** Radiograph with external fixator in place, allowing motion. **(D)** Postoperative results in flexion.

retracted and the joint is shot gunned open exposing the joint. If resistance is encountered, it is usually due to the collateral ligaments; these are inspected, ensuring complete release from the middle phalanx.

Once the joint is exposed, the loose fragments are removed and a smooth surface is created along the joint surface and along the volar margin of the middle phalanx. This will be the site of insertion of the hemi-hamate graft. Care must be taken to preserve as much of the dorsal cortex as possible as this becomes prone to fracture if insufficient bone remains. The defect for the graft should be large enough to allow fixation of the graft with at least two screws. The dimensions of the defect are measured so an appropriate size graft can be obtained.

Next, a dorsal transverse incision is outlined proximal to the base of the ring and small metacarpals to expose the distal aspect of the hamate. Fluoroscopy can be used to confirm the correct location of the incision. Care is taken to preserve the dorsal sensory branch of the ulnar nerve and a transverse capsulotomy is performed exposing the joint CMC joint of the 4th and 5th metacarpals. The dimensions of the graft are outlined and the graft is harvested slightly larger than necessary, so it can be trimmed to the appropriate dimensions. The axial and sagittal cuts are made using a small saw. A portion of the dorsal hamate can be removed proximal to the axial cut to facilitate the coronal cut from proximal to distal. Alternatively, a portion of the dorsal fourth and fifth metacarpal base can be removed to allow better visualization and access for the osteotomy from distal to proximal. This can be completed with a curved osteotome. The graft is removed and the donor site is closed. The graft is placed along the base of the middle phalanx and provisionally fixed with small K-wires. This step is crucial as proper positioning is necessary for a good outcome. The graft must be placed so the normal curvature

Fig. 7.11, cont'd Postoperative clinical photograph **(G)** and lateral radiograph **(H)**.

of the middle phalanx base is recreated. If the graft is positioned too vertically, dorsal subluxation of the middle phalanx will occur. The joint is reduced and visualized with fluoroscopy. The joint should now appear congruent, with appropriate curvature of the middle phalanx base and without evidence of the dorsal "V", The cartilage on the graft is typically thicker than the middle phalanx, so images may appear as if the graft is not in proper position. This can be ignored since direct visualization will ensure alignment of the joint surface. The joint is opened and the K-wires are replaced with small screws (1.0–1.5 mm), rigidly securing the graft to the middle phalanx. The joint is reduced and fluoroscopy is used to confirm appropriate length of the screws and position of the graft.

The volar plate is repositioned and can be repaired to the collateral ligament stumps or to the graft. K wires can be used to create small holes in the graft to secure the volar plate. The stability of the reconstructed PIP joint (and prevention of dorsal subluxation) is created by the shape and position of the hemi-hamate graft. The flexor sheath can be placed dorsal to the flexor tendons and secured to the opposite side. The skin is closed, the tourniquet is deflated and perfusion of the digit is evaluated. Occasionally, the vessels are in spasm, but the perfusion should be restored within a few minutes. A volar splint is placed from the forearm to the fingertips.[20,29] Rehabilitation is begun around day five with attention to edema control and motion. A figure-of-eight splint is used to prevent the final 10–15° of extension. A removable wrist orthosis is used for comfort to support the donor site.

The average arc of motion at the PIP joint has been reported between 65° and 100° (average 85°) with return to light activities at one month and return to manual labor at 2 months.[21,28]

If the entire base of the middle phalanx is involved, replacement arthroplasty can be considered, but there are only a few case reports of this technique. Hemiarthroplasty has been reported, but currently, the use of the PyroCarbon and surface replacement arthroplasty requires special approval and is not available for routine use in the PIP joint.

Hints and tips

- When positioning the hemi-hamate graft, ensure the graft is positioned to recreate the concavity and volar buttress to prevent dorsal subluxation.
- Postoperative therapy and a motivated patient are critical to obtain a good result following PIP joint fracture dislocations.
- The patient should be informed that the goal is to create a stable joint with motion, but the return of motion to the pre-injury level is rare.
- Some degree of post-traumatic PIP joint arthritis is inevitable, but this does not always correlate with functional outcomes.

Proximal phalanx head fractures

Fractures involving the head of the proximal phalanx are intra-articular and anatomic reduction and early motion of these injuries is the goal. Fractures can involve one or both condyles and classification systems have been described.[30] These fractures are often unstable and require treatment. Stable, non-displaced fractures can be treated with a short period of immobilization with frequent radiographic evaluation. Motion is typically started at three weeks and the finger is protected with buddy taping to an adjacent digit. Displaced or unstable fractures require reduction and stabilization.[30] Fixation is dependent on the size of the fragment and the ability to reduce the joint with closed manipulation. If anatomic alignment can be obtained with closed reduction and the fragment can be stabilized with K-wires, these can be treated as a stable non-displaced fracture. Often, anatomic reduction requires open exposure. The fragments are often large enough to hold at least one small (1.0 mm) screw and a K-wire or two screws. This provides enough stability to begin early motion and minimizes adhesions to the extensor tendons. When both condyles are involved, initial alignment and stabilization of the articular surface is preferred. Then, the

articular surface can be secured to the shaft either with K-wires or plates and screws. Although plates and screws provide good stability, they require more dissection, and adhesions to the extensor tendons are likely to occur, often requiring a secondary procedure to remove the hardware and perform a tenolysis.

Technique of open reduction and internal fixation (ORIF) of unicondylar fractures

A straight or curvilinear dorsal approach is used from the middle of the proximal phalanx to the middle of the middle phalanx. Skin flaps are elevated to expose the extensor tendon distal to the insertion of the central slip on the middle phalanx. The joint can be exposed by splitting the extensor tendons or an incision to the side of the central slip with release of the lateral band. Better visualization is obtained through exposure along the side of the central slip on the side with the fracture. The tendon is elevated off the proximal phalanx, taking care to preserve the insertion of the central slip. A capsulotomy is performed, exposing the head of the proximal phalanx. The fragments are reduced under direct visualization and temporarily stabilized with small K-wires. Fluoroscopy is used to confirm alignment and the K-wires are replaced with screws. The capsule can be repositioned, but does not need to be closed with sutures. If the tendons were split, they are repaired with a non-absorbable suture. The central slip insertion is inspected to confirm it has not been disrupted. The skin is closed and a splint is applied. Rehabilitation begins around the fifth postoperative day with edema control and a figure-of-eight splint, allowing flexion and blocking the final 10° of extension (Fig. 7.12).

Proximal phalanx shaft and base fractures

Fractures of the shaft of the proximal phalanx can be transverse or oblique. Transverse fractures typically have apex volar angulation and are unstable. Fractures of the base are typically transverse. If not reduced and stabilized, the extensor mechanism will shorten, creating an extensor lag at the PIP joint. Percutaneous fixation has the advantage of stabilizing the fracture and allowing early motion while minimizing soft-tissue injury.[31] Two crossed K-wires typically provide enough stability to allow early motion. The wires can be inserted proximally through the base with one on each side of the metacarpal head or distally, with one entering along the head or neck. Alternatively, the K-wires can be placed through the MCP joint in flexion (Fig. 7.13). The disadvantage is the K-wire is passed through the articular surface, but in cases with substantial soft-tissue edema, this may help prevent MCP joint extension contractures. By 3–4 weeks, the fracture is usually stable enough for removal of the K-wires. Protected motion should occur until complete fracture healing. Radiographic healing lags behind clinical healing, which typically occurs around 6 weeks. ORIF with plates and screws can allow immediate motion, but adherence of the tendon to the hardware can be problematic, often resulting in stiffness and need for secondary procedures.[32]

Oblique or spiral fractures should be evaluated in flexion as well as extension. These often shorten obliquely, resulting in a rotational deformity. Fixation can be accomplished with either K-wires or interfragmentary screws if the length of the fracture is two times the length of the diameter of the bone. ORIF with interfragmentary screws allows enough stability to proceed with early active motion and when anatomically

reduced, primary bone healing (Fig. 7.14). Adhesions between the screws and tendons are less when plates are not used, and although removal is sometimes necessary, often the screws can be left in place.

MCP joint fractures and dislocations

Fractures extending into the articular surface of the MCP joint should be reduced anatomically and stabilized, in an effort to minimize the development of post-traumatic arthritis.

Dislocations of the MCP joint can occur in any direction, with dorsal being the most common. The border digits (index and small finger) are most commonly involved (Fig. 7.15).[32] The volar plate ruptures from the proximal phalanx, allowing it to sublux dorsally, with the proximal phalanx extended in relation to the metacarpal. If the volar plate does not become interposed in the joint, these can be treated with closed reduction. The wrist is flexed to relax the flexor tendons and distal pressure is applied to the base of the proximal phalanx. A snap or pop is often felt, which is the reduction of the joint. Radiographs are obtained to confirm the reduction. The joint is typically stable following reduction, but an extension block splint can be used if instability exists.

When the volar plate becomes interposed in the joint, the dislocation is complex and closed reduction attempts are unsuccessful. Dimpling of the skin is seen over the dislocation. Radiographs will show the proximal phalanx and metacarpal collinear (as opposed to the convergence seen with simple dislocations). In the index finger, the lumbrical displaces around the radial side and the flexor tendons around the ulnar side. Distal pressure on the proximal phalanx base tightens the lumbrical and flexor tendons around the metacarpal neck, creating a noose effect and preventing reduction.

In the small finger, the flexor tendons and lumbrical displace radially while the flexor digiti minimi displaces ulnarly, creating the same noose-like effect when closed reduction is attempted.

Fig. 7.15 Radiographs of MCP dorsal dislocation.

Open reduction through a dorsal or volar approach is necessary.[33] The volar approach is more direct, but the metacarpal head pushes the digital nerves closer to the skin and care must be taken to avoid injuring them with the skin incision. The A-1 pulley is released, exposing the metacarpal head, and the volar plate is removed from the joint. The flexor tendons are pulled over the metacarpal, allowing reduction. The dorsal approach does not allow direct visualization, but avoids the risk of injuring the digital nerves with the incision. The extensor tendons are split longitudinally. If the volar plate cannot be easily removed from the joint, it can be split longitudinally, allowing each side to be pushed out of the joint. The joint can then be reduced with distal pressure on the proximal phalanx base while pushing the flexor tendons around the metacarpal head. The joint is typically stable following reduction, but extension block splinting can be used if instability exists.

Hints and tips

- For MCP joint dislocations, attempt closed reduction with the wrist maximally flexed; if unsuccessful, proceed to open reduction.
- The volar open approach is more direct, but it places the digital nerves at risk during the skin incision as they will be tented beneath the skin.
- The dorsal open approach often requires splitting the volar plate to allow complete reduction.

Volar dislocations of the MCP joint are rare. Interposed structures can include the dorsal capsule, extensor tendon junctura, collateral ligament or the volar plate.[33,34] When closed reduction is unsuccessful, open reduction is performed through a dorsal approach.

Metacarpal fractures

Relative to phalangeal anatomy, the metacarpals have more soft tissue between bone and tendons, making them less susceptible to adhesion formation. As such, stiffness following recovery is less common. Metacarpal fractures commonly occur as a result of a direct blow. They can occur through the head, neck, shaft, or base.[35] Fracture configuration is usually transverse, oblique, or spiral. Transverse fractures occur as a result of an axial load with bending and result in apex dorsal deformity. Oblique or spiral patterns occur with torsional stress when an axial load is received.

Indications for operative treatment of metacarpal fractures

A rotational deformity is an indication for operative treatment. Malrotation of 1° at the metacarpal translates to 5° rotation at the fingertip, furthermore malrotation of 5° in the metacarpal can result in 1.5 cm of overlap at the fingertips and thus, evaluation of the fingers in flexion is imperative. Other indications include: shortening of 2–3 mm, articular step-off greater than 1 mm, greater than 25% articular involvement, and multiple fractures. As the amount of energy increases, the amount of comminution increases and stability decreases, and the incidence of multiple fractures increases.

An open wound over the MCP joint region should be treated as a "fight bite", with irrigation of the wound and inspection of the extensor tendon and joint capsule. Alignment of the fingers is evaluated with the fingers in flexion to check for rotation. Three views of the hand (posterior–anterior, lateral, and oblique) are often adequate for diagnosis of metacarpal fractures. Additional images include a Brewerton view to improve visualization of the metacarpal heads. This is an A-P view with the phalanges flexed to 45–60° and in contact with the film (the metacarpals are elevated at a 45–60° angle and the beam is directed 15° from ulnar to radial). A 30° pronated oblique view improves visualization of the ring and small finger CMC joints, while a 30° supinated view helps visualize the index and middle finger CMC joints. CT scans can be used when plain radiographs are inconclusive, multiple CMC fracture dislocations are present, or for complex metacarpal head fractures.

Many metacarpal fractures are stable and can be treated non-operatively. Boxer's fractures (fifth metacarpal neck) are impaction fractures and although there is angulation of the metacarpal neck, they are stable. This term is a misnomer as professional boxers rarely sustain this injury; this injury commonly occurs when a firm object, such as a wall, is struck. The intermetacarpal ligaments stabilize fractures involving the middle and ring metacarpals and often alignment is maintained with minimal shortening.

Forces on the metacarpal bases result in proximal displacement and shortening, due to deforming forces that act on each digit, including the adductor pollicis longus (on the first metacarpal), the extensor carpi radialis longus and brevis (on the second and third metacarpal), and the extensor carpi ulnaris (on the fifth metacarpal). More distal metacarpal shaft or neck fractures result in apex dorsal angulation due to the pull of the intrinsic muscles of the hand.

Metacarpal head fractures

Treatment of fractures involving the metacarpal head involves anatomic reduction and stabilization. A dorsal approach is used and the extensor tendon is split or the sagittal band incised to expose the metacarpal head and MCP joint. Rigid fixation is preferred when possible, so use of small screws placed through the collateral recess or headless screws are preferred, with the goal of early motion. Severely comminuted fractures are problematic as stiffness and arthritis often result. Hemi-arthroplasty, replacing the metacarpal head, has been described, but there is no long-term data to support its routine use.

Metacarpal neck fractures

Metacarpal neck fractures are the most common metacarpal fracture and are more common on the ulnar side of the hand (fifth metacarpal, Boxer's fracture), but can occur in any of the fingers. The amount of apex dorsal angulation that is acceptable varies between patients depending on vocation and avocations, but increases from radial to ulnar. Due to the mobility at the ring and little finger CMC joints, allowing 20°–30° mobility in the sagittal plane. The lack of mobility at the index and middle fingers makes angulation of greater than 15° unacceptable. Acceptable angulation for the ring finger is between 20° and 40°, and the small finger up to 60°.[36] This deformity will result in loss of prominence of the

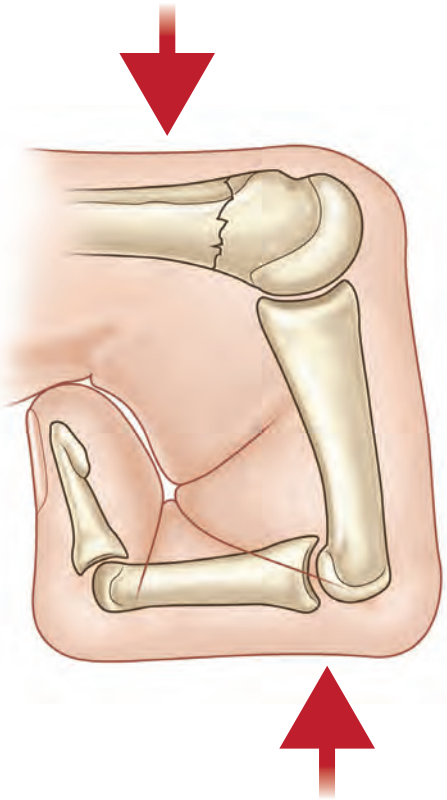

Fig. 7.16 The Jahss maneuver for reduction of a metacarpal neck fracture. The DIP and PIP joints are flexed and dorsal pressure is applied to the PIP joint while counter pressure is applied to the metacarpal shaft proximal to the fracture.

"knuckle" (metacarpal head) with a proximal prominence along the metacarpal neck and occasionally noticeable prominence in the palm; the flexed metacarpal head. This is unlikely to cause functional limitations. Occasionally, pseudo-clawing will develop secondary to the flexed position of the metacarpal head, MCP hyperextension, and PIP joint flexion.

Treatment is dependent on the existing deformity. Closed reduction and immobilization often provides adequate alignment and can be used for definitive management.[37] Flexing the MCP joint to 90°, which relaxes the deforming intrinsic muscles and simultaneously tightens the collateral ligaments, allows for control of the distal metacarpal fragment. The Jahss maneuver involves flexion of the distal interphalangeal, proximal interphalangeal, and metacarpophalangeal joints followed by dorsally directed pressure over the flexed PIP while applying a volar directed force over the apex of the fracture.[38] This maneuver delivers the three-point fixation needed for fracture immobilization and ensures reduction with appropriate angulation and rotation. After the Jahss maneuver has been performed, the hand can be immobilized, either in intrinsic plus position or with MCP and PIP joints extended, as outcomes are similar.[39] A cast or splint is not always successful in maintaining reduction, especially with the swelling associated with the fracture (Fig. 7.16).

Indications for operative treatment include malrotation or unacceptable alignment following closed reduction. Surgical options include closed reduction and percutaneous pinning (CRPP), intramedullary (IM) wires, and open reduction internal fixation (ORIF). The distal location of metacarpal neck fractures makes stabilization with plates difficult.

The MCP joint is flexed and alignment is evaluated, correcting any malrotation. Percutaneous K-wires can be placed from distal, through the collateral recess, or proximal through the metacarpal base. Alternatively, the wires can be placed transverse, stabilizing the fifth metacarpal to the fourth metacarpal, or multiple wires as intramedullary nails (bouquet pinning). This is completed through an incision proximally near the metacarpal base. After exposing the bone, an awl or similar instrument is used to creating an opening in the bone and wires are placed into the shaft. The reduction is confirmed with fluoroscopy and the wires are advanced across the fracture site and into the bone distally. These wires are typically left out of the bone proximally to allow removal following healing, but can be cut and left within the bone. Depending on stability, postoperative immobilization is often required for 4–6 weeks, followed by therapy to regain motion.

ORIF is performed when reduction cannot be attained by closed means or when there is a desire to minimize postoperative immobilization. It is completed through a dorsal approach, either splitting the extensor tendons (small or index finger) or along the side. If adequate stability is achieved, the patient can be transitioned to a removable splint and begin active motion within the first week.

Metacarpal shaft fractures

Isolated metacarpal shaft fractures are often stable and amenable to non-operative management. The intermetacarpal ligaments stabilize the distal metacarpal and maintain alignment. Similar to metacarpal neck fractures, the amount of acceptable apex dorsal angulation is debated, but increases ulnarly and distally. The amount of acceptable angulation is less in the shaft than in the neck, with <10° in the index and middle fingers and approximately 20° in the ring and 30° in the small finger.

Non-operative treatment includes immobilization for about 4 weeks, with the MCP joints flexed and the IP joints free. Operative indications include open fractures, malrotation and unacceptable angulation (Fig. 7.17). Similar to metacarpal neck fractures, closed reduction and pinning can be completed from distal or proximal, transversely into the adjacent metacarpal[40] or with IM wires.[41]

ORIF can be completed with interfragmentary screws for spiral or oblique fractures or with plates and screws for transverse fractures.[42] Coverage of the plate with periosteum, when possible, will decrease tendon irritation and need for later removal. Early motion should be initiated following ORIF to prevent tendon adhesions.

Severely comminuted fractures, those with segmental bone or soft tissue loss can be treated with external fixation, either temporarily until adequate soft-tissue healing for internal fixation, or in some cases definitively.[43–45]

Multiple metacarpal fractures

Multiple metacarpal fractures are often the result of higher energy and result in greater soft-tissue disruption. In addition, the stability provided by the transverse intermetacarpal ligament is lost and stabilization is often necessary.

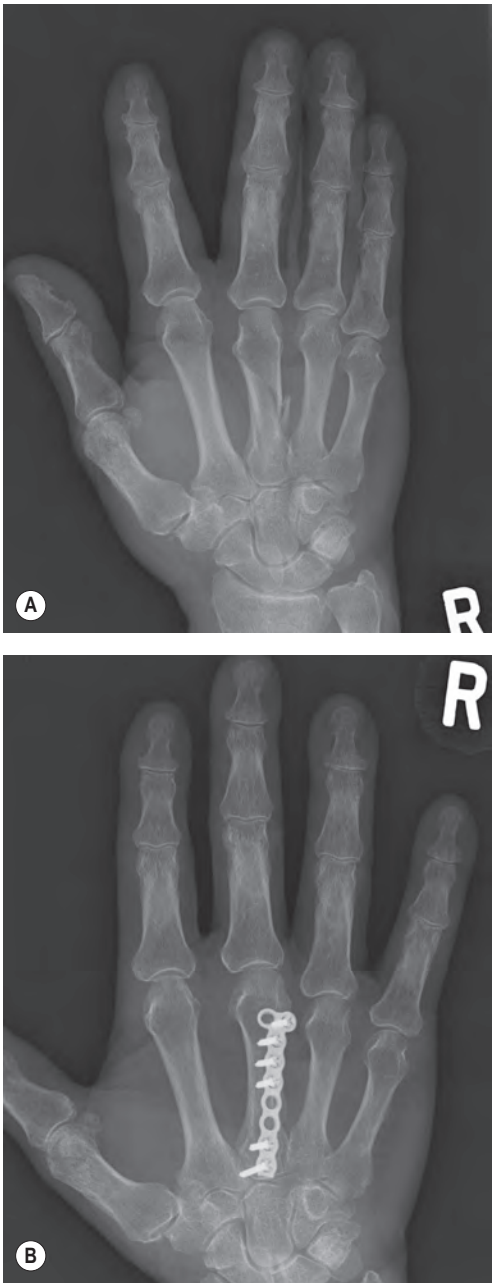

Fig. 7.17 Radiographs of metacarpal shaft fracture treated with ORIF due to malrotation **(A,B).** (See the preoperative clinical picture in Fig. 7.3.)

Technique of ORIF of multiple metacarpal fractures

For two metacarpal fractures, the skin incision can be placed between them. The incision can be curved proximally or distally as necessary as the locations of the fractures are often different in each bone. When three or four fractures are present, more than one incision will be necessary. Dissection is carried to the level of the extensor tendons, taking care to protect sensory branches of the ulnar (fourth and fifth metacarpals) and the radial (second and third metacarpals) nerves. The extensor tendons are retracted and the metacarpal is visualized. There is often hematoma and disruption of the periosteum around the fracture site. A longitudinal incision is made off axis of the metacarpal and the fracture is exposed. The adjacent metacarpal is exposed in a similar manner. Beginning with the most radial fractured metacarpal, any interposed tissue is removed from the fracture site. The fracture is reduced and provisionally stabilized (either with a fracture reduction forceps or K-wires), while alignment of the fingers is checked, making sure there is no malrotation. Interfragmentary screws or plate and screws are applied; fluoroscopy is used to confirm positioning of the hardware and the adjacent metacarpal is addressed. After all fractures are stabilized, the periosteum is closed, creating a layer of tissue between the hardware and the extensor tendons. A splint is applied for comfort and motion can begin as the swelling subsides, typically between 3 and 5 days postoperatively.

CMC dislocations/fracture dislocations

Fractures of the metacarpal base, fracture dislocations of the CMC joint and dislocations involving the CMC joint usually involve the ring and small fingers. Fracture dislocations may involve the capitate and hamate in addition to the metacarpal base.[46,47] These patients will have a prominence along the ulnar side of the hand in the region of the CMC joints. Diagnosis is confirmed in the pronated oblique view, observing the relationship between the carpus and base of the metacarpal. The dorsal aspect should be collinear and when subluxation is present, the metacarpal will be positioned dorsal to the carpus. CT scan can be used when the diagnosis is not clear on plain radiographs or to define fracture geometry. These injuries are often unstable and require operative treatment. Closed reduction and percutaneous pinning is usually successful when performed within the first several days (Fig. 7.18). Delayed presentation usually requires open reduction. Stabilization is obtained using K-wires across the CMC joints. The K-wires are removed at four to six weeks and motion is resumed with protective splinting for comfort. Alternatively, a plate can be applied across the CMC joints with planned removal once soft-tissue healing has occurred.

Treatment: thumb

Injuries to the thumb distal and proximal phalanges can be managed similarly to the fingers. Metacarpal shaft fractures can tolerate more rotation and angulation due to the greater degree of freedom in three planes (flexion/extension, radial/ulnar deviation, pronation/supination) of the CMC joint. Injuries involving the MCP joint, specifically collateral ligament injuries and those involving the CMC joints require special consideration.

MCP joint injuries

The primary motion of the MCP joint is flexion/extension. The radial condyle of the metacarpal head has a greater height (dorsal/volar dimension), allowing rotation (pronation) with increasing flexion. Stability of this joint is provided by the collateral ligaments, the dorsal capsule and the volar plate, the thenar muscles and the adductor pollicis.

Injuries involving the ulnar collateral ligament are more common than the radial collateral ligament (RCL) and have been reported to occur at a 10:1 ratio.[48,49] This typically results from forced abduction (radial directed stress), such as falling with an object, such as a ski pole, in the first web space. The

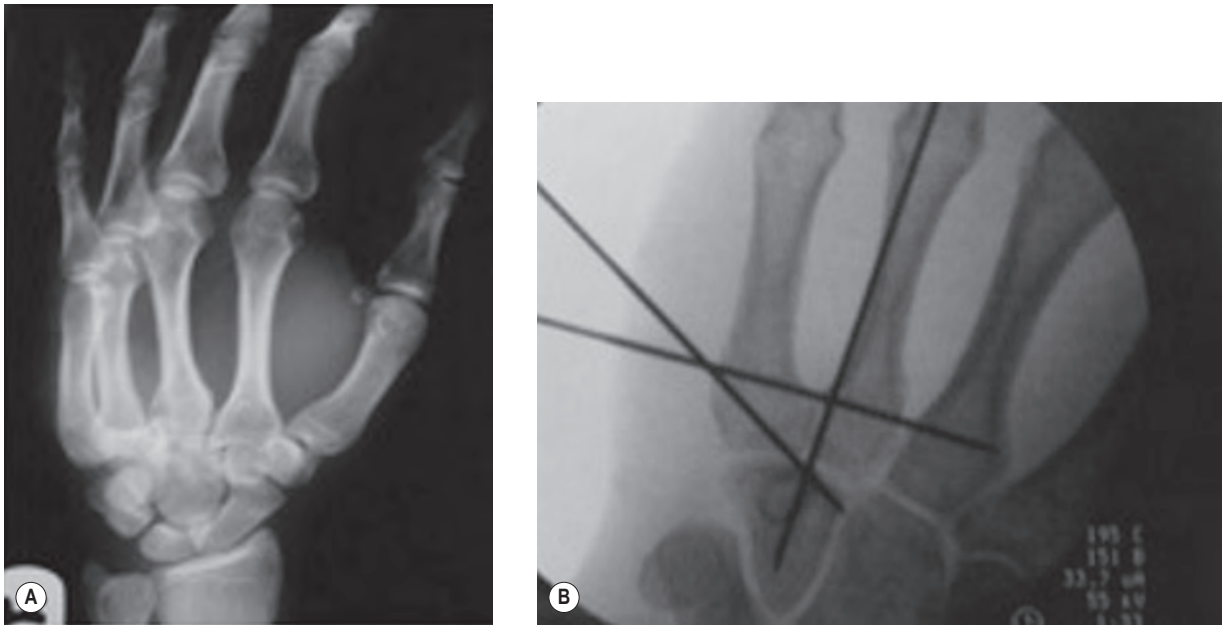

Fig. 7.18 Preoperative radiograph **(A)** and intraoperative flouroscopic image **(B)** of fourth and fifth CMC dislocations.

dorsal capsule tears along the ulnar aspect of the joint and the proximal phalanx supinates around the intact RCL, creating a prominence of the ulnar aspect of the metacarpal head. Although commonly used to describe this injury, the term "gamekeeper's thumb" more accurately defines a chronic injury from repetitive radial directed stress resulting in attenuation of the ligament. This occurred in Scottish gamekeepers while breaking the necks of rabbits between their thumb and index fingers. The term "skier's thumb" is more accurate and the preferred term when referring to acute injuries.

Injuries typically involve disruption of the ligament from the base of the proximal phalanx. This can occur as a bony avulsion or pure ligamentous injury. Larger fractures (those >2 mm), those involving >10% of the articular surface, or those with articular incongruity are best treated with open reduction and stabilization.[49,50]

Isolated ligamentous injuries can be more challenging to diagnose. Avulsion from the proximal phalanx is five times more common than midsubstance tears or avulsion from the metacarpal.[51]

Stener lesion

In 1962, Stener described the injury where the complete ulnar collateral ligament tear retracted proximally and the adductor aponeurosis was interposed between the ligament and the site of avulsion along the base of the proximal phalanx (Fig. 7.19). Without contact between the ligament and bone, healing

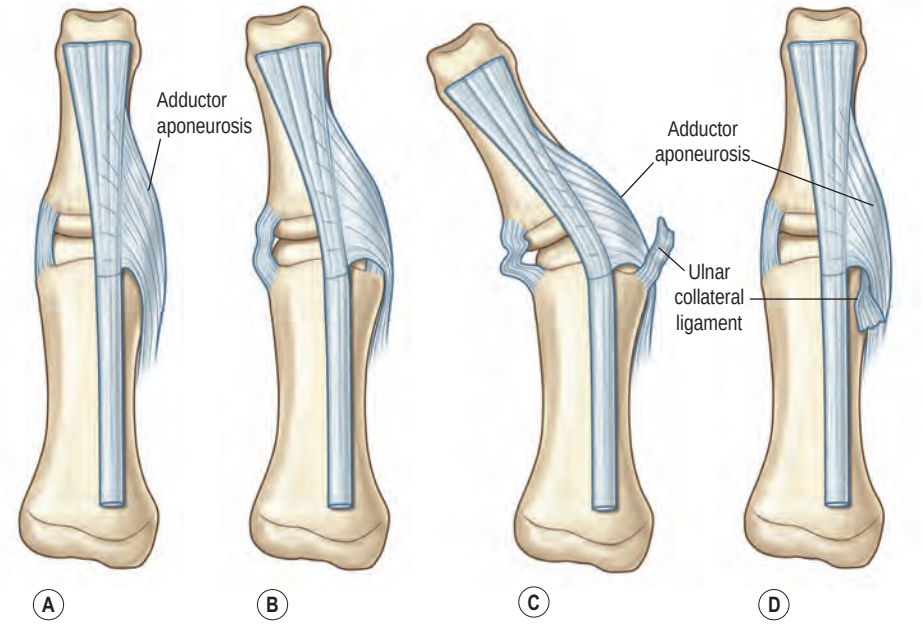

Fig. 7.19 Stener lesion of the MCP joint of the thumb. **(A)** Normal relationship of the adductor aponeurosis. With a radial directed stress **(B)**, the ligament is avulsed from the bone and retracts proximal to the adductor aponeurosis **(C)**. When the joint is reduced, the adductor is interposed between the ligament and bone **(D)**, preventing healing.

cannot occur and chronic instability will result.[52] A complete rupture and retraction of the ligament is necessary for the Stener lesion to occur and therefore it is important to differentiate between partial or complete tears without retraction and those where the ligament has retracted proximal to the adductor aponeurosis. Unfortunately, there is not an absolute clinical criterion for making this diagnosis. The MCP joint is observed for swelling and tenderness along the ulnar side. A palpable mass at the level of the metacarpal neck may be consistent with the retracted ulnar collateral ligament (UCL). The joint should be tested in both flexion and extension, checking for a definite endpoint and comparing to the opposite thumb. Multiple reports exist in the literature, all using different clinical criteria for diagnosis of a complete tear.[53–56] Stress radiographs may assist in making the diagnosis. In addition, MRI and ultrasound can be used in cases of uncertainty following clinical exam and plain radiographs.

When a Stener lesion is present, operative treatment is required. Open ligament repair is the most common procedure performed, but arthroscopic repositioning of the ligament has been described, placing the ligament deep to the adductor aponeurosis and allowing it to heal to the bone.[57,58] Delayed presentation may make it difficult to repair the ligament primarily and reconstruction may be indicated. With late presentation, radiographs should be evaluated for presence of arthritis and when present, arthrodesis should be considered. Reconstruction techniques produce dynamic (tendon transfers and adductor advancement) and static reconstructions (creation of a static restraint to radial directed stress with a graft).

Dynamic reconstructions typically involve transfer of a tendon to stabilize the MCP joint. Procedures include transfer of the extensor indicis proprius (EIP) to the extensor mechanism, transfer of the extensor pollicis brevis (EPB) to the ulnar side of the proximal phalanx[59,60] and advancement of the adductor.[61] The adductor is transferred from its insertion on the sesamoid to the proximal phalanx. Static reconstructions involve replacement of the ligament with a graft, such as palmaris longus tendon, through holes created in the metacarpal and proximal phalanx.[49,62]

Primary repair can be completed as long as there is adequate ligament to repair. When the procedure is greater than 6 weeks following the injury, the surgeon should be prepared to proceed with reconstruction in the event the ligament is not amenable to primary repair. Repair or reattachment too distal or volar will result in loss of flexion and placement too dorsal may result in persistent instability. With an acute injury, it is often possible to determine the site of avulsion and reattach it to the site of avulsion. The ligament runs from dorsal to volar in a proximal to distal direction. The origin of the proper collateral ligament is 7 mm proximal to the joint and 3 mm from the dorsal cortex. The insertion of the base of the proximal phalanx is located 3 mm distal to the joint and 3 mm from the volar cortex (Fig. 7.20).[63] Reattachment can be completed using suture anchors or a pull-out suture exiting the opposite side tied over a button or directly over the bone.

Radial collateral ligament injuries are much less common than their ulnar counterparts. On the radial side of the thumb, the abductor aponeurosis is broad, covering a larger percentage of the joint and there is no interposition of the aponeurosis between the ligament and the bone (Stener lesion). Tear of the RCL typically results from forced adduction on a flexed joint. The dorsal capsule tears along the radial aspect and the proximal phalanx pronates around the intact UCL, creating a prominence of the radial aspect of the metacarpal head. The location of the tear is more variable than the UCL counterpart, with equal frequency between proximal and distal avulsions[48] and mid-substance tears.[49]

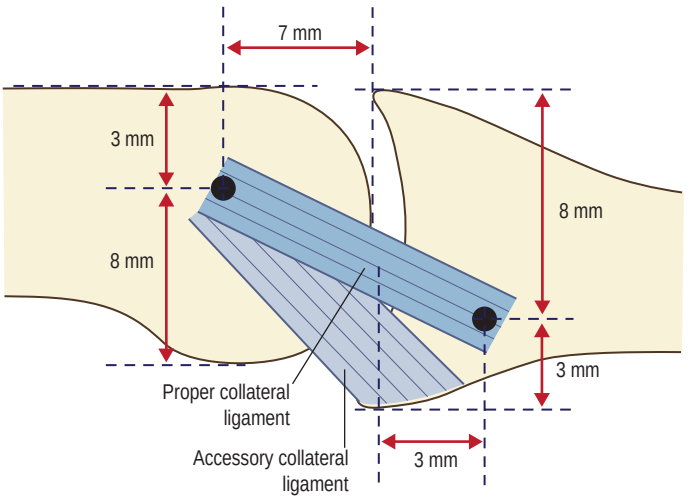

Fig. 7.20 Location of thumb MCP joint UCL on metacarpal and proximal phalanx. The ligament runs from dorsal to volar in a proximal to distal direction. The origin of the proper collateral ligament is 7 mm proximal to the joint and 3 mm from the dorsal cortex. The insertion of the base of the proximal phalanx is located 3 mm distal to the joint and 3 mm from the volar cortex.

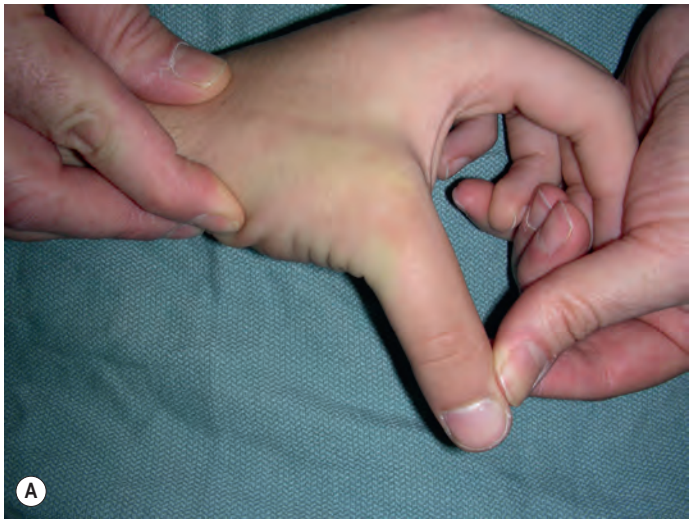
Surgical repair of an acute UCL tear

The skin incision is outlined in a straight or lazy "S" configuration from the ulnar base of the proximal phalanx to the dorsal aspect of the metacarpal head/neck region (Fig. 7.21). After the skin incision is completed, spreading to the level of the adductor aponeurosis is carefully performed. Care should be taken to identify the cutaneous branch of the radial nerve, as injury to this structure can cause a painful neuroma, compromising the final outcome. When a Stener lesion is present, the ligament will be identified proximal to the adductor aponeurosis. The adductor aponeurosis is incised, splitting the fibers until the base of the proximal phalanx can be identified. The ligament is debrided of hematoma and fibrous tissue in preparation for repair. The joint can be opened and irrigated to remove hematoma and the site of attachment is identified. When a larger fragment of bone is present, this can be reduced and secured with a screw or K-wires. When the fragment is small, it can be excised and the ligament repaired to the site of avulsion with a suture anchor. The adductor aponeurosis is repaired and the skin is closed. If there is a concern about the stability of the repair, a K-wire can be placed across the joint, but this is generally not necessary.

A plaster thumb spica splint is applied, leaving the IP joint free and converted to a short arm cast at 1 week. Motion of the IP joint is encouraged to prevent adhesions of the extensor tendons. At 4 weeks, the cast is removed and a therapy program is instituted to regain motion. A thermoplastic orthosis is used between exercises with avoidance of radial directed stress. Pinch strengthening is begun at 10 weeks and unrestricted activities are allowed at 12 weeks. Final motion is typically 80% of the non-injured side with grip and pinch strength approximately 90% of the contralateral side.



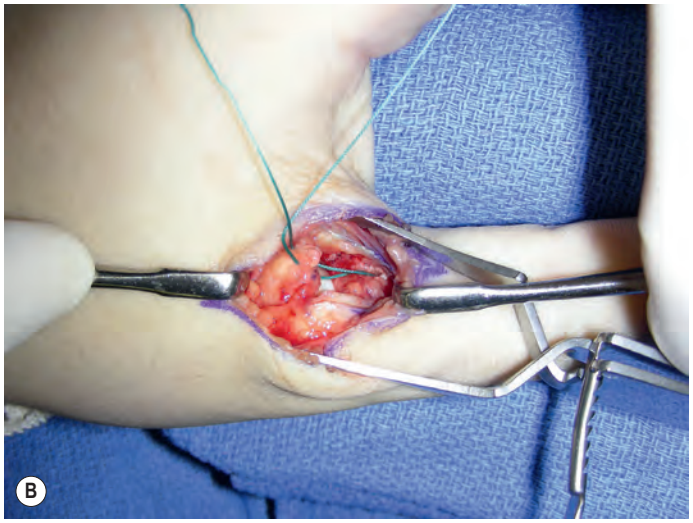


Fig. 7.21 Surgical repair of thumb MCP joint UCL. **(A)** Preoperative clinical photograph illustrating laxity at MCP joint. **(B)** Intraoperative photograph illustrating suture anchor in base of proximal phalanx with suture through the UCL.

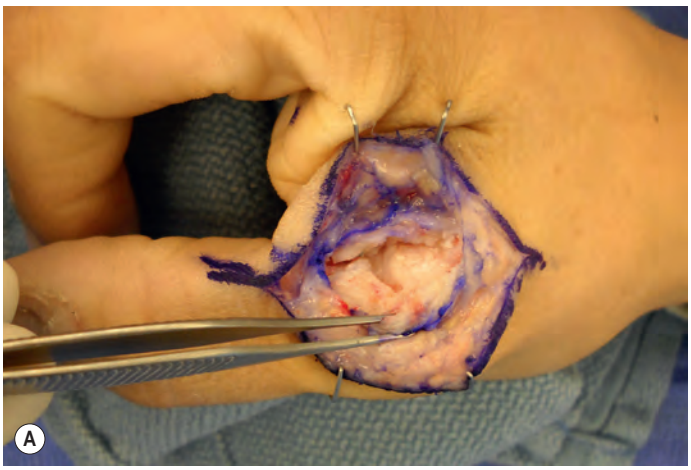
Reconstruction of chronic UCL tear with tendon graft

This creates a static restraint to radial directed stress and although not the same as the ligament prior to the injury, can provide a stable thumb MCP joint. The approach to the joint is the same as for acute repairs. After exposing the joint, the remaining collateral ligament is excised. The site of origin and insertion of the graft is identified (Fig. 7.22). A tendon graft is harvested using palmaris longus when present or a strip of flexor carpi radialis (FCR) in the event the palmaris longus is not present. The graft can be attached either through drill holes or with tenodesis screws (alternatively, the collateral ligament can be left attached to the metacarpal and the graft secured to the native ligament). The tendon is attached to the metacarpal head just dorsal to the dorsal volar axis, approximately 8 mm from the joint surface. The proximal phalanx insertion site is 3 mm from the volar cortex and 3 mm distal to the joint. The tendon can be attached to the bone with suture anchors, biotenodesis screws or transosseous sutures. The joint is pinned in slight flexion and ulnar deviation. The adductor aponeurosis and skin incisions are closed and a thumb spica splint is applied. Postoperative rehabilitation is similar to acute repairs except the joint is immobilized for 6 weeks and pinching is avoided for 3 months. Unrestricted activities are allowed at 4–5 months. Motion tends to be less following reconstructions than acute repairs, but 70% of the flexion/extension and 80% grip and pinch strength can often be obtained. The goal of the reconstruction is to produce a stable painless thumb and the slight loss of motion is compensated for at the CMC joint.

Thumb metacarpal fractures

Fractures of the thumb metacarpal are more tolerant of displacement and rotation due to the motion in three planes (flexion/extension, abduction/adduction, pronation/supination). Fractures can occur through the shaft or the base at the metaphyseal–diaphyseal junction. Angulation <20° can be tolerated, but greater than this may result in compensatory MCP joint hyperextension, compromising the function of the thumb. The distal fragment tends to supinate, so closed reduction is performed by applying longitudinal traction, downward pressure of the apex of the thumb, and pronation and



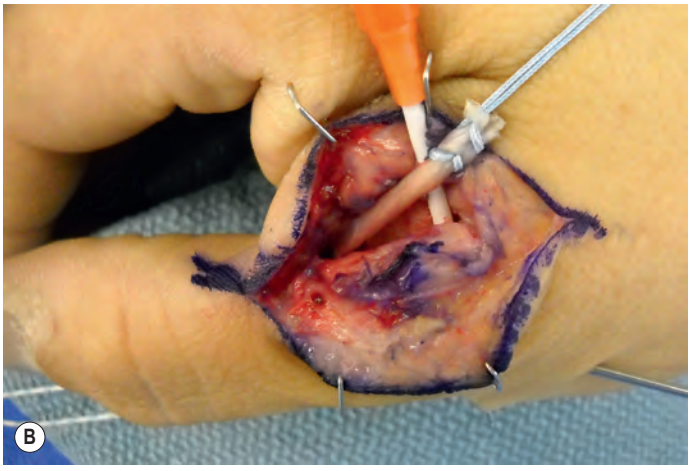


Fig. 7.22 Technique of thumb MCP joint UCL reconstruction with palmaris longus tendon graft. **(A)** Intraoperative exposure of the joint following resection of scar and remnants of UCL. **(B)** Tendon graft secured to the proximal phalanx in preparation for securing to metacarpal.

extension of the distal fragment. K-wires can be used to stabilize the fracture or, alternatively, plates and screws.

Thumb CMC joint injuries

The anatomy of the thumb CMC joint resembles two interlocking saddles (thumb metacarpal and trapezium), which allow motion parallel (abduction and adduction) and perpendicular (pronation and supination). Joint stability is maintained through multiple ligaments, with the anterior oblique, posterior oblique, anterior and posterior intermetacarpal and dorsal radial ligaments being the major stabilizers.[64] Compressive forces are 12 times greater at the CMC joint than the tip of the thumb, so arthritis may develop if incongruence is present at the CMC joint.[65,66]

Isolated dislocations occur much less frequently than CMC fracture dislocations (Bennett and Rolando fractures). When pure dislocations occur, they are dorsal and result from an axial compression of a flexed thumb. There are 16 ligaments that stabilize the thumb CMC joint, with some considered major and other considered minor stabilizers. The anterior oblique (volar beak ligament) and the dorsal radial ligament are disrupted to allow dorsal dislocation of the metacarpal. Partial ligament tears may result in subluxation and may be treated with reduction and immobilization, typically with K-wires. Complete ligament tears result in dorsal dislocation and are unstable. Because these injuries are rare, most reports in the literature are case reports or small series.[67,68] For acute and chronic dislocations, ligament reconstruction with a portion of the FCR, as described by Eaton and Littler[69,70] should provide reasonable results.

Fracture dislocations are much more common. The *Bennett fracture* (Video 7.1 ▶) is a fracture subluxation, which occurs when a flexed metacarpal receives an axial load (Fig. 7.23).[71] The Bennett fragment is maintained due to the attachment of the anterior oblique ligament, while the remainder of the metacarpal subluxes radially, dorsally, and proximally, due to the abductor pollicis longus and adductor pollicis muscles. The goals of treatment of this injury are to restore stability to the joint by allowing the displaced metacarpal to heal to the Bennett fragment and restoration of articular congruity to the base of the thumb. Bennett fractures can be treated with closed reduction and pinning. Indications for ORIF include inability to reduce the fracture by closed means. Some surgeons advocate ORIF when the Bennett fragment involves a substantial amount of the joint.[72]

The reduction is performed with longitudinal traction on the thumb, pressure at the metacarpal base, and pronation. It is not necessary to secure the Bennett fragment as long as alignment is maintained and K-wires can be placed in a variety of configurations, most commonly, either through the metacarpal base and into the trapezium or trapezoid, or through the thumb metacarpal and into the index metacarpal. The hand is immobilized in a thumb spica cast, with the fingers and IP joint of the thumb free, for 4–5 weeks, followed by a protective orthosis for an additional 4 weeks.

When ORIF is performed, a Wagner incision is used, along the junction of the glabrous and non-glabrous skin, extending from the mid-metacarpal to the region of the FCR tendon. The thenar muscles are reflected subperiosteally, and the capsule is incised to expose the joint. Hematoma is removed from the joint, and then the fracture is reduced and stabilized with small screws or K-wires. If screw fixation is used, a removable orthosis and motion can be initiated at one week.

The *Rolando fracture*, as originally described, is a metacarpal base fracture with a "T"- or "Y"-shaped intra-articular pattern.[73] Currently, the term is used to describe any comminuted intra-articular fracture of the base of the thumb metacarpal. The treatment goals are the same as for the Bennett fracture, but may be more difficult to obtain, as the comminution often makes it difficult to align the articular surface. The true Rolando fracture can be treated with closed reduction, using the same technique as for the Bennett fracture. Comminuted fractures are more difficult to treat and open reduction can lead to devascularization of the small fracture segments. Bone grafting can be used if there is extensive comminution or a void in the metaphysis, to assist with healing. Stabilization is best accomplished with K-wires from the thumb to index metacarpal or an external fixator. Various designs have been described, including stabilization to the trapezium, or multiple rods securing the thumb to the index metacarpal[74] or in a triangular configuration, securing the thumb and index metacarpals to the radius.[75]

Hints and tips

- Metacarpal base articular fractures are often more comminuted than the appearance on radiographs, and the thumb does not develop stiffness following immobilization, so the authors prefer K-wire fixation for these fractures.
- Reduction of thumb metacarpal base articular fractures requires distraction, pronation and abduction of the metacarpal base.
- K-wires can be placed in the metacarpal, the fracture reduced and the K-wires advanced into the trapezium.

Pediatric fractures

Classification of pediatric fractures has been described in Fig. 7.2, Salter–Harris classification of fractures, but fractures of the distal phalanx and the proximal phalanx head deserve special mention. Generally, pediatric fractures are stabilized with smooth K-wires. Effort should be made to minimize the number of passes through the physis and remanipulation of the fracture.

The Seymour fracture is a fracture involving the epiphyseal region of the distal phalanx (Fig. 7.24).[76] This injury appears as an open mallet fracture, with extension of the proximal segment with the attachment of the extensor tendon and flexion of the distal fragment with the FDP attached. There is a transverse laceration of the nail matrix, which is often interposed in the physeal fracture site. The nail plate is displaced proximally out of the eponychial fold. Treatment is irrigation and debridement with reduction of the fracture and repair of the nail matrix. The nail plate is used as a stent on the proximal nail fold to help maintain reduction. A splint of longitudinal K-wire is used to maintain the reduction.[77–79]

Proximal phalanx neck fractures

Fractures of the proximal phalanx neck and occasionally the middle phalanx neck are common in children and result from withdrawal of a finger when caught in a door. These are visualized on a lateral X-ray and are classified according to

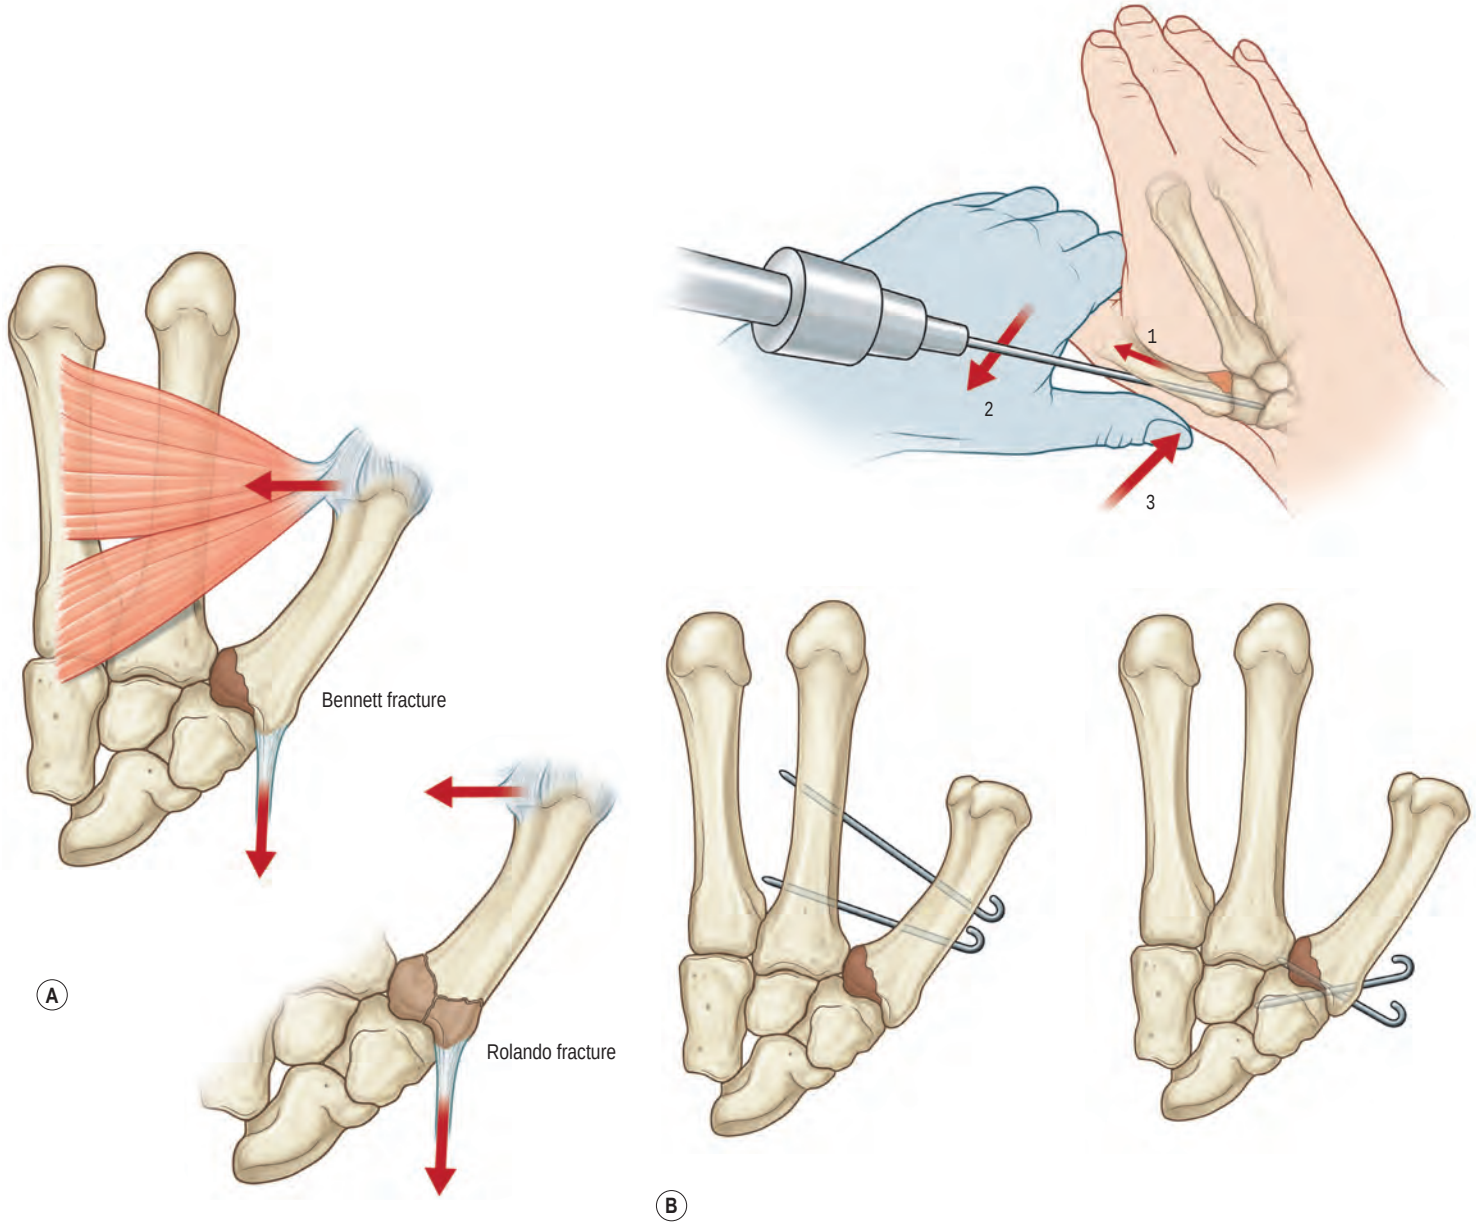

Fig. 7.23 **(A)** Comparison of Bennett and Rolando fracture (Bennett fracture has one articular segment while Rolando fracture has at least two articular segments, commonly in "Y" or "T" configuration). **(B)** Reduction (distraction, pronation, and dorsal pressure) and pinning of thumb CMC fracture dislocation (Bennett fracture and Rolando fracture).

the amount of displacement (Fig. 7.25).[80–82] The distal fragment can rotate 90°, so the head is directed dorsally and the fracture surface is volar. These should be reduced anatomically and stabilized with K-wires. If alignment is not restored, a bony block may occur in the retrocondylar fossa resulting in decreased flexion. If this occurs, an ostectomy of the volar spike can be performed to remove the bony block and restore flexion.

Complications

Many patients with phalangeal fractures have some residual stiffness following treatment. This is not a complication, but a result of the need for tendons to glide along all sides of the proximal and middle phalanx and the adhesions that form between the bone and the tendon.[32]

True complications include infection, loosening of K-wires, malunion, non-union and compartment syndrome. Infections should be managed with antibiotics. If K-wires have been used, a course of antibiotics will often allow enough healing prior to removal of the implant that the fracture is stable.[83] Malunions can be extra-articular or intra-articular and can occur in any bone in the hand and may cause cosmetic or functional problems. Angular and rotational malunions often cause dysfunction, which must be corrected. Non-unions are uncommon and typically occur with infection, substantial bone loss or associated severe soft tissue injuries. They can be

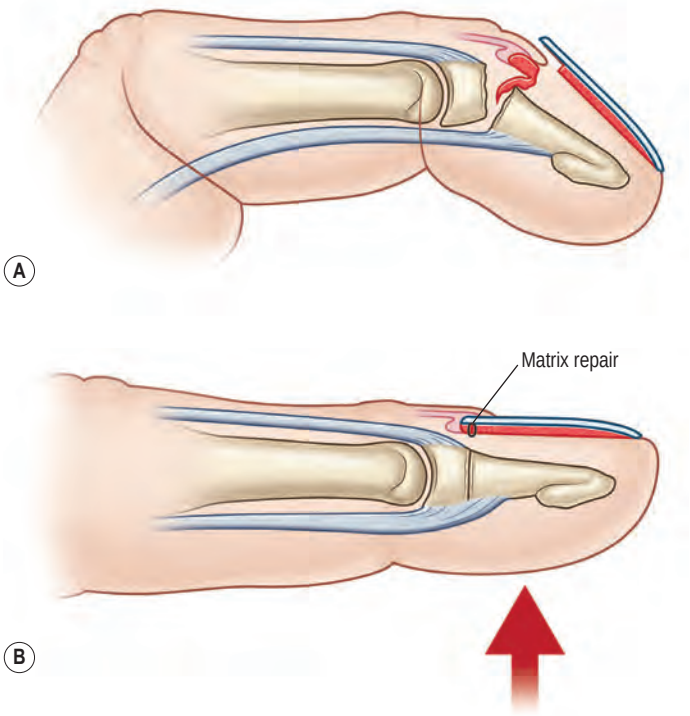

Fig. 7.24 **(A)** Seymour fracture with nail bed interposed into physis and nail plate dorsal to eponychial fold and **(B)** following repair of nail matrix.

atrophic or hypertrophic and are managed with resolution of the infection, providing a stable soft tissue environment and reconstruction with stable fixation and, in some instances, bone grafting (atrophic non-unions).

Compartment syndromes are not common in the hand, but may occur with crush injuries. Notable pain following a crush injury to the hand, which is exacerbated by passive stretching of the digit, should raise the suspicion for compartment syndrome. In the unresponsive patient with substantial swelling, compartment pressures can be measured. Pressures >30 mmHg or within 30 mm of diastolic pressure should be treated with urgent fasciotomies, thereby releasing the interosseous, thenar, hypothenar, adductor pollicis muscles and transverse carpal ligament.

Secondary procedures

Secondary procedures can be performed to correct a problem, such as malunion or non-union, or in an attempt to improve motion for stiff digits. All wounds should be healed and soft tissues supple before secondary procedures are performed.

Malunion correction

Malunion typically occurs as angular or rotational deformities. Correction of an angular malunion involves an opening or closing wedge osteotomy with internal fixation.[84] Closing wedge osteotomies are easier to perform and are stable, while opening wedge osteotomies often require bone graft. These are best treated at the site of the malunion. Rotational malunions are treated with derotational osteotomies. These can be performed as transverse[85,86] or step-cut osteotomies[87–89] and rigid

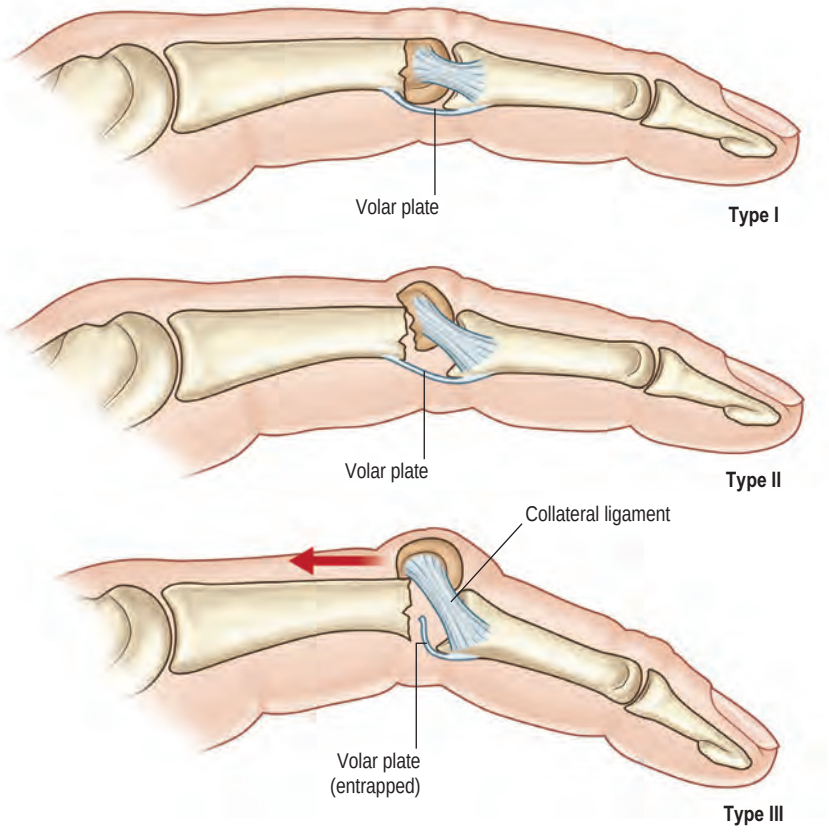

Fig. 7.25 Pediatric proximal phalanx neck fractures. Type I is a stable, non-displaced fracture. Type II is a fracture with dorsal displacement of the condyles, but contact between the bony surfaces. Type III fractures are defined by dorsal displacement of the condyles with rotation of 90°, so the fracture surface is perpendicular to the dorsal aspect of the proximal phalanx.

fixation is used to provide stability and early motion (Fig. 7.26). Intra-articular malunions can be corrected with an intra-articular[90] (Fig. 7.27) or extra-articular[91] osteotomy.

Figs. 7.26 & 7.27 appear online only.

Non-union correction

Non-unions are rare in the hand, but can be managed by following principles of non-union reconstruction in long bones.[92] Any underlying infection should be treated and a good soft-tissue envelope should be present prior to reconstruction. Hypertrophic non-unions demonstrate bone formation around the fracture without bridging bone at the non-union site. These will typically heal if stability and compression are provided at the non-union site. Atrophic non-unions require bone grafting in addition to internal fixation. Metabolic conditions, such as vitamin D deficiency, should be evaluated with blood tests and corrected if necessary, as low vitamin D levels will prevent ossification.

Hardware removal, tenolysis, capsulotomy

Patients with residual stiffness may benefit from secondary procedures to improve motion. When internal fixation with plates and screws has been used for initial treatment of the fracture, adhesions between the plate and the extensor tendons often occur. Removal of the hardware and extensor tenolysis will often improve flexion. Indications include a motivated patient who will be compliant with the postoperative therapy program, complete osseous healing and supple soft tissues with passive motion that is greater than active motion. When joints become stiff, the results are much less predictable and outcomes not as good. Results following release of MCP extension contractures are better than PIP flexion or extension contracture release.

Hints and tips

- Tenolysis can be performed as a wide-awake procedure, using local anesthesia with epinephrine, avoiding the use of a tourniquet.
- Tenolysis knives are specifically designed to free adhesions between tendon and bone, flexor sheath and the tendons themselves.
- Active motion after releasing adhesions will often allow rupture of additional adhesions, illustrating when adequate release has been completed.
- Begin therapy, focusing on active motion, immediately following the release. This can be demonstrated in the OR when done wide-awake.

Future directions

There have not been substantial advances in management of hand fractures over the last decade. K-wires are still commonly used and provide functionally stable fixation. Ideally, something to minimize adhesions, whether something used locally or systemically, or increase the rate of bony healing could improve motion and ultimate outcome. Comparative studies including randomized trials comparing fixation methods may help surgeons determine better treatments.

Fractures and dislocations of the wrist and distal radius

Steven C. Haase and Kevin C. Chung

SYNOPSIS

- Wrist injuries are common, and proper management relies on an understanding of normal anatomy, alignment, and kinematics.
- Scaphoid fractures can be subtle, and due to the precarious blood supply to this bone, may go on to nonunion if not properly managed.
- Indications for scapholunate ligament repair and/or reconstruction depend on the patient's symptoms and on the chronicity of the injury.
- For distal radius fractures requiring stabilization, external fixation and dorsal plating have largely been supplanted by volar fixed-angle locking plates, which provide the necessary stability for fracture healing, even in osteoporotic individuals.
- Ulnar styloid fractures only require fixation in the setting of distal radioulnar joint instability.

Introduction

The wrist is a complex articulation that connects the hand to the forearm. Entire textbooks have been devoted to detailed discussions of the anatomy, physiology, and pathology of this important joint. This chapter will review some of the more common injury patterns seen in the wrist, including fractures of the carpal bones, ligamentous injuries of the wrist, and fractures of the distal radius and ulna.

The epidemiology of wrist fractures has been investigated in detail. Each year, nearly 1.5 million hand and wrist fractures are estimated to occur in the United States, accounting for 1.5% of all emergency department visits.[1] Of these, approximately 208 000 are carpal fractures.

The scaphoid is the carpal bone most commonly fractured; it accounts for 60–80% of all carpal fractures.[2,3] Incidence estimates range from 2.9/10 000 person-years in the United Kingdom[4] to 12.1/10 000 person-years in the US military population.[5] The highest incidence is found in the 20–24-year-old age group, and there is a clear male predominance.[4,5]

Distal radius fractures are the most common upper extremity fracture; the annual incidence is estimated at 643 000 fractures per year in the United States.[1] When the incidence is examined by age, there are two distinct peaks identified (Fig. 8.1), representing the 5–14-year-old group (55.7/10 000 person-years) and the 75–84-year-old group (35.2/10 000 person-years).

Although a common injury, these fractures should never be treated casually. There is significant potential for patient disability if these injuries are not managed with great care and expertise. Khan and Giddins' review of hand and wrist surgery negligence claims in the UK from 1995–2001 revealed that wrist fracture was the most common condition in which negligence was alleged, comprising 48% of claims.[6]

Basic science/disease process

Anatomy

Normal anatomy of the wrist is covered in detail in Chapter 1 of this textbook. However, there are a few points that merit emphasis in this chapter with regard to these injuries.

The vascularity of the scaphoid bone bears particular consideration. The scaphoid bone has a single dominant vascular pedicle that enters from the distal pole of the bone. Therefore, the proximal pole relies wholly on the intramedullary blood supply for survival. It is for this reason that proximal pole fractures typically take longer to heal and have increased incidence of nonunion. Furthermore, in cases of nonunion, the proximal pole is susceptible to avascular necrosis, which further complicates these injuries.[11]

Detection of ligamentous injuries of the wrist is made easier by attention to the Gilula arcs (Fig. 8.4). Dr. Gilula, a radiologist, described three arcs that can be noted on the posteroanterior radiograph of the wrist, formed by the

Historical perspective

The carpus was not well described until the 1500s, when Andreas Vesalius first identified the eight carpal bones. Before then, drawings of the hand connected the metacarpals directly to the distal radius, with no mention of wrist anatomy. Carpal bones are generally named for their shapes. For example, the scaphoid resembles a boat, whereas the lunate resembles the crescent moon. The names of the carpal bones were not solidified until 1955 when *Nomina Anatomica* established the official nomenclature for the carpal bones that we use today (Fig. 8.2).[7]

Historically, the carpal bones have been grouped together in various ways, based on function and kinematics. The earliest classification separates the wrist joint into two rows, consisting of the distal carpal row (trapezium, trapezoid, capitate, hamate) and the proximal carpal row (scaphoid, lunate, triquetrum). The carpus can also be divided into columns: a radial column (scaphoid, trapezoid, trapezium), a central column (lunate, capitate), and an ulnar column (triquetrum, hamate). The pisiform bone is not involved in wrist motion, so it is not typically included in these groupings.

Abraham Colles (1773–1843) is credited with the first clinical description of fractures of the distal radius. His 1814 manuscript provides an eloquent description of closed reduction and splinting, in an era before the development of radiographs, anesthesia, and plaster of Paris. On the results of treatment, he proclaimed, "The cases treated on this plan have all recovered without the smallest defect or deformity of the limb, in the ordinary time for the cure of fractures."[8]

More than 200 years later, closed reduction and immobilization is still the predominant method of treatment for distal radius fractures, though internal fixation has been steadily gaining in popularity.[9] It is now commonly believed that restoration of anatomic alignment of the distal radius leads to better outcomes, although the age and activity level of the patient certainly contribute to this equation. To achieve these ends, technology has advanced to allow for precise fracture fixation with a variety of techniques. Over the past several decades, pins-and-plaster and external fixation systems have largely given way to internal fixation methods, heavily encouraged by AO (Arbeitsgemeinschaft für Osteosynthesefragen). AO is a Swiss organization started in the late 1950s for promoting more consistent fracture care, chiefly using rigid internal fixation. Despite the development of hundreds of fixators, plates, rods, and other devices, there is little high-level evidence to support the use of one technique over another. In some ways, Colles' conservative approach was probably correct – many patients, especially the low-demand elderly population, achieve excellent outcomes even in the presence of significant malunion or malalignment.[10]

Many textbooks discourage the use of eponyms, believing them to be of historical interest only. However, the various eponyms for distal radius fractures often convey precise information regarding the fracture pattern and the type of injury sustained. The major eponyms for distal radius fractures are: Colles fracture (extra-articular fracture with dorsal displacement of distal fragment) (Fig. 8.3A); Smith fracture (also called reverse Colles fracture; extra-articular with volar displacement of distal fragment) (Fig. 8.3B); Barton fracture (intra-articular shear fracture of the radiocarpal joint, may be dorsal or volar) (Fig. 8.3C,D); and Chauffeur fracture (intra-articular fracture involving the radial styloid) (Fig. 8.3E). For some cases, these eponyms may help in selecting a treatment modality.

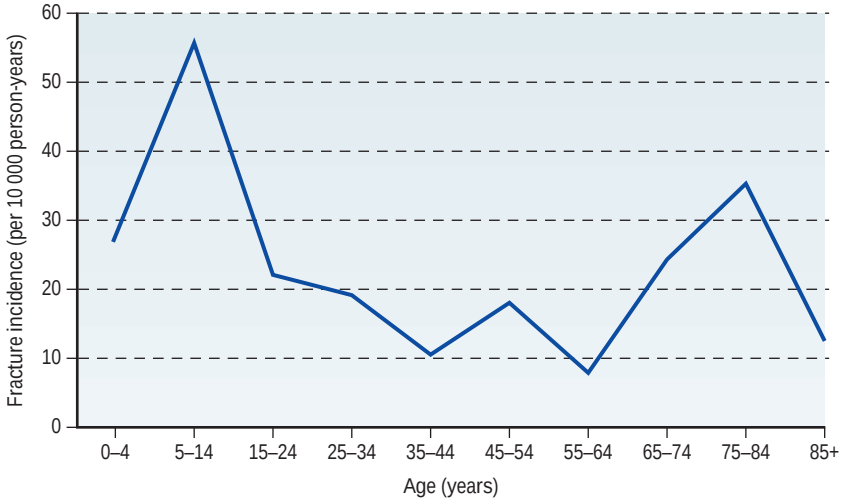

Fig. 8.1 Age-related variation in radius/ulna fracture incidence. *(Data from Chung KC, Spilson SV. The frequency and epidemiology of hand and forearm fractures in the United States.* J Hand Surg Am. *2001;26:908–915.)*

proximal and distal articular surfaces of the proximal row, and the proximal articular surface of the distal row. Increased joint space or deviation of carpal bones from these lines is indicative of wrist instability.[12]

The bones of the wrist are linked by a complex system of intrinsic and extrinsic ligaments (Fig. 8.5). The strength of these wrist ligaments helps determine the injury patterns observed. For example, the very strong short radiolunate ligament tends to resist lunate dislocation, retaining the lunate in its fossa on the distal radius in all but the most severe traumas. Instead, the surrounding carpal bones typically dislocate away from the lunate. This perilunate pattern of injury (Fig. 8.6) involves: rupture of the scapholunate interosseous ligament; capsular disruption through the space of Poirier, an area of inherent weakness of the volar capsule between the lunate and capitate, and rupture of the lunotriquetral interosseous ligament. If the dislocated carpus rebounds, then the capitate will settle into the lunate fossa, and the lunate rotates volarly, hinged on the short radiolunate ligament (Fig. 8.7).[13,14]

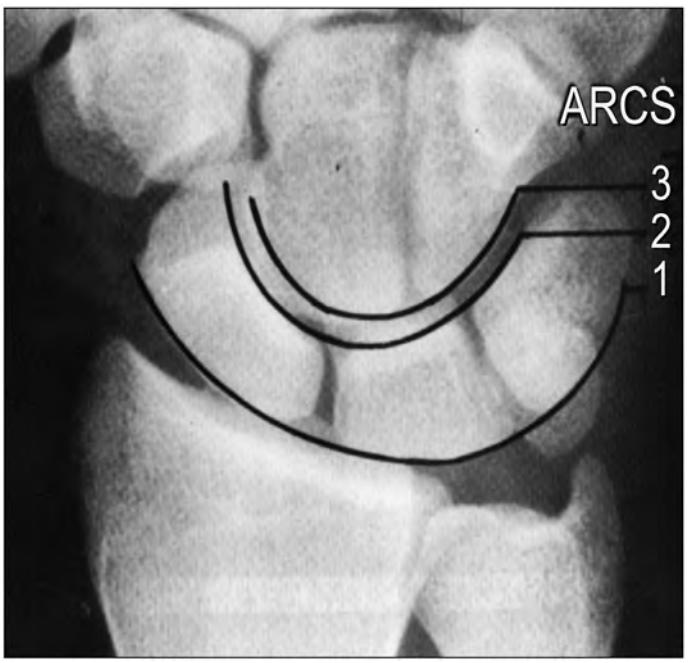

Fig. 8.4 The Gilula arcs are used to detect alterations in carpal alignment and stability. The lines are defined by (1) the proximal and (2) the distal articular surface of the proximal row, as well as (3) the proximal articular surface of the distal row.

Injury patterns are also influenced by the details of bony anatomy and structure. For example, both the diaphysis and the articular surface of the distal radius have thicker cortical bone than is found at the metaphysis. The thinner cortical bone at the metaphysis is what makes it vulnerable to fracture, especially in the osteoporotic population. Furthermore, within the metaphysis, there is a distinct difference between the dorsal and volar cortices. The dorsal cortex is much thinner, resulting in extensive comminution in most cases of distal radius fracture from falls on outstretched hands, where the force is directed in a volar-to-dorsal direction.

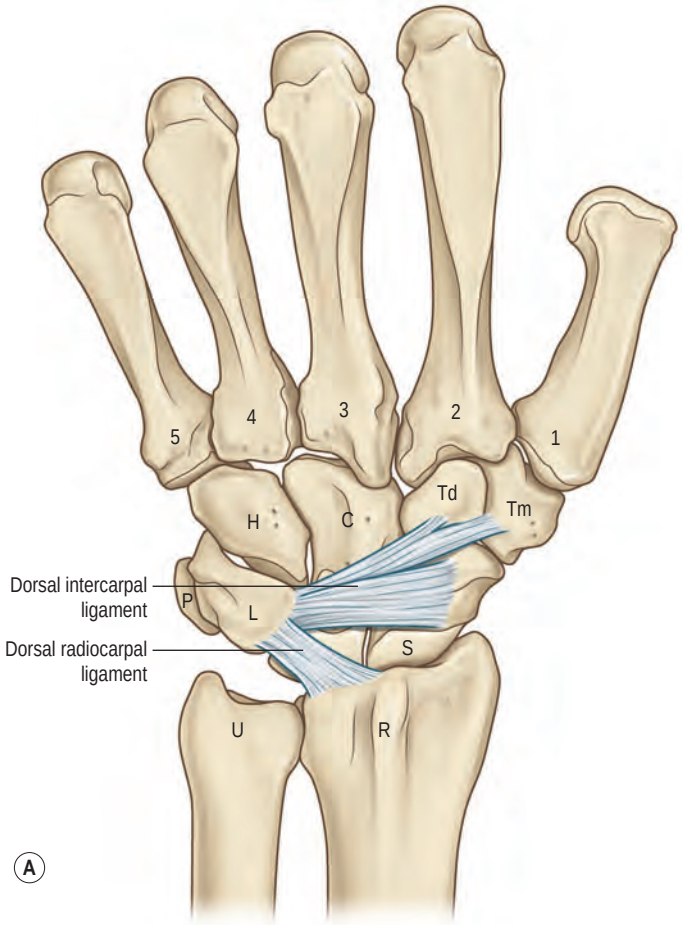
The extensor pollicis longus (EPL) is the tendon most likely to rupture after a distal radius fracture. Of note, rupture is more common with non-displaced fractures, and has been reported in cases of wrist injury without fracture. The etiology of this appears to be related to interruption of the tendon's nutritional supply, leading to attritional rupture. This most commonly occurs at the Lister tubercle, where there is a natural watershed area of this tendon's intrinsic blood supply. If the extrinsic (diffusion-mediated) nutritional supply is also interrupted by fracture callus, fracture displacement, or swelling from edema or hematoma, rupture of the EPL can occur.[15]

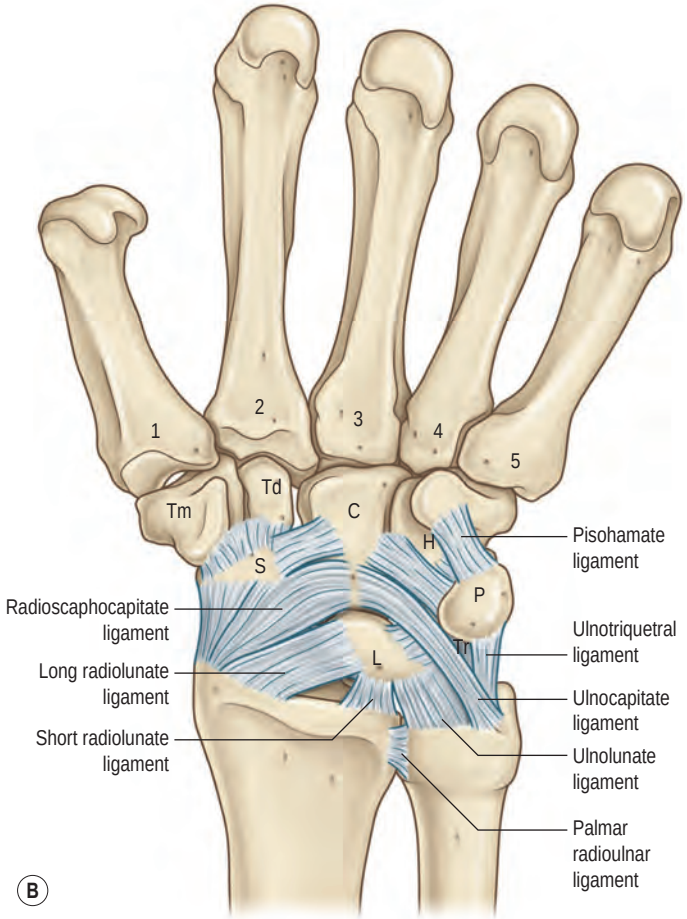
Biomechanics

The biomechanics of the hand and wrist were reviewed in Chapter 1, but there are a few points to revisit here.

Disruption of the normal linkages between the bones of the wrist – whether due to ligamentous rupture or fracture – can lead to carpal instability. The concept of carpal instability has evolved rapidly over the past 50 years as we have learned more about the ways in which the wrist bones move (kinematics) and transfer a load (kinetics). Specifically, a wrist is unstable if it is unable to transfer functional loads without sudden changes in stress on the articular cartilage, and if it is unable to maintain motion throughout its range without sudden alterations of intercarpal alignment.[16]

Carpal instability has been thoughtfully classified into four major patterns (Table 8.1). Carpal instability dissociative (CID) occurs when there is a disruption within or between the





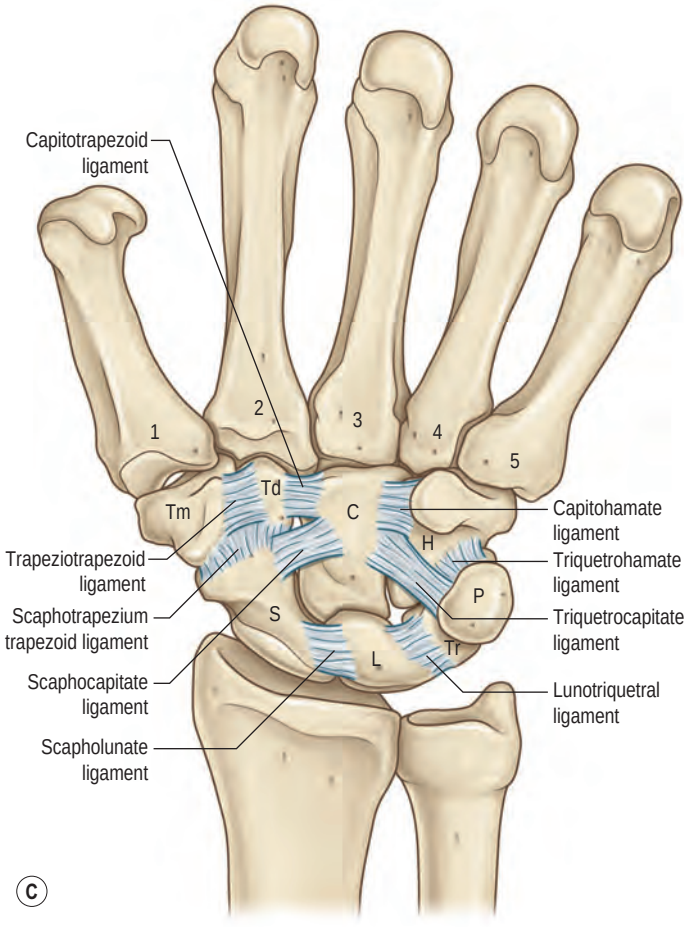


Fig. 8.5 **(A)** Dorsal extrinsic wrist ligaments. **(B)** Volar extrinsic wrist ligaments. **(C)** Intrinsic wrist ligaments. C, Capitate; L, lunate; P, pisiform; R, radius; S, scaphoid; Td, trapezoid; Tm, trapezium; U, ulna.

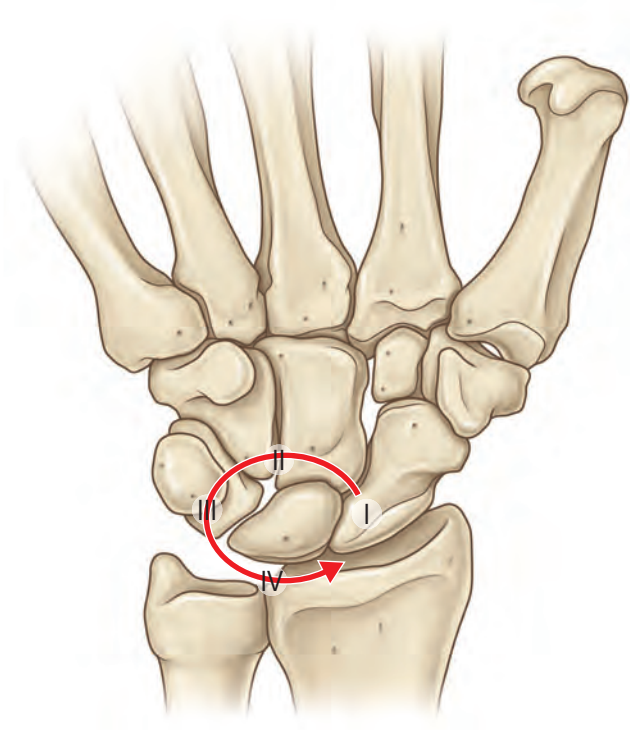

Fig. 8.6 Mayfield stages of perilunate instability: (I) scapholunate ligament rupture; (II) volar capsule tear at the space of Poirer; (III) lunotriquetral ligament rupture; (IV) lunate dislocation.

bones of the same carpal row. Carpal instability non-dissociative (CIND) refers to a disruption between the distal radius and the proximal carpal row, or between the proximal and distal carpal rows. When a combination of elements of both CID and CIND exist, it is referred to as carpal instability complex (CIC). Finally, when the instability is an adaptive response to a problem proximal or distal to the wrist itself, it is called carpal instability adaptive (CIA).[17]

Carpal kinematics has perhaps the biggest clinical impact on scaphoid fractures and scapholunate ligament injuries. The proximal carpal row is "pre-tensioned", with the scaphoid subject to a flexion moment, and the triquetrum tending to follow an extension moment. Any breakage of the connections within this row, whether intracarpal (e.g., scaphoid fracture) or intercarpal (e.g., scapholunate ligament rupture), will result in carpal instability because the disconnected carpal bones rotate in opposite directions. This natural tendency for the components in this row to fall away from each other is in part responsible for the high rate of complications after these types of injury.

Two particular instability patterns that result from CID within the proximal row are dorsal intercalated segment instability (DISI) and volar intercalated segment instability (VISI) (Fig. 8.8). DISI deformity is commonly associated with scapholunate ligament disruption or displaced scaphoid fractures; whereas VISI deformity is associated with lunotriquetral ligament disruption.

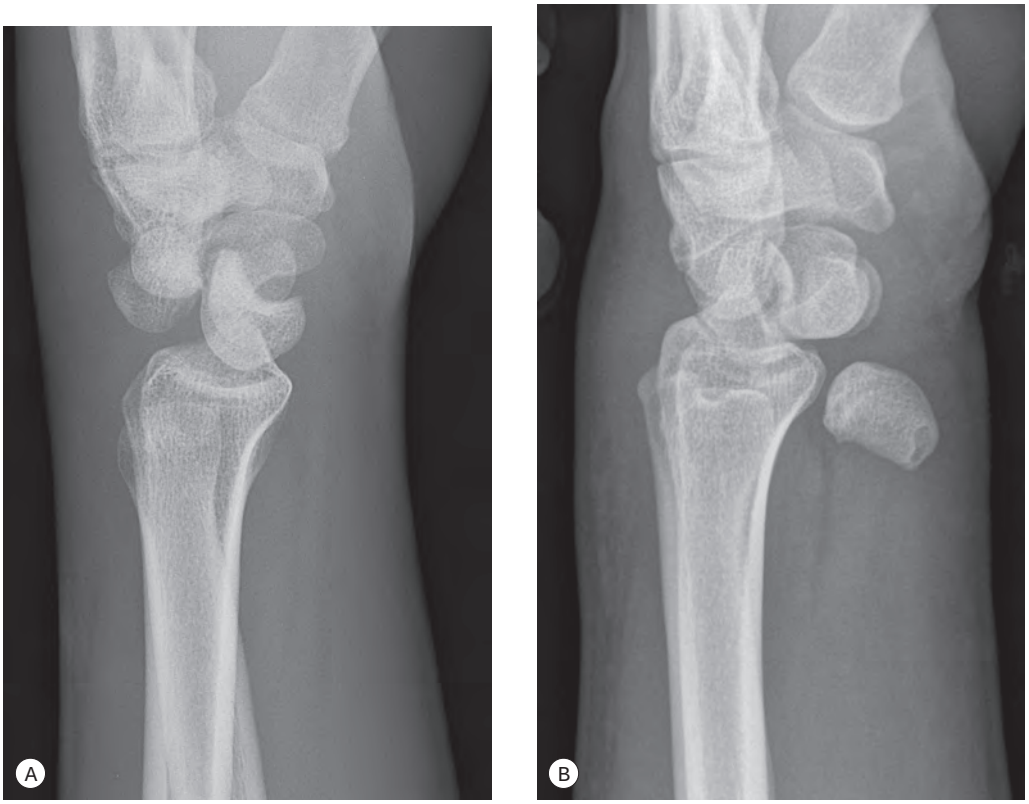

Fig. 8.7 Lateral radiograph examples of **(A)** perilunate dislocation and **(B)** lunate dislocation injury patterns.

Table 8.1 **Patterns of carpal instability**

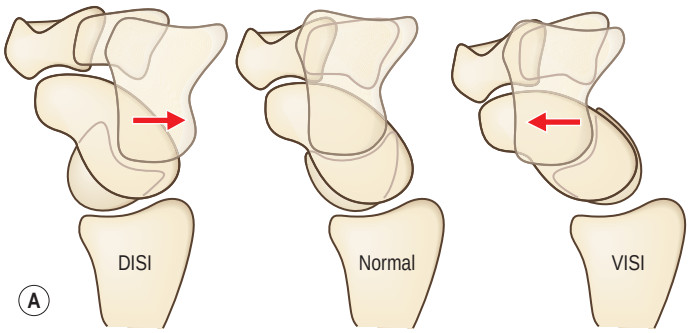
Pattern	Definition	Example(s)
Carpal instability dissociative (CID)	Disruption within or between bones of the same carpal row	Scapholunate dissociation; Scaphoid nonunion
Carpal instability non-dissociative (CIND)	Disruption at the radiocarpal or midcarpal joints, with intact proximal and distal rows	Midcarpal instability
Carpal instability complex (CIC)	Derangement both within and between carpal rows (CID plus CIND)	Perilunate dislocation with ulnar translation
Carpal instability adaptive (CIA)	Instability due to injury proximal or distal to wrist	Distal radius malunion

(Data from International Wrist Investigators' Workshop Terminology Committee. Wrist: terminology and definitions. *J Bone Joint Surg Am.* 2002;84-A(Suppl 1):1–73.)

Because of the scaphoid's natural tendency to flex when loaded, delayed treatment of comminuted fractures of the scaphoid waist tend to result in the so-called "humpback deformity" (Fig. 8.9). This term describes the shape of the scaphoid as seen on lateral tomograms, reflecting malunion of the bone with an abnormally acute angle between the proximal and distal poles of the scaphoid.[18]

Mechanisms of injury

In elderly osteoporotic patients, wrist injuries are commonly seen after falls from a standing height. Very often, this is an extra-articular fracture with apex volar angulation, the so-called "Colles fracture" (see Fig. 8.3). The younger population typically experiences fractures caused by higher energy



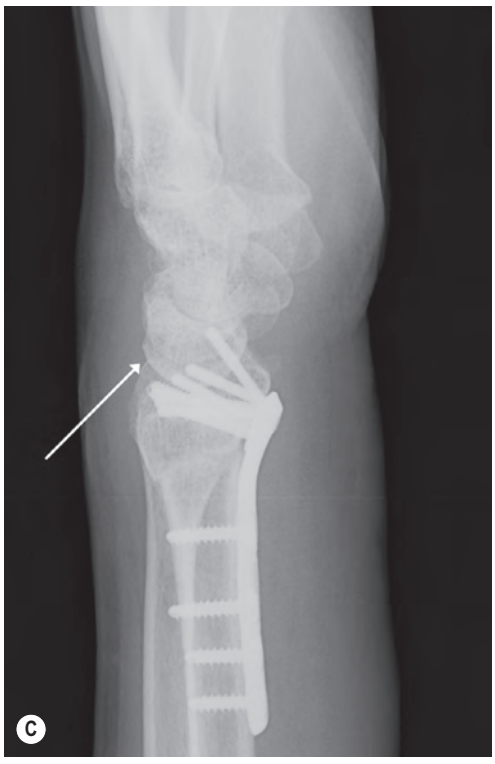


Fig. 8.8 **(A)** Lunate position in DISI and VISI deformities of the wrist. X-rays of **(B)** DISI and **(C)** VISI deformities.

Fig. 8.9 Fracture at the waist of the scaphoid, resulting in a humpback deformity.

injuries, such as motor vehicle collisions or sports-related trauma, resulting in more complex fracture patterns. With increasing force of injury, the chance of associated carpal fracture, intercarpal ligament injury, or triangular fibrocartilage complex injury increases.

Diagnosis/patient presentation

History

A detailed history begins with careful documentation of the circumstances or mechanism of the injury. Patients involved in high-energy falls or collisions should be evaluated for associated injuries by an emergency medicine physician or trauma specialist. The patient's handedness, occupation, important hobbies or recreational activities, medical and surgical history, and social history should be recorded. It is important to ask about numbness and/or tingling in the hand, because these patients are prone to acute carpal tunnel syndrome which may need to be addressed at the time of operation.

Physical examination

The examination of the patient's upper extremity should be thorough and systematic. Although the focus of this chapter is on the wrist, both the elbow and the hand should be included in the scope of examination, to avoid missing associated injuries. Examination begins with inspection. The signs of acute trauma should be noted: wounds, ecchymosis, bleeding, swelling, etc. Subacute or chronic changes may be more subtle, and comparison to the patient's contralateral uninjured extremity can be helpful in detecting slight differences in swelling, alignment, and skin characteristics.

Palpation of the extremity can help localize the site of injury. The examining surgeon should be familiar with the topography of the wrist, and be able to identify injury to specific structures by careful, systematic palpation. For instance, focal tenderness just distal to the Lister tubercle could indicate injury to the scapholunate interosseous ligament, whereas pain with palpation of the floor of the anatomic snuffbox may signify a scaphoid waist fracture.

Before assessing the range of motion or performing any provocative testing, it is important to review the radiographs of the extremity to rule out any unstable fractures that might be displaced or otherwise worsened by vigorous physical examination. While assessing the patient's active and passive range of motion, palpation over the joints being moved can yield other useful information about crepitus, clicks, or clunks in the wrist. A complete examination should also include assessment of grip strength, pinch strength, and sensibility. It is particularly important to detect median neuropathy in wrist injury patients, because acute carpal tunnel syndrome may require treatment. Provocative testing of specific intrinsic ligaments of the wrist can be valuable in reaching a diagnosis, but should be conducted with caution when unstable fractures are present to avoid unwanted fracture displacement.

The Watson scaphoid shift test stresses the scapholunate ligament to detect injury or instability (Fig. 8.10). The examiner applies pressure (typically with the thumb) over the distal scaphoid tubercle, while moving the patient's wrist from ulnar to radial deviation.[19] In ulnar deviation, the scaphoid is extended, whereas in radial deviation it is flexed. Thus, in the intact wrist, the scaphoid's ligamentous attachments resist subluxation during this maneuver. However, in cases of scapholunate dissociation, the scaphoid may be forced dorsally out of the scaphoid fossa into a painful position for the patient. Upon releasing pressure, a clunk may be detected, indicating the self-reduction of the scaphoid back over the dorsal rim of the radius. A painful Watson test in the absence

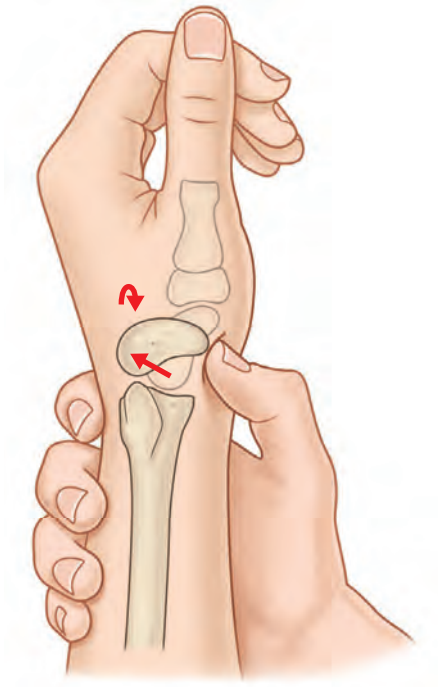

Fig. 8.10 Watson scaphoid shift test.

of an obvious clunk may be a sign of scapholunate ligament damage without complete disruption of the ligament.

The lunotriquetral interosseous ligament can be assessed by the Kleinman shear test (Fig. 8.11). The examiner grasps the patient's wrist in one hand, specifically applying stabilizing pressure over the lunate, which is palpable dorsally just beneath the fourth extensor compartment tendons. With the other hand, the examiner applies dorsally directed pressure over the pisiform, which applies a shear force directed across the lunotriquetral articulation.[20] Laxity can be assessed by further grasping the pisiform and triquetrum "unit" and moving it both palmarly and dorsally in a "shucking"-type maneuver. This latter is referred to as the lunotriquetral ballottement test.[21] Pain and/or instability may indicate injury or disruption of the lunotriquetral ligament.

Diagnostic tests

At a minimum, assessment of wrist injuries should include four radiographs: posteroanterior (PA), oblique, lateral, and PA ulnar deviation. The ulnar deviation view is particularly important in detecting scaphoid injuries. The lateral view can evaluate the relationship between scaphoid and lunate; the normal scapholunate angle is between 30–60° (Fig. 8.12). Another helpful view for detecting dynamic instability of the scapholunate ligament is the clenched fist view. When making a tight fist, load is placed across the wrist, and the capitate is driven toward the scapholunate articulation, which will make scapholunate ligament laxity or rupture more evident. To increase the accuracy of the diagnosis, both anteroposterior (AP) and PA stress views should be considered.[22]

With regard to distal radius fractures, there are a few key metrics that help guide management, and plain radiographs are generally sufficient to determine these measurements. Changes in radial height (normal = 10–13 mm), radial inclination (normal = 21–25°), and volar tilt (range 2–20°, average = 11°) help define the extent of fracture displacement (Fig. 8.13).[23]

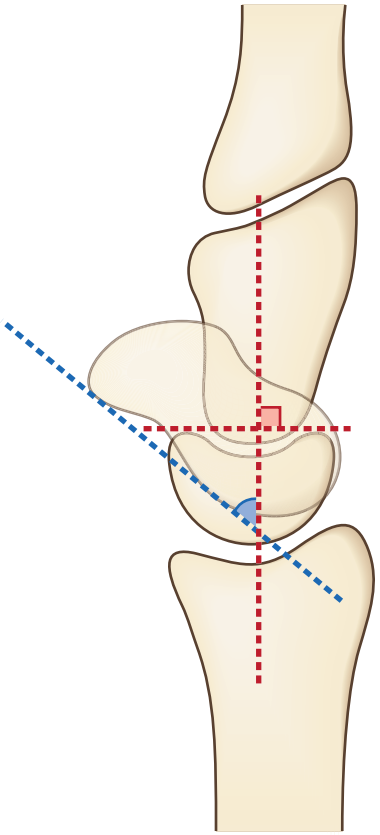

Fig. 8.12 The normal angle between the mid-axis of the scaphoid to the lunate ranges from 30–60° (average 47°).

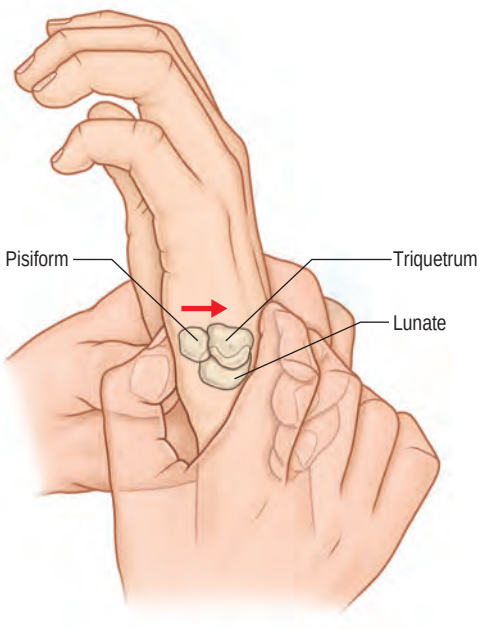

Fig. 8.11 Kleinman shear test.

Cross-sectional imaging modalities, such as computed tomography (CT) and magnetic resonance imaging (MRI), are also used routinely to investigate wrist injuries. CT is an X-ray-based modality, and as such it is best for assessing complex fracture-dislocation patterns. In particular, CT can help assess joint congruity and/or depressed articular fragments. CT is also better than MRI at determining osseous healing across a fracture site. On the other hand, MRI is the preferred modality for assessing nonosseous structures, and has the added benefit of providing some information about vascularity of parts of the carpus. MRI technology continues to evolve, and modern machines can detect very small ligamentous injuries. When the modalities of MRI and arthrography are combined, even small perforations in the interosseous ligaments can be detected.

Clinical tip

CT scans are better at showing fracture details and bony bridging/healing. MRIs are better at showing soft tissue injury, occult (non-displaced) fractures, and bony edema.

The use of bone scans has decreased substantially over the years because of the effectiveness of MRIs. Nevertheless, bone scans are still helpful in identifying "hot areas" of the wrist in difficult cases when the etiology of the patient's wrist pain

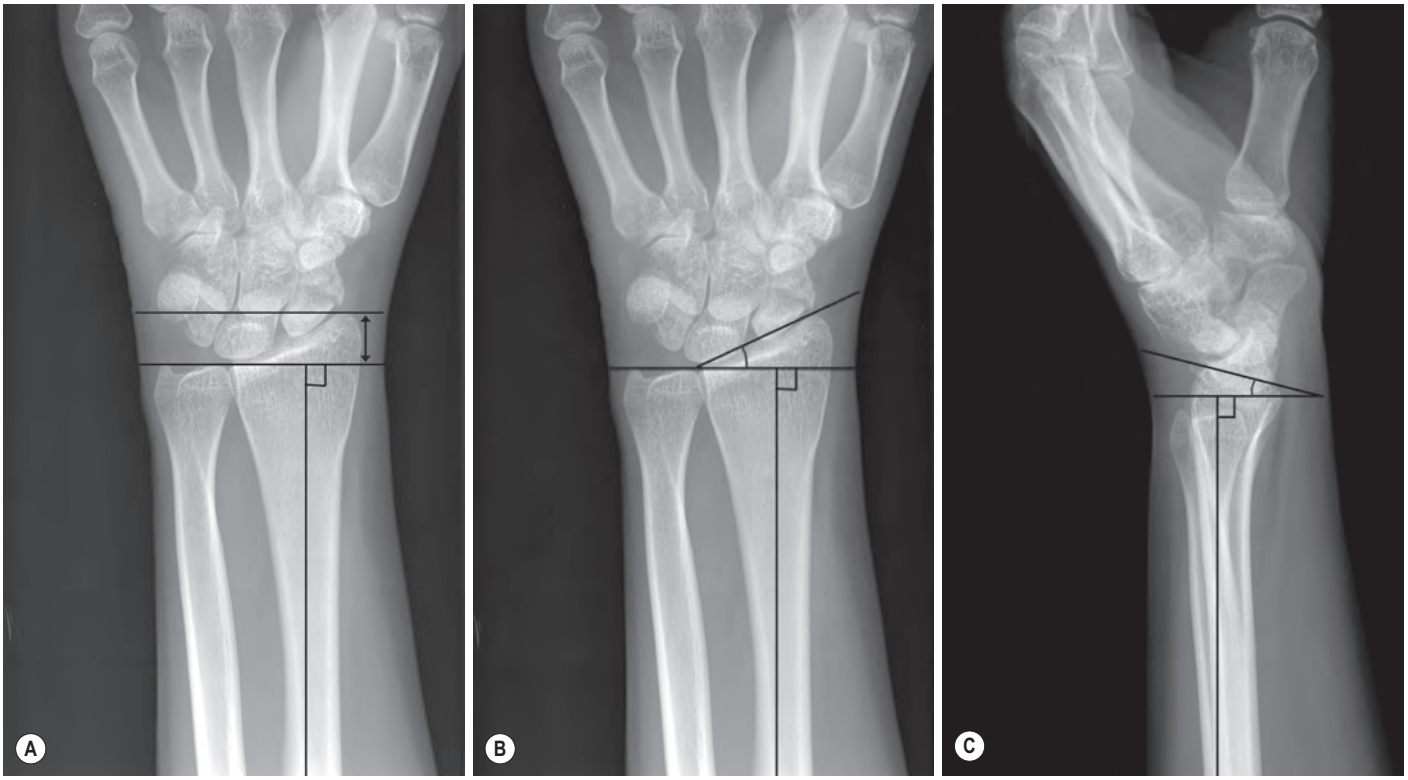

Fig. 8.13 **(A)** Radial height measured as the distance between two lines, the first line perpendicular to the longitudinal axis of the radius and intersecting the distal surface of the ulnar head, and the second line that passes through the distal tip of the radial styloid. **(B)** Radial inclination represented by the angle between the line perpendicular to the longitudinal axis of the radius and a second line connecting the ulnar aspect of the distal radius and the tip of the radial styloid. **(C)** Volar tilt is the angle between the line perpendicular to the longitudinal axis of the radius and a line along the distal articular surface of the radius.

is uncertain. However, the nonspecific nature of the bone scan limits its usefulness in the evaluation of most injuries.

Diagnostic wrist arthroscopy, while more invasive than the tests mentioned above, must still be considered the "gold standard" for detecting intra-articular wrist injuries. In a recent systematic review comparing MRI results with findings at arthroscopy, the negative predictive value of MRI for scapholunate injury ranged from 72–94%.[24] In other words, MRI can never completely rule out ligamentous injury in the wrist.

One pitfall associated with the increasingly widespread use of MRI is the inevitable detection of "false positive" findings in the wrist. It is not uncommon to find multiple minor abnormalities on high-resolution wrist MRI, many of which have nothing to do with the patient's complaints. Therefore, it is important for the treating physician to use MRI wisely, in cases where there is reasonable suspicion of injury or occult pathology, rather than use it indiscriminately.

Patient selection

Indications for fixation of scaphoid fractures are fairly well established. Because displaced scaphoid fractures cannot be reduced in a closed fashion, open reduction and internal fixation (ORIF) is required to restore anatomic alignment. This is important to facilitate healing in the scaphoid, due to its tenuous blood supply, and to restore normal scaphoid shape and alignment, which is important for carpal kinematics.[25] Other relative indications are listed in Table 8.2.

Operative fixation of non-displaced scaphoid fractures has been debated. Advocates cite many advantages, including earlier return to active military duty and increased quality-adjusted life-years.[26,27] Despite some evidence of improved functional outcomes and less time off work, surgical treatment does present some risk of complications and should not be considered lightly, since the majority of these fractures will heal nicely with immobilization alone.[28,29]

Acute scapholunate ligament injuries require operative repair to maintain carpal alignment and avoid collapse which can lead to predictable patterns of wrist arthritis.[30] However, unlike bone fixation, which reliably leads to union in most cases, techniques for repair of interosseous ligaments are not as predictable. Furthermore, the healing capacity of intercarpal ligaments seems to deteriorate over time, so patients presenting more than 6 weeks after injury may not have any suitable ligament remnants to attempt an operative repair.

Table 8.2 **Relative indications for scaphoid fracture fixation**

Displaced fractures
Proximal pole fractures (regardless of displacement)
Fractures associated with perilunate injuries
Open fractures
Fractures in multiply injured patients
Fractures not healing after a trial of immobilization (3–4 months)

The evidence favoring acute repair of lunotriquetral tears is less convincing. Many authors believe a trial of nonoperative treatment with immobilization is indicated prior to considering operative repair.[21,31]

The American Academy of Orthopaedic Surgeons has published guidelines regarding treatment of distal radius fractures.[32] Non-displaced distal radius fractures typically heal with immobilization alone and do not require surgical intervention. Displaced distal radius fractures should undergo a reduction maneuver before deciding if surgery is needed. Stable fractures that remain reduced will not require an operation, but should be followed weekly for 2–3 weeks to be sure the fracture does not collapse or re-displace. Although the available evidence does not lend itself to many definitive recommendations, there is moderate evidence to support operative fixation of fractures with post-reduction radial shortening >3 mm, dorsal tilt >10°, and/or intra-articular displacement or step-off >2 mm.[32]

Despite the existence of these guidelines, patient selection does not depend on X-ray findings alone. A patient's overall health, comorbidities, pre-injury activity level, job requirements, and expectations all play a role in the decision for surgery. This concept is exemplified in the ongoing investigation of the optimal treatment of distal radius fractures in the elderly.

With the development of volar fixed-angle plates with locking screws, fixation of distal radius fractures quickly became easier and more predictable, especially for fragility fractures in older adults.[33,34] This has led to an increase in the operative management of these fractures in the elderly, increasing from 3% in 1996 to 16% in 2005.[9] Without surgery, these fractures predictably result in malunion, with the majority having less-than-excellent radiographic results.[35] However, patient-reported outcome studies have shown that older adults tolerate greater degrees of malalignment without difficulty.[36] Therefore, an independent, active retiree might do better with surgical fixation, whereas a low-demand, infirm patient of the same age might do better with nonoperative treatment.

Treatment and surgical techniques

Scaphoid fractures

The scaphoid appears to be in the shape of a cashew nut, and can be divided into three segments: distal pole (tubercle), waist, and proximal pole. Due to the distally-located blood supply, fractures of the distal pole or tubercle heal reliably with 6–8 weeks of immobilization, and rarely need surgical fixation unless significantly displaced. However, as the location of the fracture line moves more proximally, the incidence of nonunion increases, and any measurable displacement increases this risk. Even non-displaced proximal pole fractures will take considerable time to heal if treated nonoperatively; cast treatment can last as long as 6–9 months before healing is confirmed.

Internal fixation of scaphoid fractures is most commonly accomplished with a headless compression screw. Placement of the screw can be challenging, as complete visualization of the scaphoid is difficult, and the screw should be placed down the long axis of the bone for best bony purchase with least risk of extrusion. We advocate a dorsal approach for proximal pole fractures; waist fractures can be repaired through a volar or dorsal approach. Although minimally invasive (percutaneous) techniques have been developed for scaphoid fractures, these are not for the novice hand surgeon.

The dorsal approach for ORIF of a scaphoid fracture (Fig. 8.14A) begins with a longitudinal incision just distal and ulnar to the Lister tubercle, extending over the dorsal wrist (Fig. 8.14B). The third compartment is identified through this incision, and EPL is partially released, without completely opening the compartment. With EPL protected, the wrist capsule is opened longitudinally to expose the scaphoid, identify the fracture, and examine the nearby scapholunate ligament. The fracture is then reduced; this can be aided by bone reduction forceps, or another similar instrument.[37] The wrist is then flexed to fully expose the proximal pole, and the guidewire for the cannulated headless compression screw is placed down the long axis of the bone. Ideally, a second wire should be added to prevent displacement of the fracture during drilling and screw placement (Fig. 8.14C). This stabilizing wire should be placed across the fracture into the trapezium for maximum stability, but it must not interfere with screw placement. Multiplanar mini C-arm fluoroscopy is used to confirm that the guidewire is through the central axis of the scaphoid and that the fracture is reduced. Most screw sets utilize a measuring tool at this point to select a screw length, based on the length of guidewire that is protruding from the bone.

Clinical tip

When basing the scaphoid screw measurement on the guidewire, one must take into account the position of the wire relative to the distal cortex. If the wire abuts the distal cortex, at least 2 mm should be subtracted from the given measurement to ensure the screw does not penetrate into the scaphotrapezial joint. Generally, screw measurements are around 22–24 mm for men and 18–20 mm for women.

A cannulated drill or reamer is then used to gently drill the hole by hand, frequently checking progress using fluoroscopy. Consider advancing the guidewire into the trapezium to stabilize it further before drilling. It is important to maintain a straight trajectory with the drill and avoid bending the guidewire, so as to avoid damaging or breaking the wire. The cannulated screw is then placed on the guidewire and advanced across the fracture line (Fig. 8.14D). The K-wires are then removed, final position of the screw is verified with fluoroscopy, and the incision closed (Fig. 8.14E).

Scaphoid nonunion

Scaphoid nonunion is not an uncommon occurrence, both because scaphoid fractures can be missed upon initial examination, and because the scaphoid's precarious blood supply puts it at risk. Many of those who suffer from a scaphoid nonunion are active young adults who are involved in athletic activities, and their fracture was either misdiagnosed as a sprain, or not diagnosed at all. The natural history of scaphoid nonunion is not precisely known. It is clear that there is an increased risk of post-traumatic arthritis – the scaphoid nonunion advanced collapse (SNAC) wrist – due to the disruption of the proximal row biomechanics. What is not known is the incidence of symptoms, since many asymptomatic patients

Fig. 8.14 **(A)** Scaphoid fracture to be treated with ORIF using a screw. **(B)** The incision is made ulnar to the Lister tubercle. **(C)** Two K-wires are passed into the scaphoid, one of which is the guidewire for the cannulated screw. **(D)** Finally, a compression screw is inserted into the bone. **(E)** Final fracture reduction showing the screw placement.

never present for treatment of their nonunion.[38] Asymptomatic patients do not need surgical intervention, but should probably be followed periodically to monitor for the development of symptoms and/or radiographic signs of arthritis.

Patients with symptomatic scaphoid nonunion may be candidates for operative treatment.[39] Advanced imaging is indicated to determine the exact deformity present in the scaphoid, and may also provide clues as to the vascularity of the proximal fragment. Correction of a "humpback" deformity (see Fig. 8.9) is easiest from the volar approach, as it requires the fracture site to be opened and a structural graft from either the iliac crest or from the distal radius inserted to restore the height of the scaphoid. This approach can also be used to treat established malunion of the scaphoid with similar deformity.

If there is concern for avascular necrosis, vascularized bone grafting should be considered to increase the blood flow to the scaphoid. Typically, this situation arises in proximal pole fractures, and dorsal approach is preferred. Pedicled grafts from the dorsal distal radius, such as those based on the 1,2-intercompartmental supraretinacular artery, reach the scaphoid easily.[40] Although more technically demanding, a free vascularized bone graft from the medial femoral condyle is another option (Fig. 8.15).[41]

Scapholunate ligament injury

Scapholunate ligament injury is the most common form of carpal instability. It is critical to establish the chronicity of the injury before developing a treatment plan.

Acute scapholunate injuries present with localized pain and swelling, but rarely have dramatic findings on radiographs. The diastasis between scaphoid and lunate and the DISI deformity that characterize this injury often develop over time as secondary supporting structures attenuate and degenerate (Fig. 8.16). If radiographs are normal, identification of these injuries demands a high degree of clinical suspicion, and may require confirmation with MRI arthrography or arthroscopy.

Acute partial tears will not have any gross instability and should heal with 4–6 weeks of immobilization alone. Acute

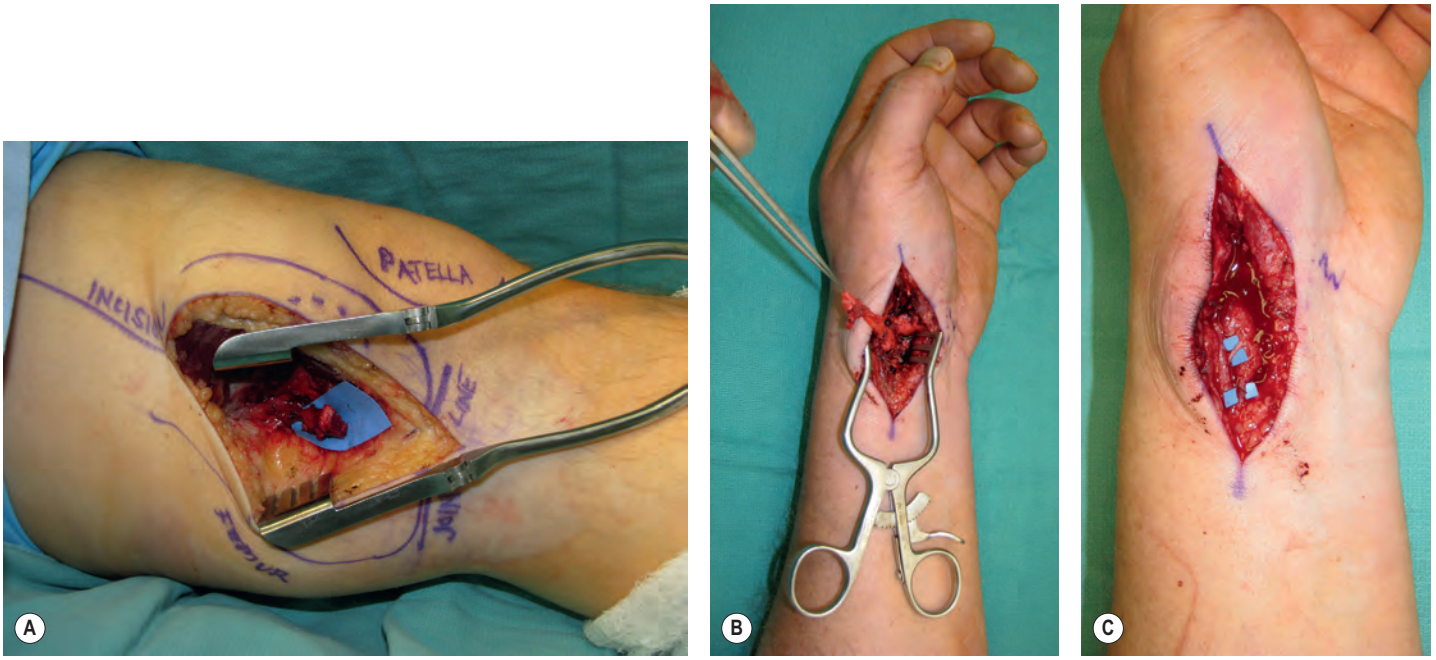

Fig. 8.15 **(A)** The medial femoral condyle flap is taken from the leg and **(B,C)** grafted into the wrist.

complete tears should be treated with open repair of the ligament using suture anchors or other suitable method. The repair should be protected with scapholunate and scaphocapitate (midcarpal) pinning for 8 weeks to allow the ligament to heal. Many surgeons reinforce such acute repairs with additional capsulodesis, especially in subacute repairs.[42] Repairs delayed greater than several weeks may be difficult, as the ligament remnants tend to deteriorate over time.[30]

Fig. 8.16 A widened interval between scaphoid and lunate as a result of a scapholunate ligament tear.

For patients with chronic tears, the treatment becomes more complex. Patients with a reducible scapholunate diastasis without arthritic changes may benefit from reconstruction. Arthroscopy is often utilized to determine the status of the cartilaginous surfaces and the reducibility of the carpals, but sometimes a final decision can only be made after open exploration of the joint. It is important to discuss all potential options with the patient prior to surgery.

Reconstruction of chronic scapholunate dissociation can take many forms. For an easily reducible diastasis with some ligament remnants present, repair with capsulodesis can be performed, much like in a more acute injury. Our preference is to perform a dorsal capsulodesis by inserting a mini-bone anchor into the distal pole of the scaphoid (Fig. 8.17) to anchor this part of the scaphoid to the dorsal wrist capsule, thereby preventing volar flexion of the scaphoid and subsequent impingement on the radial styloid.

Clinical tip

A good indicator of the "reducibility" of chronic scapholunate dissociation is the ease with which the diastasis can be corrected using K-wire "joysticks" in the bones to manipulate them. If the scapholunate articulation can be reduced without permanently deforming 0.062-inch K-wire joysticks, then reconstruction can be considered.

If the ligament is not repairable, there have been many strategies developed to restore the scapholunate linkage, usually relying on tendon grafts to perform some variety of tenodesis between the unstable bones. Our preferred technique uses a slip of the flexor carpi radialis (FCR) tendon passed through a drill hole in the scaphoid, woven through the

Fig. 8.17 A mini-bone anchor used to anchor the distal pole of the scaphoid to prevent its flexion, which can cause arthritis change at the radial styloid.

dorsal radiocarpal ligament, and secured to the lunate, which has been referred to as a three-ligament tenodesis (Fig. 8.18).[43]

If uncorrected, scapholunate dissociation can lead to wrist arthritis. Depending on the stage of arthritis at presentation, various salvage procedures may be indicated. These are addressed more fully in Chapter 20 of this textbook.

Lunotriquetral ligament injury

Lunotriquetral ligament injuries are more subtle than scapholunate ligament tears. A true lunotriquetral diastasis is rarely seen on radiographs, although a mild VISI deformity or minor disruption in the first Gilula arc may help identify the injury (Fig. 8.19). Because of this subtlety, these injuries are rarely diagnosed acutely.

If no collapse (VISI deformity) is present, both acute and chronic injuries can be treated initially with immobilization and other conservative measures. Operative intervention is reserved for those wrists that progress to VISI deformity, or otherwise fail nonoperative management. Surgical treatment options include ligament repair, ligament reconstruction, arthrodesis, and ulnar-shortening osteotomy.

Lunotriquetral ligament repair is technically challenging, typically requiring both dorsal and volar approaches. The ligament tends to be short and is not amenable to repair in chronic injuries. Reconstruction with a slip of the extensor carpi ulnaris tendon passed through drill holes in these bones has been used with some success to recreate the lunotriquetral linkage, and is superior to repair in chronic cases.[31,44] Ulnar shortening osteotomy can be useful in unloading a painful ulnocarpal joint, as in cases of ulnocarpal abutment leading to lunotriquetral injury, and may help to re-tension secondary stabilizers in these cases.[45]

Perilunate dislocation

Perilunate injuries are usually diagnosed immediately, as these patients present with a major wrist injury and often have acute median neuropathy (Fig. 8.20A). Reduction should be performed immediately to alleviate this pressure on the nerve and restore carpal alignment. This maneuver typically requires sedation, analgesia, and distraction. With careful manipulation of the wrist into extension, while applying traction, the capitate can be re-located onto the lunate in most cases. If the lunate is completely dislocated into the carpal tunnel, gentle volar pressure should be used to relocate it back into its place between capitate and radius. Patients presenting in a delayed fashion will be more difficult to reduce. If reduction is not possible, consideration should be given to a more urgent operative intervention, especially in patients with ongoing nerve impingement.

For definitive repair, we believe both dorsal and volar approaches are required.[13] Volarly, an extended carpal tunnel incision is performed, crossing the wrist crease (Fig. 8.20B). After reducing the lunate, the volar capsule tear is closed using permanent sutures. This repair often incorporates closure of the space of Poirier as well as repair of the volar lunotriquetral ligament, if sutures are placed deep enough. Proponents of a dorsal-only approach to this injury argue that these ligaments are nicely opposed after reduction, and sutures are unnecessary.[14] However, given the need for carpal tunnel decompression in the vast majority of these patients, we perform the capsular repair through this incision as well.

A dorsal wrist exposure (Fig. 8.20C) is then used to confirm accurate carpal alignment, pin the reduced carpus, and repair the dorsal scapholunate ligament, typically with suture anchors. A capsulodesis can be added to reinforce the repair. The pins are cut below the surface of the skin, to remain in place for 8 weeks (Fig. 8.20D). We prefer burying the pins to reduce the risk of postoperative pin track infection. Interestingly, although the lunate is often stripped of all its attachments in this type of injury, avascular necrosis of the lunate is rare in these patients.

Clinical tip

In perilunate dislocations, it is important to make sure the carpus is "rebuilt" with the lunate in neutral position (no DISI or VISI). We begin by placing a temporary pin across the radiolunate joint, with the lunate in neutral position, verified with lateral fluoroscopy. The scaphoid and triquetrum are then reduced to the lunate, and pinned in the appropriate reduced position. After repairing the dorsal ligaments, the radiolunate pin is removed.

Distal radius fractures

Most distal radius fractures present as closed injuries; those that fail conservative treatment can be electively fixed on an outpatient basis, preferably within 1 week. If fixed within this time frame, we find that most fragments are easily reducible, and the deposition of healing callus that can obscure an accurate reduction is minimized. However, there are a couple of situations where more urgent intervention might be needed.

Open fractures of the distal radius are a surgical emergency, especially if there is gross contamination of the fracture site.

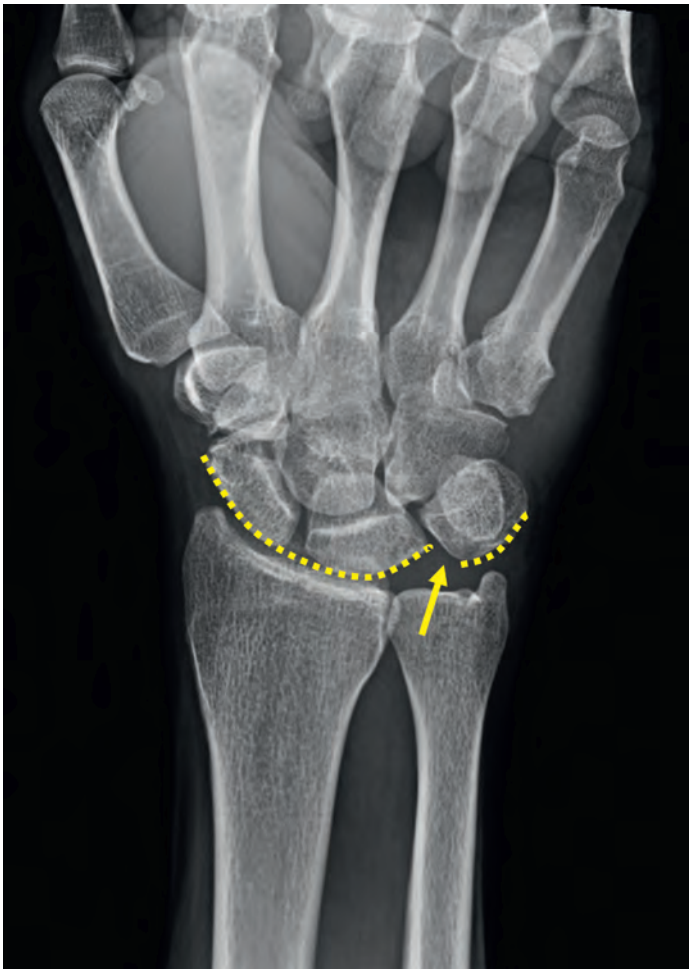

Fig. 8.19 Disruption of the first Gilula arc as a result of a lunotriquetral ligament injury.

Any fracture-related wound more than a tiny puncture should probably be washed out formally in the operating room to reduce the risk of osteomyelitis.

Patients with median nerve symptoms that do *not* improve after reduction of the fracture should be considered for an acute carpal tunnel release. It is our experience that these patients typically have a prolonged recovery due to their nerve contusion/crush injury, so relieving any ongoing compression of the nerve can be important to their ultimate recovery. If median nerve symptoms *do* improve with fracture reduction, the carpal tunnel should still be released at the time of surgical fixation.

Operative treatments for distal radius fractures include percutaneous K-wire fixation, external fixation, internal fixation, or combinations of these techniques. Internal fixation can be further subdivided into dorsal plating, volar plating, and fragment-specific plating configurations.

The introduction of volar fixed-angle plates with locking screws has revolutionized the treatment of these fractures.[33] Historically, the dorsal approach was thought to be safer, as it avoided the important neurovascular structures found at the volar wrist. Furthermore, dorsal buttress plates seemed more logical, since these fractures tend to displace dorsally. However, dorsal plating was soon found to be associated with many complications, especially extensor tendon ruptures, due to the difficulty of protecting these soft tissues from the hardware in this location.

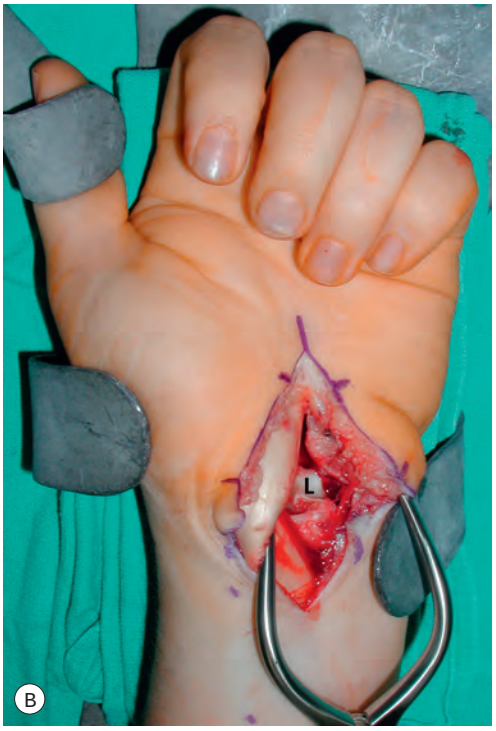
The modern volar approach is intended to overcome the problems of dorsal plating. The advantage of the volar plating technique is the ability to place the plate under the pronator quadratus muscle, which can shield the plate from injuring the overlying tendons and nerves. In addition, the introduction of locking screws made rigid fixation from the volar side possible irrespective of the amount of comminution of the dorsal metaphysis (Fig. 8.21). Traditional non-locking screws must adequately engage both cortices in order to secure the plate to bone using friction. While locking screws do engage the bone to some extent, they also have threads on the screw head to engage the plate itself. This prevents the screw from "toggling" due to pressure across the fixed fracture. Furthermore, each screw can be firmly positioned in space to lend three-dimensional support beneath the articular surface of the radius. This construct is rigid enough in most cases to allow for early gentle motion of the wrist in routine cases.

Volar plating does have several nuances that one must pay attention to during exposure to prevent unnecessary complications.[46] First, the volar incision must be made radial to the FCR tendon to protect the palmar cutaneous branch of the median nerve, which is found immediately ulnar to the FCR at the wrist. Next, instead of incising the pronator quadratus down the middle, the muscle should be elevated as an ulnarly based flap by dividing its insertion on the radius. This makes coverage of the plate easier at the conclusion of the case. For the distal locking screws, the lengths should be measured very carefully. We advocate using screws 1–2 mm shorter than the depth gauge measurement to prevent screw-tip related injuries to the extensor tendons. Finally, once the plate has been completely installed, fluoroscopy should be performed in multiple planes to ensure correct implant and screw position. Specifically, an offset lateral view should be used to examine the radiocarpal joint. By angling the wrist about 30° (equal to the radial inclination of the joint), one can get a view down the articular surface to make sure no distal screws penetrate the joint (Fig. 8.22). Adhering to these guidelines will allow for effective plating, with minimal complications.

Ulnar styloid fractures

The distal radioulnar ligaments connect the distal radius to the ulna, inserting via the triangular fibrocartilage complex (TFCC) to both the fovea and the styloid of the ulna. Because of this mechanical connection, the ulnar styloid often sustains some degree of an avulsion fracture when distal radius fractures displace (see Fig. 8.21). Even in cases where the ulnar styloid is not fractured, avulsion injuries of the TFCC can lead to instability of the distal radioulnar joint (DRUJ). For this reason, the stability of this joint should be tested in every case of distal radius fracture. When instability is detected, it should be addressed by performing fixation of the styloid fracture, or by repair of the TFCC attachment in cases without styloid fracture. In some ways, the ulnar styloid fracture is analogous to the volar lip avulsion fracture seen in PIP joint hyperextension injury: it serves as a marker of injury severity, but does not need to be treated unless instability is present.

Despite evidence of nonunion in many cases, patients without DRUJ instability do very well without ulnar styloid fixation.[47] Biomechanical studies have shown that DRUJ



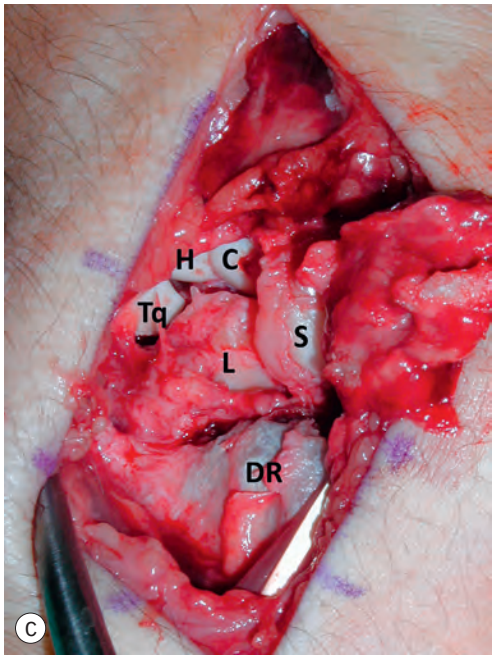


Fig. 8.20 **(A)** Lateral X-ray showing perilunate dislocation. **(B)** Extended carpal tunnel release, showing lunate in the carpal tunnel. Fig. 8.21 **(A)** A complex distal radius fracture that has been **(B)** reduced using a volar locking plate. Note the displacement of the ulnar styloid fracture, which does not need to be fixated because the distal radioulnar joint is stable with manual testing.

Fig. 8.22 Fluoroscopic 30° offset lateral view, showing that each of the distal screws is outside the radiocarpal joint.

stability in these cases can be maintained by the distal oblique bundle of the interosseous membrane.[48] This makes it all the more important to obtain anatomic distal radius reductions, so that the appropriate tension on the interosseous membrane is maintained.[49]

In cases where the DRUJ is unstable, the ulnar styloid can be fixed with tension-band constructs or small "hook plates", which have recently been developed (Fig. 8.23). Hardware in this location is not particularly dangerous to the nearby tendons, but is often symptomatic to the patient, since it is on the subcutaneous border of the wrist and forearm, without much soft tissue padding to cover the hardware.

Future directions

The problem of scaphoid nonunion with avascular necrosis of the proximal pole has led to tremendous amounts of research and innovation over the years. The latest development in this field is a further refinement of the medial femoral condyle flap. While the traditional flap was described as an osteoperiosteal flap, Drs. Higgins and Burger have developed a version of the flap that is an osteocartilaginous construct, termed the *medial femoral trochlear flap*.[50] This free flap can be used to replace the entire proximal pole of the scaphoid, as long as one takes the time to precisely "carpenter" the graft to the correct shape. Although logic dictates that there must be some

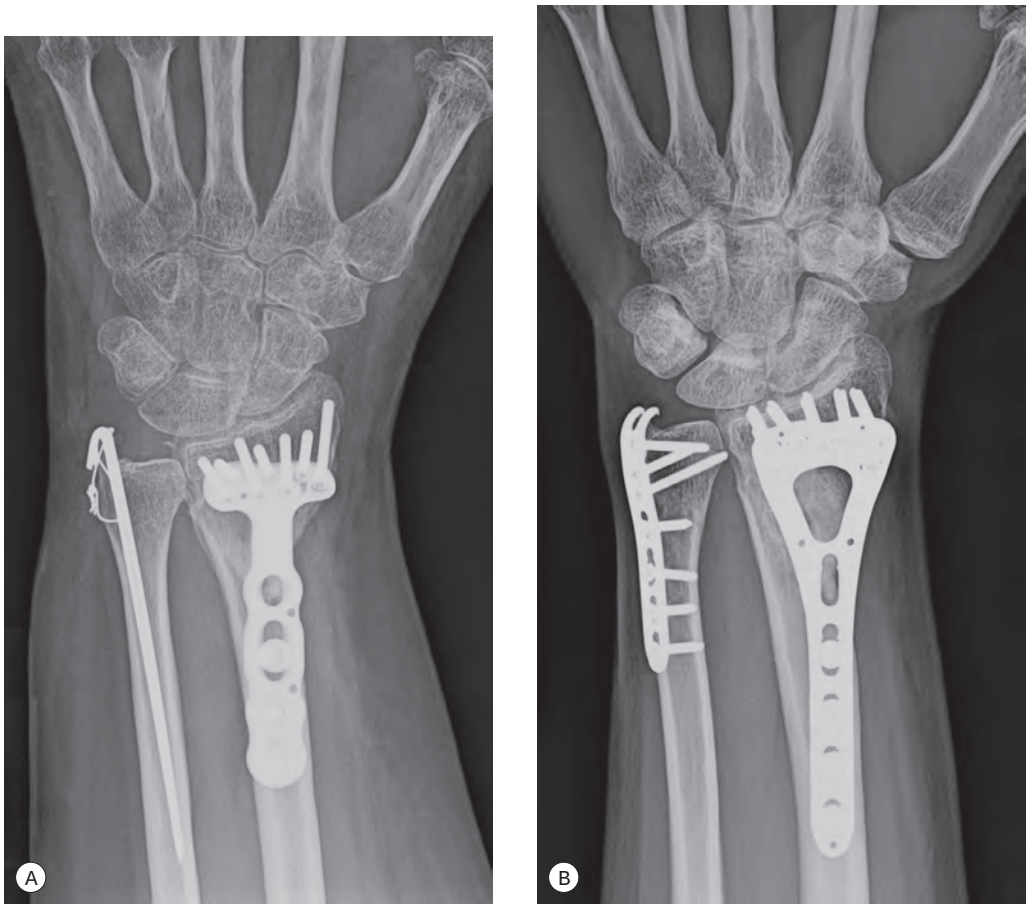

Fig. 8.23 Options for ulnar styloid fixation include **(A)** K-wires, with or without a tension band, and **(B)** ulnar hook plate, which works well for larger styloid or ulnar head fractures.

disadvantage to the loss of the scapholunate ligament, it does not appear that these patients develop automatic instability. In fact, Dr. Higgins has shown that scapholunate stability can be effectively restored by "overstuffing" the scaphoid dimensions using a larger-than-anatomic graft to reconstruct this troublesome carpal bone.[51]

Treatment of distal radius fractures in the elderly, as mentioned before, is still an area where we would like better outcomes data to guide treatment decisions. It is clear that the elderly perhaps adapt more easily to malunion, or are somehow more tolerant of wrist malalignment. Furthermore, it is not clear which method of fixation (K-wires, external fixation, or internal fixation) will lead to the most acceptable result. A large, 21-center, international trial is underway (Wrist and Radius Injury Surgical Trial, or "WRIST") to help answer the question of which is the best treatment for this patient population.[52]

Flexor tendon injuries and reconstruction

Jin Bo Tang

Access video content for this chapter online at expertconsult.com

SYNOPSIS

- Tendons transmit forces generated by muscles to move joints or to create action power. Flexor tendon injuries are common, but recovery of satisfactory function, particularly after injuries within the digital sheath, is sometimes difficult. Lacerated flexor tendons should be treated by primary surgical repair whenever possible.
- The current trend of end-to-end surgical tendon repairs is to use multistrand core sutures (four-strand repairs such as cruciate, double Tsuge, Strickland, modified Savage, or six-strand repairs such as modified Savage, Tang, or triple Kessler).
- In tendon repairs in the digital sheath area, a number of surgeons advocate that the A2 pulley can be released up to two-thirds of its length, and the A4 pulley can be entirely released when necessary and tendon repair is in the proximity of the pulley, given the integrity of the other pulleys. The release may reduce the resistance to tendon motion and the chance of repair ruptures. This technique is somewhat controversial.
- Postoperatively, early tendon mobilization should always be employed, except in children or in some rare instances; motion protocols vary greatly among different treatment centers.
- Repair rupture, adhesion formation, and joint stiffness are major complications of primary surgery.
- Combined use of multistrand core repairs, release of constricting pulley parts, and well-designed postoperative combined passive and active motion protocols – that do not overload, but sufficiently move the tendon – can help minimize adhesions, avoid repair ruptures, and restore optimal function. Full extension and flexion of the operated digit should be tested right after repair, ideally in a wide-awake setting, to ascertain no gapping of the repair and smooth tendon gliding.
- Secondary surgeries include tenolysis, free tendon grafting, and staged tendon reconstruction. Tenolysis is indicated when restricting adhesions hamper tendon gliding and soft tissues and joint conditions of the hand are favorable. Free tendon grafting is a salvage operation for failed primary repairs, delayed treatment (>1 month) of an acute cut, or lengthy tendon defects. Staged reconstruction is indicated in case of extensive scar formation or multiple failed surgeries. Preservation or reconstruction of major annular pulleys is vital to restoring function of the digits during these secondary surgeries.
- Closed rupture of flexor tendons usually requires surgical repair.
- Success of flexor tendon surgery is very expertise-dependent. A thorough mastery of anatomy and meticulous surgical technique are requirements for satisfactory restoration of function.

Introduction

Tendons are composed of dense connective tissues that transmit forces generated by muscles to move the joints or to create action power. Functionally, the hand is dependent upon the integrity and ample gliding of the tendons. Among all the tendons in the body, those in the hand are most frequently injured, due to their length and the varied nature of the activities of the hand. The pursuit of ideal repair techniques has drawn the attention of surgeons ever since hand surgery became a subspecialty. For over a century, flexor tendon repairs have presented challenges to hand surgeons.

Difficulties in restoration of function of digital flexor tendons relate chiefly to the intricate anatomy of flexor tendon systems: the coexistence of superficialis and profundus tendons within a tight fibro-osseous tunnel. Peritendinous adhesions jeopardize tendon gliding. Tendons within the synovial sheath (intrasynovial tendons) were once considered to lack self-reparative capacity; therefore, ingrowth of adhesions from peritendinous tissues was believed to be a prerequisite in the tendon healing process.[1–4] As the concepts regarding tendon healing biology evolved, tendon cells have been proven capable of proliferating and of producing collagen to heal tendons.[5–10] However, the tendon is innately low in cell density and growth factor activity, limiting its early healing strength.

In the early and middle 20th century, secondary tendon grafting dominated the repair of digital flexor tendons. During this period, tendon implants were developed for staged tendon reconstruction. However, as the practice of primary repair prevailed in recent decades, the number of cases indicated for secondary tendon grafting or staged reconstruction

BOX 9.1 General tips for surgeons of flexor tendon repairs

1. Repairing flexor tendons is based on a thorough mastery of anatomy and biomechanics. The surgeon should know the anatomy in detail, including the lengths of major pulleys, characteristic changes in the diameter of the sheath, and tendon gliding amplitude.
2. Primary repairs should be performed by experienced surgeons whenever possible.
3. Mastery of atraumatic techniques is essential for the operator. The outcomes of the repairs are very expertise-dependent; repair of tendons by an inexperienced surgeon is a frequent cause of tendon adhesions and poor function, and thus should be avoided.
4. Conventional two-strand repairs are weak; stronger surgical repairs are preferable.
5. Complete closure of the tendon sheath is not necessary. Venting of a part of sheath (<2.0 cm), including a critical portion of the pulleys, provides easy access to the injured tendons, and may decrease resistance to tendon gliding after surgery; this procedure does not lead to loss of digital function when other sheath parts are intact.
6. Surgeons should emphasize strong suture techniques and decreasing compression to the tendons, which will aid in achieving improved outcomes with hand therapy.

decreased drastically. Primary repair of injured digital flexor tendons was pioneered by Verdan[11] and Kleinert *et al*.[12] in the 1960s and is the essential approach underlying current practice. Current primary repair and early tendon motion are based on the recognition of intrinsic healing capacity of the tendon in the 1970s and 1980s by Lundborg, Manske *et al*., and Gelberman *et al*.[5–10]

Nevertheless, despite the widespread use of primary repairs, surgical outcomes remained unpredictable, and sometimes even disappointing. In the last two to three decades, major efforts were thus devoted to tackling this problem, with the goal of achieving consistently optimal outcomes and minimizing repair ruptures and adhesions. In this regard, a number of multistrand core surgical repairs – such as Savage, Strickland, cruciate, Lim–Tsai, or Tang techniques[13–19] – have been developed to replace weaker, conventional two-strand repairs. Subdivisions of zones 1 and 2 of digital flexor tendon systems were proposed by Moiemen and Elliot[20] and Tang,[21] which offer precise nomenclature in recording the locations of tendon cuts, discussing treatments, and comparing outcomes. Surgical procedures to release critical parts of the pulleys have been advocated by Tang[22] and Kwai Ben and Elliot[23] to decompress the tendon and "free" tendon motion. In the past few years, we have witnessed reports in which repair ruptures have been minimized, with recovery of excellent or good function in the majority of cases.[19,24,25] These recent reports represent some remarkable steps towards satisfactory flexor tendon repairs and highlight the promise of predictable tendon repairs (Box 9.1).

Basic science

Anatomy

There are 12 flexor tendons in the hand and forearm region. They include finger and thumb flexors and wrist flexors. Finger flexor tendons are the flexor digitorum superficialis (FDS) and the flexor digitorum profundus (FDP), and the tendon in the thumb is the flexor pollicis longus (FPL). They originate from muscles at about the mid forearm. The tendons of the FDP, except the index finger, come from a common muscle belly. The tendons of the FDS originate from the separate muscle bellies, which allow more independent finger flexion. The FPL tendon arises from the volar aspect of the midportion of the radial shaft and from its adjacent interosseous membrane. Three wrist flexors are flexor carpi radialis (FCR) and ulnaris (FCU), and palmaris longus. Palmaris longus is absent in about 15–20% of the normal population. Wrist flexion power is not affected by absence of this muscle.

Within the carpal tunnel, nine tendons exist – four FDS, four FDP, and one FPL. The relationship of these tendons within the carpal tunnel is fairly constant. The FDS tendons to the ring and middle fingers lie superficially, deeper are the FDS tendons to the index and small fingers, and deeper still are the FDP tendons. The FPL tendon is located deep and radially adjacent to the scaphoid and the trapezium. After emerging from the carpal tunnel, the tendons enter the palm. At about the level of the superficial palmar artery arch, the lumbrical tendons originate from the FDP tendons.

The most intricate portions of the flexor tendons are within the fingers, where the tendons glide within a closed fibro-osseous sheath with segmental, semirigid, constrictive dense connective tissue bands present. The digital sheath forms a closed synovial compartment extending from the distal palm to the middle of the distal phalanx. Proximally, the synovial sheath ends just proximal to the neck of the metacarpus, forming the proximal reflection of the digital flexor sheath. The FDS tendons lie superficial to the FDP tendons up to the bifurcation of the FDS tendon at the midportion of the proximal phalanx. Then, FDS tendons become two slips coursing laterally and then deeper to the FDP tendons. This FDS bifurcation is in the A2 pulley area. This part of the FDS tendon also serves to constrain the FDP tendon; the FDS segment at bifurcation may be viewed as a structure functioning similarly to a pulley. Deep to the FDP tendon, the FDS slips rejoin to form Camper's chiasm (a fibrous interweaved connection between two FDS slips), and distally insert on the proximal and middle parts of the middle phalanx as two separate slips. The FDP tendon inserts into the volar aspect of the distal phalanx. The FPL tendon is the only tendon inside the flexor sheath of the thumb and inserts at the distal phalanx.

The digital flexor sheath consists of synovial sheath and interwoven condensed fibrous bands ("pulleys"). Synovial sheath is a thin layer of continuous smooth paratenon covering the inner surface of the fibrous sheath, providing a smooth surface for tendon gliding and nutrition to the tendons. The pulley system of the digital flexor tendon is unique; it consists of annular pulleys (condensed, rigid, and heavier annular bands) and cruciate pulleys (filmy cruciform bands) (Fig. 9.1).[151] There are five annular pulleys (A1–A5), three cruciate pulleys (C1–C3), and one palmar aponeurosis

Historical perspective

Documentation and treatment of tendon injuries dates back to antiquity. Hippocrates and other ancient physicians observed a white slender tubular structure entering skeletal muscle, and considered it as a nerve. Galen, who lived in the Roman Empire in the second century, advised physicians not to repair tendons because it was believed to result in pain, twitching, and convulsions of the limb. Over the following 15 centuries, surgeons were largely influenced by the teaching of Galen. The seminal challenge to Galen's assertion did not occur until the mid-eighteenth century when Von Haller showed that the placement of a suture in canine Achilles tendons did not have detrimental effects.[26]

The first experimental investigation of the tendon healing process was performed in 1767 by John Hunter, who recorded that the canine Achilles tendon healed by the formation of callus, similar to that seen in healing bone.[26,27] However, specific studies of the flexor tendon healing within digital sheath were not started until about 150 years later, in the early twentieth century. Around 1920, Bier and Saloman observed poor tendon healing of sutured canine flexor tendons.[28] Saloman thus advocated to leave a defect in the tendon sheath which allowed contact between the repaired tendon and the subcutaneous tissue. Bunnell and Garlock observed frequent occurrence of restrictive adhesions at the flexor tendon laceration site.[29–32] Bunnell coined the term "no man's land" to describe the region where the flexor tendons passed through the digital sheath and advised surgeons to be cautious when repairing tendons within this region. In 1940, Mason advised some specific conditions for repairing lacerated digital flexor tendons, which included never repairing both tendons, wide excision of the overlying sheath, and adequately eliminating contaminates from the wound.[33] Because of the generally unsatisfactory results of primary flexor tendon repairs, many surgeons preferred tendon grafting, despite the fact that a few surgeons had demonstrated that primary surgeries were practicable at that time.

In the early half of the 20th century, repairing the lacerated tendons within the digital sheath was predominantly by means of secondary tendon grafting. The first series of flexor tendon grafts in the hand was reported by Lexer in 1912.[34] He used grafts to repair flexor tendons after rupture, old lacerations, infections and cases with ischemic contracture. In 1916, Mayer published articles that have served as the basis of the present day concepts of free tendon grafting.[35–37] He emphasized the need for existing surgical techniques, direct juncture of the tendon to bone, the use of adequate muscle as a motor, and preserving peritenon around a graft to lessen adhesions. In 1918, Bunnell published a classic article on tendon grafting in which atraumatic technique, a bloodless field, perfect asepsis, and preservation of pulleys were emphasized.[30] The surgical techniques of tendon grafting were subsequently modified by various leaders in the field, including Pulvertaft, Graham, Littler, Boyes and Stark.[38–42]

In an effort to combat serious scarring in the tendon gliding bed in which conventional one-stage free tendon graft likely failed to restore tendon function, various materials have been implanted into the fingers to stimulate formation of a smoother tendon gliding bed. In 1936, Mayer inserted a celloidin tube into seriously scarred tendon gliding bed, and after 4 to 6 weeks of implantation he then introduced a tendon graft.[43] Mayer brought forth the pseudosheath concept. In the 1950s, Bassett and Carroll began working with flexible silicone rubber rods to build pseudosheaths in badly scarred fingers, adding passive motion into this procedure.[44] This method was later refined into a two-stage tendon reconstruction by Hunter *et al*. in the 1960s.[45] Hunter *et al*. also developed the active tendon implant.[46] These implants and two-stage reconstruction procedures are still used currently, effective for those patients with badly scarred digits and serving as a salvage procedure after other surgery attempts failed.

It was not until the 1960s that reports of surgical techniques and outcomes of primary repair from Verdan,[11] and Kleinert *et al*.[12] became the turning point in establishing the practice of primary repair of digital flexor tendons. The emerging popularity of primary tendon repair stimulated experimental studies to elucidate mechanisms of the healing process. In the 1970s and 1980s, Manske *et al*. demonstrated diffusion of nutrients through synovial fluid to be an effective source of nutrition of intrasynovial tendon, thus obviating the need of vascularization in the healing process.[47–50] Matthews and Richards observed healing of lacerated rabbit flexor tendons within the intact digital sheath in the absence of adhesions.[5,51–54] Lindsay *et al*. noted that both epitenon and endotenon cells proliferate and migrate to the laceration site, subsequently bridging it.[5,55–57] Lundborg *et al*. demonstrated healing of lacerated flexor tendon segments when placed within the synovial environment of the knee joint or in a synthetic membrane pouch placed in a subcutaneous pocket of the back of the rabbit.[6,7] In the 1980s, Manske, Lesker, Gelberman, and Mass *et al*. demonstrated healing of lacerated flexor tendon segments of different animals when placed in tissue culture in the complete absence of extrinsic cells.[9,10,58–61]

In the last three decades, major advancements in the field of flexor tendon repairs were made with respect to the development of novel surgical repair techniques, accumulation of biomechanical information regarding tendon repairs or gliding mechanisms, modifications of postsurgical rehabilitation methods, and an emerging trend of exploring biological approaches to enhance tendon healing. In 1985, Savage[13] published an influential experimental study that later stimulated a widespread interest in developing multistrand suture techniques to repair the tendon.[62–74] The cruciate repair, a simple yet strong four-strand repair developed by McLarney *et al*.[16] in the late 1990s, is used in many hand centers. In the same period, multistrand repair using Tsuge's looped suture lines, as developed by Lim and Tsai, Tang (and its modification, M-Tang method),[17–19,68] were used by surgeons in hand centers in Asia, Europe, and North America. In 1995 and 1998, Tang[22] and Elliot[23] presented an anatomical study and clinical results of the release of a major flexor pulley (A2) to accommodate gliding of the repaired tendons, respectively. Elliot and Tang also proposed to vent the A4 pulley when the tendon repairs are in the areas.[19,23]

The flexor tendons were divided into five zones by Verdan in the 1960s. In the 1990s, subdivisions of zone 1 by Moiemen and Elliot[20] and zone 2 by Tang[21] were added into the existing zoning system, in order to describe the location of injuries and repairs more specifically. These zoning and sub-zoning systems provide hand surgeons with the nomenclature to document the tendon injuries and outcomes, and discuss the principles of treatment.

In the past 30 years, biomechanics of the flexor tendon system has become a subject of intense interest for both surgeons and basic scientists. A large volume of information regarding tendon gliding and repair biomechanics has been obtained,[74–122] including surgical repair techniques (mainly from labs of Gelberman, Manske, Mass, McGrouther, Tang, Trumble, and Wolfe), gliding resistance of tendons within the sheath or against annular pulleys (Amadio and Tang), mechanics of the pulleys (Amadio, Mass, and Tang), postsurgical rehabilitation (Amadio and Boyer), and edema formation (Tang). In recent years, as advocated by Lalonde,[123,124] flexor tendon repair and tenolysis are popularly performed in some centers around the globe under wide-awake settings (without tourniquet) with local anesthesia plus epinephrine. This approach allows the tendon to move actively during surgery to ascertain good quality of tendon repair or tenolysis.

In the past two decades, investigations exploring molecular events in the tendon healing process, tendon tissue engineering, and biological approaches to enhance the healing came into the center stage of basic science investigations. Chang *et al*. reported a series of investigations exploring function of growth factors in tendon healing, molecular methods to prevent adhesions, and tendon tissue engineering.[125–135] Tang and colleagues performed a series of studies of molecular events in tendon healing and gene therapy approaches to enhance the strength or to limit adhesions.[136–145]

Comprehensive history and development of flexor tendon repairs were covered in more detail in the reviews written by Verdan (1972),[146] Manske (1989),[147] Strickland (1995),[148] Elliot (2003),[149] Manske (2005),[26] and Tang (2007)[19] and Tang *et al* (2014).[150]

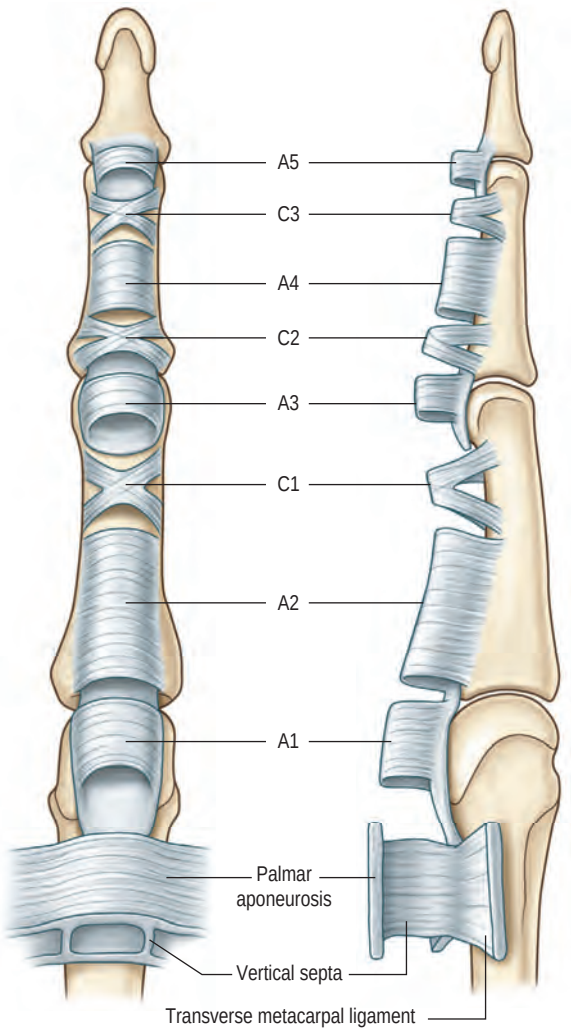

Fig. 9.1 Annular pulleys (condensed, rigid, and heavier annular bands) and cruciate pulleys (filmy cruciform bands) are present in the fingers. There are five annular pulleys (A1–A5), three cruciate pulleys (C1–C3), and one palmar aponeurosis (PA) pulley.

pulley.[151,152] The A1, A3, and A5 pulleys originate from the palmar plates of the metacarpophalangeal (MCP), proximal interphalangeal (PIP) and distal interphalangeal (DIP) joints, and the A2 and A4 pulleys originate from the middle portion of the proximal and middle phalanges, respectively. The broadest annular pulley is the A2 pulley, which covers the proximal two-thirds of the proximal phalanx and encompasses the bifurcation of the FDS tendon at its middle part. The A4 pulley is located at the middle third of the middle phalanx. The A2 and A4 pulleys are the largest among five annular pulleys and have the most important function. The annular pulleys maintain the anatomical paths of tendons close to bones and phalangeal joints, thus optimizing the mechanical efficiency of digital flexion. The more compressible cruciate pulleys allow for digital flexion to occur with condensation of the fibro-osseous sheath at the inner part of flexed fingers. This is called the "concertina effect".

The length of the A2 pulley is about 1.5–1.7 cm in the middle finger of an average adult, and the length of the A4 pulley is about 0.5–0.7 cm. The diameter of the flexor sheath is at its narrowest at the level of the A4 pulley and in the middle and distal parts of the A2 pulley. The A2 and A4 pulleys are easily recognizable, because both are remarkably denser and more rigid than their adjacent flexor sheath. The A1 pulley, with a length of about 1.0 cm, is located proximal to the A2 pulley; in some instances, both A1 and A2 pulleys merge to form an especially lengthy pulley complex. The A3 pulley is located palmar to the PIP joint, but it is very short (0.3 cm) and may be difficult to distinguish from the synovial sheath.

In the thumb, there are three pulleys (A1, oblique, and A2) with no cruciate pulleys (Fig. 9.2). The A1 and oblique pulleys are functionally important. The A1 pulley, 0.7–0.9 cm long, is located palmar to the MCP joint. The oblique pulley, 0.9–1.1 cm long, spans the middle and distal parts of the proximal phalanx. The A2 pulley is near the site of insertion of the FPL tendon, which is thin and 0.8–1.0 cm long.

The FDP tendon has two vincula: a fan-like short vinculum and a cord-like long vinculum. The short vinculum is located at the insertion of the FDP tendon (Fig. 9.3). The long vinculum connects the FDP tendon through the short vinculum of the FDS tendon to the floor of the palmar surface of the phalanges. The FDS tendon also has two vincula; one connecting to the proximal phalanx, and another at the insertion of the FDS tendon. Vincula carry blood vessels to the dorsum of these tendons, providing limited nutrition. Tendon insertion sites to bones also carry vessels into tendons over a very short distance.

According to anatomical features, the flexor tendons in the hand and forearm are divided into five zones, which offers

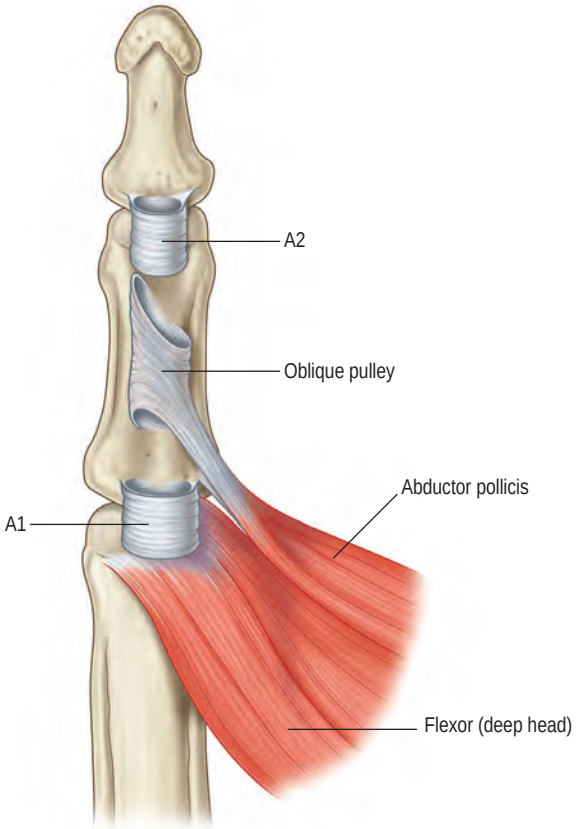

Fig. 9.2 Locations of flexor pulleys of the thumb. There are three pulleys in the thumb: A1, oblique, and A2 pulley, from distal to proximal.

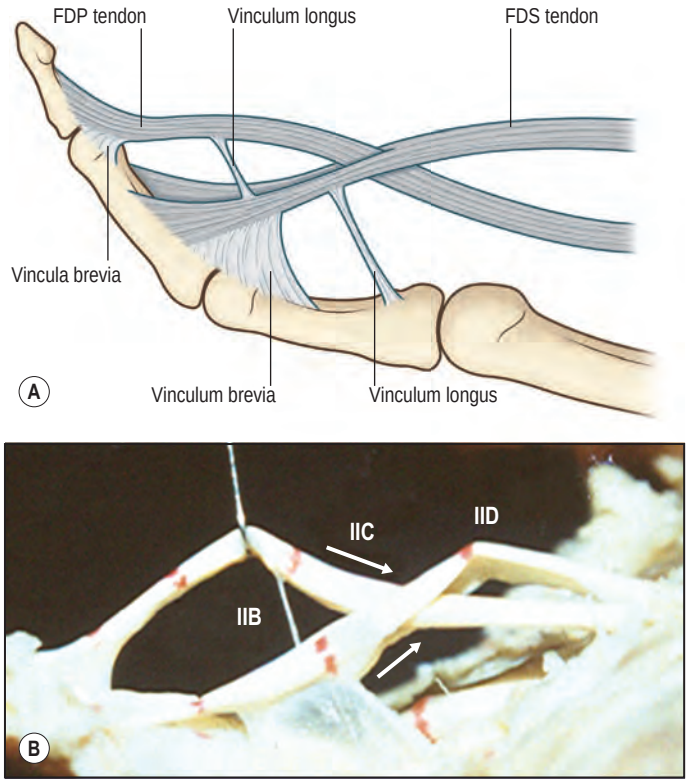

Fig. 9.3 Insertions and relative positions of the flexor digitorum superficialis (FDS) and flexor digitorum profundus (FDP) tendons and vincula. Each of the FDS and FDP tendon has two vincula, one short and one long. The relation of the FDS and FDP tendons are complex in the middle part of the proximal phalanx under the A2 pulley (zone 2C).

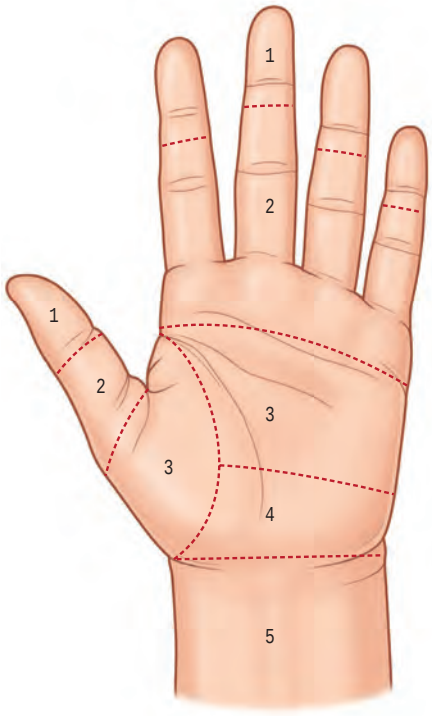

Fig. 9.4 Divisions of the flexor tendons into five zones according to anatomical structures of the flexor tendons, presence of the synovial sheath, and the transverse carpal ligament.

the fundamental nomenclature for flexor tendon anatomy and surgical repairs.[153] In the 1990s, the most complex areas – flexor tendons in the digital sheath – were subdivided by Moiemen and Elliot,[20] and by Tang.[21] The zoning is described below, and its relation to the locations of pulleys is shown in Figs. 9.4 and 9.5:

- Zone 1: from the insertion of the FDS tendon to the terminal insertion of the FDP tendon
- Zone 2: from the proximal reflection of the digital synovial sheath to the FDS insertion
- Zone 3: from the distal margin of the transverse carpal ligament to the digital synovial sheath
- Zone 4: Area covered by the transverse carpal ligament
- Zone 5: Proximal to the transverse carpal ligament

In the thumb, zone 1 is distal to the interphalangeal (IP) joint, zone 2 is from the IP joint to the A1 pulley, and zone 3 is the area of the thenar eminence.

The subdivisions of zone 1 by Moiemen and Elliot are:

- 1A: the very distal FDP tendon (usually <1 cm)
- 1B: from zone 1A to distal margin of the A4 pulley
- 1C: the FDP tendon within the A4 pulley

The subdivisions of zone 2 by Tang are:

- 2A: the area of the FDS tendon insertion
- 2B: from the proximal margin of the FDS insertion to the distal margin of the A2 pulley
- 2C: the area covered by the A2 pulley

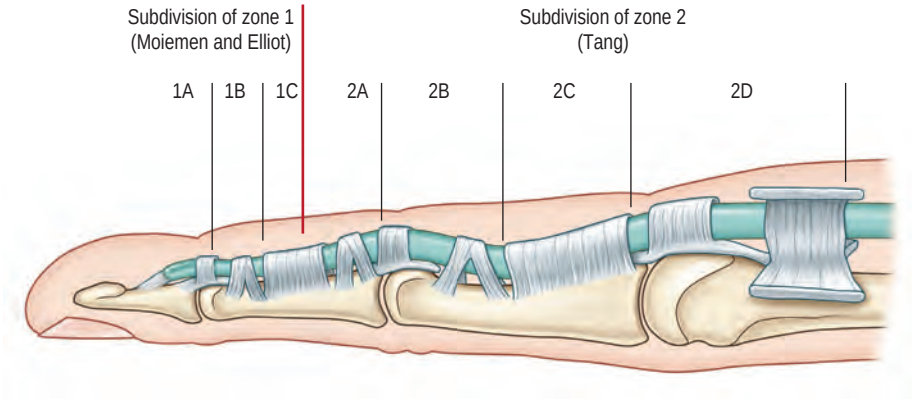

Fig. 9.5 Subdivisions of zones 1 and 2 of flexor tendons in the fingers and their relations to the flexor pulleys.

- 2D: from the proximal margin of the A2 pulley to the proximal reflection of the digital sheath

Flexor tendon healing

Flexor tendons derive nutrition from both synovial and vascular sources. Flexor tendons outside the synovial sheath are supplied with a segmental vascular network through the paratenon, and the vascular supply plays an important role in nutrition of these tendons. However, the tendons within the synovial sheath are mostly deprived of a vascular network. Only limited dorsal regions around vincular insertions are vascularized. A series of experiments by Manske *et al*. showed that intrasynovial flexor tendons are nourished by synovial fluid and that nutrition through vascular supplies is insignificant.[47–50] While the general healing process of the tendon has long been recognized as having early inflammatory, middle collagen production, and late remodeling phases, the healing potential of the intrasynovial flexor tendon was a subject of intense investigations and debate over several decades in late 20th century.[1–10,52–61]

Before the 1970s, it was widely accepted that the digital flexor tendon lacked intrinsic healing capacity.[1–4] However, in subsequent decades, the intrinsic healing capacity of the tendon came to light in a series of elegant experimental studies. These experiments by Matthews, Lundborg, Manske, Gelberman, and Mass and others, included observation of the repair process in lacerated flexor tendons within the synovial sheath, investigation of cellular activity in the lacerated tendon within the knee joint, detection of cellular activity, and the ability to produce matrix by *in vitro* tendon cultures.[5–10,51–61] The work led to the well-supported conclusion that cells in the intrasynovial tendon can proliferate and participate in the healing process, making the tendon itself capable of healing without forming adhesions. This became the scientific basis of early postoperative tendon mobilization.

It is now agreed that intrasynovial flexor tendons can heal through two mechanisms – intrinsic and extrinsic. Intrinsic healing takes place through the proliferation of tenocytes and production of extracellular matrix by intrinsic cells. Growth of tissues or cell seeding from outside the tendon is extrinsic healing. The tendon's intrinsic healing capacity is innately weak; extrinsic healing becomes dominant when intrinsic healing capacity is disabled (such as in the case of severe trauma to the tendon or peritendinous tissues) or under conditions (such as postsurgical immobilization) favoring extrinsic healing. Tendon healing exclusively through the intrinsic healing mechanism occurs only under a few experimental conditions.[7–9] Clinically, the lacerated tendon heals through a combination of both intrinsic and extrinsic mechanisms, whose balance depends upon the condition of the tendon and surrounding tissues. Extrinsic healing may act on the tendon healing process through either forming adhesions or seeding of the extrinsic cells without adhesions to laceration site. On the other hand, adhesions do not necessarily consist of extrinsic cells. Tenocytes may migrate out of the laceration site for a very limited distance to become part of adhesions. Conceptually, extrinsic healing does not equal adhesion formation. However, it is extrinsic healing in the form of restrictive adhesions that hampers tendon function.

The following five variants (grades) of adhesions are seen clinically: (1) no adhesions; (2) filmy adhesions: formation of visible, filmy, and membranous tissue from tendon to outside tissues; (3) loose adhesions: loose and largely movable; (4) moderately dense adhesions: of limited mobility; and (5) dense adhesions: dense, almost immovable, and invading deep into the tendon.

The first two grades do not affect tendon motion; the third affects motion mildly. Because the fourth and fifth affect motion dramatically, those are the adhesions that surgeons seek to prevent. The density of adhesions relates to the tissues from which they arise. The adhesions arising from bones, periosteum, or major annular pulleys are dense. The density of adhesions can be altered to some extent by tendon motion. Some adhesion fibers can be disrupted as well. Surgeons should do their utmost to preclude or minimize the formation of adhesions that will restrict tendon gliding.

Many strategies have been attempted or suggested to prevent adhesion formations, including medications, use of artificial or biological barriers, and chemical or molecular approaches, with varied results. However, few medications or barriers have become clinically routine. So far, the most effective methods to prevent adhesions in clinic are meticulous surgery and early postoperative motion; the prime cause of adhesions is tendon repair by inexperienced surgeons.

Biomechanics of tendon repairs and gliding

Forces generated during normal hand action range from 1 to 35 N, except tip pinch, according to *in vivo* measurements.[154] Therefore, a surgically repaired tendon should be able to withstand a tension of at least 40 N during motion, with power sufficient to resist gap formation. The repair should be able to withstand cyclic loads under both linear and curvilinear load conditions. Laboratory tests have shown that conventional two-strand core repairs plus running peripheral sutures yield a maximal strength from 20 to 30 N;[93] this is lower than forces generated during normal hand actions and explains why some repairs are disrupted during postoperative motion exercise. Studies showed that failure forces of four-strand repairs are around or beyond 40 N;[16,65,94] six-strand repairs fail with loads over 50–60 N.[13,71,85]

Many factors affect the strength of a surgical repair (Fig. 9.6): (1) the number of suture strands across the repair sites – strength is roughly proportional to the number of core sutures;[74–76,81–83,85,94–97] (2) the tension of repairs – most relevant to gap formation and stiffness of repairs;[19,98] (3) the core suture purchase;[84,86,88,94] (4) the types of tendon–suture junction – locking or grasping;[79,88,95,97] (5) the diameter of suture locks in the tendons – a small-diameter lock diminishes anchor power;[80,91] (6) the suture calibers (diameter);[82,116,117] (7) the material properties of suture materials;[95,155] (8) the peripheral sutures,[156,157] (9) the curvature of tendon gliding paths – the repair strength decreases as tendon curvature increases;[89,90] and (10) above all, the holding capacity of a tendon, affected by varying degrees of trauma and post-traumatic tissue softening, plays a vital role in repair strength.

To achieve an optimal surgical repair, the above-outlined factors must be considered and incorporated into repair design. A core suture purchase of at least 0.7 to 1.0 cm is necessary to generate maximal holding power, as recommended by Tang *et al*.[86,93] and Cao *et al*.[94] Slight tension in the core sutures is necessary to resist gapping at the repair site.[98] A locking tendon–suture junction is generally better than a grasping

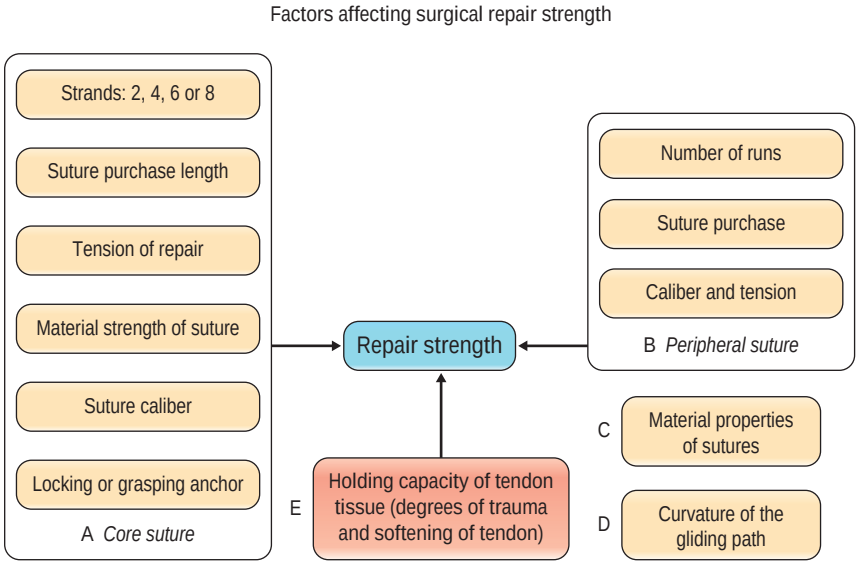

Fig. 9.6 Factors affecting the surgical repair strength of the tendon.

junction in terms of holding power. Diameter of the suture locks must reach or exceed 2 mm, according to Xie *et al*.[91] Tan and Tang recommend a greater core suture purchase (>1.2 cm) and locking repairs for an obliquely cut tendon.[86–88] Barrie *et al*.[116] and Taras *et al*.[117] greatly improved repair strength by increasing suture calibers. Clinically, the caliber of suture used in adults is either 3-0 or 4-0; sutures of 2-0 or greater are too large and rigid in the hand.

Tendon–suture junctions in surgical repairs are either grasping or locking; locking junctions vary greatly (Fig. 9.7). Grasping repairs are generally weaker than locking repairs. Among locking junctions, cross-locks provide identical strength to circle-locks.[94] Exposed and embedded cross-locks create the same strength.[92] With an identical number of suture strands across the tendon, different locking junctions result in minor differences in the strength. Nevertheless, repairs with cross- or circle-locks appear slightly stronger than Kessler-type repairs with Pennington locks. Pennington locks provide a looser junction than cross- or circle-locks.

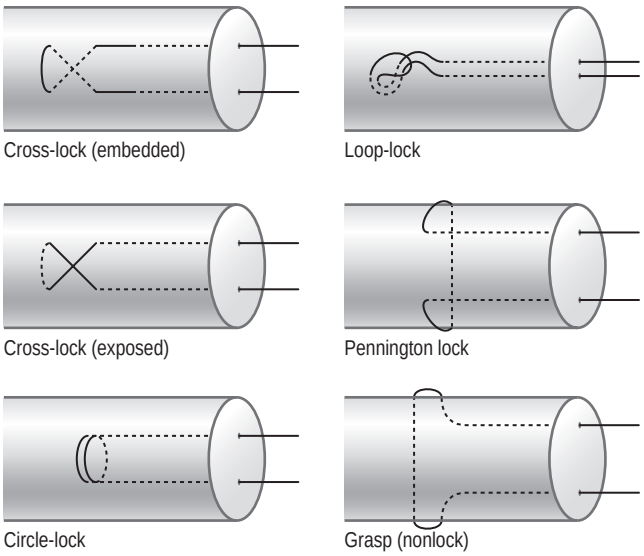

Fig. 9.7 Different tendon–suture junctions in tendon repairs: locking and grasping junctions

Peripheral sutures serve to "tidy up" the approximated tendon stumps; they may add strength to repairs as well. Deep-bite peripheral sutures increase repair strength.[156] Increases in suture purchase or complex peripheral sutures, as typified by the Silfverskiöld method,[64] increase overall strength. However, most surgeons choose to insert only simple peripheral stitches. Some surgeons even do not supplement peripheral stitches when multistrand core sutures have been used.[25] In the presence of a strong multistrand core repair, peripheral sutures contribute little in terms of strength. In fact, to simplify repair maneuvers, multistrand core sutures (with or without a few peripheral sutures) may be sufficient.

In addition to surgical factors, tendon curvature affects strength as well. Surgical repair in a tendon under a curvilinear load is weaker than that under a linear load; the repair strength decreases as the curvature increases.[89,90] Mechanically, a tendon under linear tension is pulled without being bent, whereas a tendon under curvilinear tension is subjected to both linear pulling and bending forces. Therefore, the repair fails more easily in the flexed finger under curvilinear loads. When the finger moves to approach full flexion, a strongly bent tendon is particularly prone to fail (Fig. 9.8).

Annular pulleys are critical to the function of the digital flexor tendons. The pulleys keep the tendons' course close to the phalanges for optimal mechanical efficiency of tendon excursion. Lengthy loss of the sheath and pulleys causes anterior displacement – bowstringing – of the flexor tendon during finger flexion. In fingers, the A2 and A4 pulleys are most critically located and functionally important. Preservation or reconstruction of the two pulleys is necessary in the absence of other pulleys or sheath. Nevertheless, given the presence of other pulleys and sheath, loss of any individual pulleys – including the A2 or A4 pulley – appears to result in few detrimental consequences. Both Tang[22] and Tomiano *et al*.[111,112] showed that incision of the A2 pulley up to one-half or two-thirds of its length or of the entire A4 pulley results in no tendon bowstringing and little loss of digital flexion. In *in vivo* settings, incision of the A2 pulley decreases resistance to

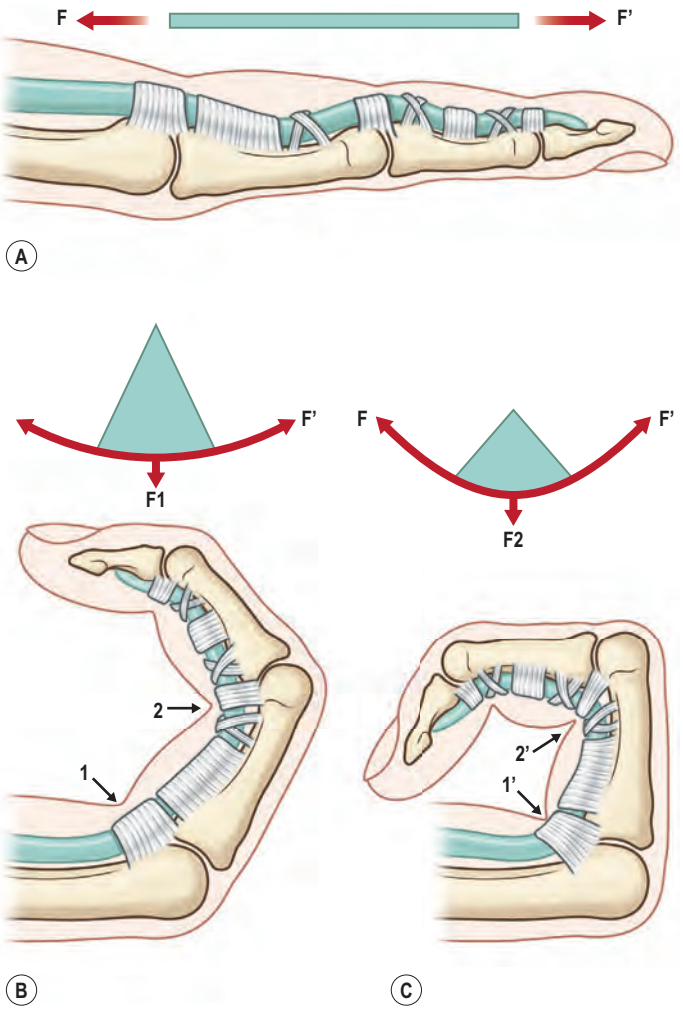

Fig. 9.8 The forces acting on the tendon are different when the tendon is subjected to linear pulling **(A)** or a curvilinear tension **(B,C)**. **(A)** The tendon subjected to linear pulling is loaded by only a linear pulling force. **(B,C)** The tendon subjected to a curvilinear tension is loaded by both linear and bending forces. The repaired tendon fails more easily while being linearly pulled and bent. From **(B)** to **(C)**, as the curvature of the gliding path increases, the bending force on the tendon is increased (F2>F1). Under greater gliding curvature, the tendon fails with a smaller linear pulling force. From **(B)** to **(C)**, as the finger flexes progressively, the tendon fails with an increasingly smaller linear tension. **(C)** The tendon is particularly prone to fail when the finger approaches full flexion. The tendon is easier to disrupt in **(C)** when gliding over joints (1′ and 2′) with greater curvature than in **(B)** with smaller curvature.

tendon motion and lessens the chance of repair failure.[109,110] Loss of the A3 pulley alone has few consequences as well, but a lengthy sheath cut adjacent to the A3 pulley, containing the C1 or C2, causes tendon bowstringing.[107] Therefore, significant loss of sheath should be avoided to maintain tendon function; however, loss of a small portion (<2 cm in length) of the sheath–pulley, even including a part of the most critically located A2 pulley, has no substantial mechanical consequence.

Flexor tendons in the digits glide in a fairly resistance-free synovial environment. Resistance to tendon motion is increased when the tendons are injured and repaired. The following create resistance to tendon gliding: (1) rough tendon gliding surface; (2) biological reactions of the wound, e.g., subcutaneous and tendon edema; (3) friction caused by exposure of suture materials; (4) increases in tendon bulkiness due to placement of sutures; (5) tight closure of sheath or pulleys that narrows the tendon gliding tunnel; (6) tendon-catching at pulley or sheath edges; (7) postsurgical extensor tethering and joint stiffness that burden the movement of the flexor tendon; and (8) adhesions that restrict tendon gliding.

Following trauma and surgery, tendons undergo inflammation, healing, and edema. The volume of the tendons is increased, which increases the resistance within the narrow sheath tunnel. Subcutaneous edema outside the sheath also impedes tendon motion. These factors affecting the resistance to tendon gliding should be considered in deciding how rigorous the postoperative motion program should be. The safety margin can be enhanced by a strong surgical tendon repair or appropriately decompressing the tendon to avoid repair ruptures.

Biological healing strength is a central issue underlying all tendon repairs. Urbaniak *et al.*,[76] Aoki *et al.*,[77] Kubota *et al.*[78] and Boyer *et al.*[114] have characterized the strengths of the healing flexor tendon using animal models. They found that strength either remained consistent or actually decreased somewhat over the initial few weeks after surgery.[76–78] Decreases in strength, typically those in the second postsurgical week, are thought to be caused by softening of the tendon stumps, which lower the suture's holding power. Our investigations using a chicken model indicated that the strength of a healing tendon is steady during the initial 4 weeks, followed by a substantial increase (greater than threefold) in the fifth and sixth weeks; thereafter, the tendon heals strongly and is difficult to disrupt. The fifth and sixth weeks after surgery appear very crucial to regaining strength. Accelerating the healing, aiming to move this critical "strength gain" period to earlier weeks, is a current focus of research into molecular modulation of tendon healing.

Diagnosis

Flexor tendon injuries are open in most cases, resulting from a sharp cut or a crush, but they can also present as closed injuries. Open injuries due to extensive trauma are frequently associated with neurovascular deficits. Closed injuries often relate to forced extension during active flexion of the finger. Flexor tendon rupture can also occur as a result of chronic attrition in rheumatoid disease, Kienböck disease, scaphoid nonunion, a hamate or a distal radius fracture.

Careful attention to the patient's history and the mechanism of injury can alert the surgeon to the extent of the tendon trauma and associated injuries. The natural resting posture of the wounded digits is important for evaluation. Complete lacerations of both FDP and FDS tendons are easily diagnosed when the affected fingers are seen in a relatively extended position with loss of active finger flexion at PIP and DIP joints. If the patient can actively flex the DIP joint while the motion of the PIP joint is blocked, no injuries or only partial injuries to the FDP tendon can be diagnosed (Fig. 9.9). To assess the continuity of the FDS tendon, the adjacent fingers are held in full extension by the examiner. If the patient cannot actively flex the PIP joint, the FDS tendon is severed completely (Fig. 9.10). Variations of the FDS tendons in the little finger are frequent. The FDS in 30–35% of the little fingers has a connection with the FDS in the ring or middle fingers. Some little

Fig. 9.9 Examination of flexor digitorum profundus (FDP) tendon continuity and function. When the proximal interphalangeal joint flexion is blocked, flexion of the distal interphalangeal joint indicates continuity and function of the FDP tendon.

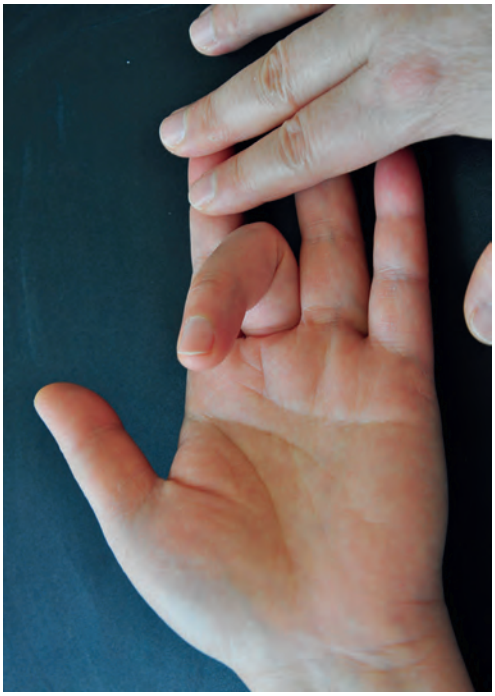

Fig. 9.10 Examination of flexor digitorum superficialis (FDS) tendon continuity and function. If the patient is unable to flex the proximal interphalangeal joint of the examined finger while flexion of the other fingers is blocked, this indicates loss of function of the FDS tendon. Complete flexion of the proximal interphalangeal joint indicates function and continuity of the FDS tendon.

fingers (10–15%) are missing an FDS tendon. These patients have limited or no PIP flexion of the little finger during testing. Weakness during resisted finger flexion indicates a possible partial tendon cut. To test the FPL tendon, the thumb MCP joint is stabilized in neutral position. The patient is asked to flex the IP joint. Loss of active flexion at the joint indicates complete severance of the FPL tendon.

Nerve and vascular function should be assessed routinely, because accompanying injuries in the neurovascular bundles in one or both sides of the fingers or median and ulnar nerves at carpal tunnel or distal forearm are common. Loss of sensation in the finger pulps or loss of function of some intrinsic muscles in the hand are indicative of such accompanying injuries; treatment of neurovascular injuries must be included when planning surgical strategies. If fingers or hands are found to be hypovascular or avascular due to vascular lacerations, vascular anastomosis should be a surgical emergency. Otherwise, after wound debridement, either the lacerated flexor tendons can be repaired (when experienced surgeons are readily available) or the skin can be closed to allow for delayed primary repairs within days by experienced surgeons.

Radiographs should always be taken. Associated fractures are not infrequent and require treatment. Computed tomography (CT) scan or magnetic resonance imaging (MRI) are usually not necessary to diagnose open tendon injuries. However, for diagnosis of closed tendon ruptures or suspected ruptures of the primary end-to-end surgical repair, these tools are of particular value. MRI should be utilized if there is a suspicion of closed tendon rupture. Ultrasonographic examination may also reveal rupture of the tendons.

Treatment/surgical techniques

Primary and delayed primary repairs

Whenever possible, acutely lacerated flexor tendons in the hand and forearm should be treated primarily or at the delayed primary stage. Primary tendon repair is the end-to-end repair performed immediately after wound cleaning and debridement, usually within 24 hours after trauma. Delayed primary repair is defined as the repair performed within 3 or even 4 weeks after tendon lacerations. No clinical investigations actually validated the best time for primary repair. The ideal situation is that of a patient with digital flexor tendon lacerations brought into the clinic soon after injury; surgery begins within a few hours, and an experienced surgeon is readily available. The tendon injured in critical areas (such as zone 2) should not be repaired by an inexperienced surgeon. Rather, the tendon repair can be delayed until an experienced surgeon is available. My preferred period of deliberate delay is 4–7 days, when the risk of infection can be properly addressed and edema has reduced substantially. Delay of the repair beyond 3–4 weeks may cause myostatic shortening of the muscle–tendon unit; for these late cases, lengthening the tendon within the muscles in the forearm can ease the tension (Fig. 9.11).

Rupture of the repaired flexor tendons after surgery can be re-repaired if the rupture occurs within a few weeks up to a month after surgery; secondary tendon grafts may be the only choice for ruptured cases in the presence of obvious retraction

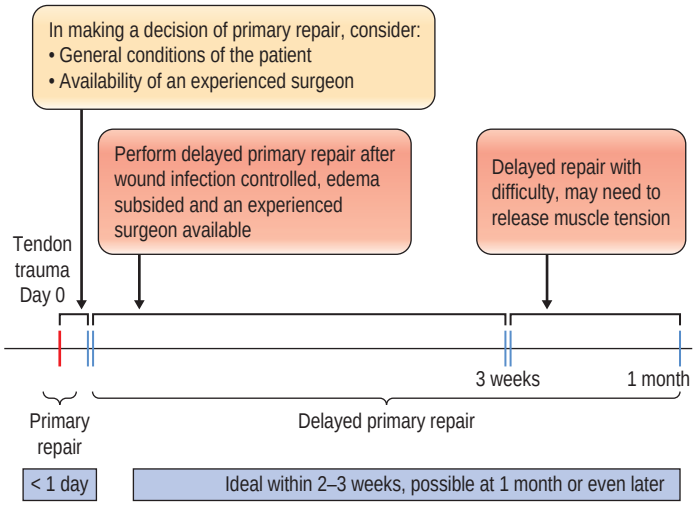

Fig. 9.11 A decision-making flow chart of primary and delayed primary flexor tendon repairs.

of the tendon end or extensive scarring in the intact FDS tendon when the FDP tendon ruptures.

Indications and contraindications

Primary or delayed primary end-to-end tendon repairs are indicated mainly in clean-cut tendon injuries with limited damage to peritendinous tissues. Neurovascular injury is not a contraindication for primary repairs. Loss of soft-tissue coverage over the tendon and the presence of fractures are borderline indications. Local defects in skin and subcutaneous tissues can be covered by flap transfer. A simple fracture limited to the phalangeal or metacarpal shaft can be securely fixed with screws, wires, or intramedullarly placed headless screws, and then tendons can be repaired. However, serious crush injuries, severe wound contamination, loss of extensive soft tissues, or extensive destruction of pulleys and tendon structures are contraindications for primary tendon repairs. Severe injuries to multiple joint components and fractures involving bones at different levels or not yielding stable internal fixation are contraindications for primary tendon repairs (Box 9.2).

Anesthesia

Brachial plexus block is usually sufficient; general anesthesia can also be used when associated injuries are severe. A tourniquet is placed on the upper arm. Nevertheless, local anesthesia without tourniquet with the patient being wide awake during entire surgery can be more beneficial, called "wide-awake" flexor tendon repair as advocated by Lalonde.[123,124] This approach allows the patient to actively flex and extend the operated digits, enabling the surgeons to confirm that the motion is smooth, does not lead to gapping in the repair site, and the repair strength is sufficient for early active motion on the operating table. The anesthetic mixture of 1% lidocaine with 1:100 000 epinephrine is given in the surgical waiting room 20 to 30 minutes before making surgical incisions (Box 9.3). Epinephrine acts to stop bleeding from capillaries and produces maximal capillary constriction about 25 minutes after infiltration to the surgical field.

BOX 9.2 Primary flexor tendon repairs

Indications

1. Clean-cut tendon injuries
2. Tendon cut with limited peritendinous damage, no defects in soft-tissue coverage
3. Regional loss of soft-tissue coverage or fractures of phalangeal shafts are borderline indications
4. Within several days or at most 3 or 4 weeks after tendon laceration

Contraindications

1. Severe wound contamination
2. Bony injuries involving multiple joint components or extensive soft-tissue loss
3. Destruction of a series of annular pulleys and lengthy tendon defects
4. Experienced surgeons are not available

Surgical techniques

The hand and arm are scrubbed and draped. The wounds should be thoroughly debrided, devitalized tissues excised, and the wounds washed with antibiotic solution. Position of the fingers or hand is determined by levels of cuts in the tendons in relation to their superficial tissues. The hand is usually held by an assistant, so that it can be adjusted during surgery. Loupe magnification is advised for surgery. The tendons are exposed through zigzag skin incisions on the volar side of the fingers, e.g., Bruner's incision, or a lateral incision. When the wounds are in the palm or forearm, incision by extending the opening of wounds is often necessary (Fig. 9.12).

BOX 9.3 How to perform local anesthesia for a wide-awake repair

1. Primary or delayed primary repair of the flexor tendons can be performed under local anesthesia, without tourniquet, while the patient is wide awake during entire operation.
2. For the repair in zones 1–3, the method of local anesthesia is to inject 1% lidocaine premixed with 1:100 000 epinephrine. The surgeon should prepare 10 ml of such an anesthetic for each finger with tendon repair. The local anesthetic is injected 20–30 min before beginning the surgical repair.
3. For zone 1 and 2 injuries, the point of first injection is at the midpalm level, just proximal to the MCP joint; a total of 5 ml of anesthetic is injected. The needle should be perpendicular to the skin to minimize pain, and injection is into the subcutaneous tissue.
4. After waiting 5–10 minutes, the second injection (2 ml) is given to the middle part of the proximal phalanx at the volar midline. Immediately after that, the third and fourth injections (2 ml and 1 ml, respectively) are administrated to the middle parts of the middle and distal phalanx along the palmar midline.
5. 15 minutes after completing the above four injections, surgery can begin.
6. For repair in the forearm (zone 5), 20–50 ml of 1% lidocaine with 1:200 000 epinephrine is injected to the multiple sites where surgical incisions will be made 15 minutes before surgery.

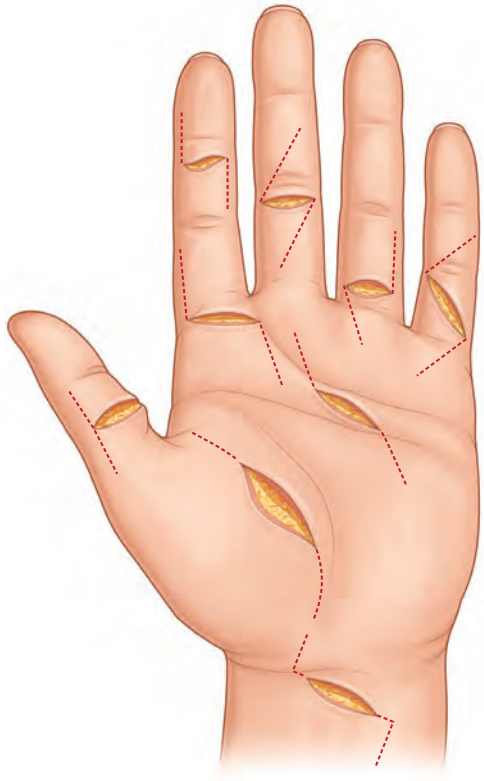

Fig. 9.12 Skin incisions utilized to approach the tendons in the digits and palm.

Zone 1 injuries

In this area, only the FDP tendon is located. When the tendon laceration is in the distal part of this zone (zone 1A and 1B), because the vincula connects to the proximal tendon to prevent retraction, both the proximal and distal ends can be easily found not far from the skin wound in many cases. When cut in zone 1C and some distal tendon cuts, the tendon may retract more proximally. Often it is necessary to make an incision to find the retracted proximal stump. Using a forceps the surgeon can feed the proximal tendon forward from the incision in the palm, bit by bit, to the distal incision in the finger (Fig. 9.13). This maneuver does not traumatize the sheath tunnel or the end of the proximal tendon. Then, a 25-gauge needle is inserted at the base or middle of the finger through the proximal tendon to hold the tendon temporarily.

For zone 1A injuries, the distal stump is very short. The proximal tendon end can be sutured with Bunnell or modified Becker suture with 3-0 polypropylene, and an osteoperiosteal flap is raised at the base of the distal phalanx (Fig. 9.14). The suture is led through an oblique drill-hole, brought out through the nail, and tied over a button above the nail. To avoid passing the suture through the nail, the proximal tendons can be sutured to a fish-mouth opening in the distal tendon stump using reinforced suture repairs or mini-anchors (see Fig. 9.14).[157,158] Another method is to drill a transverse hole through the distal phalanx. After the tendon stump is

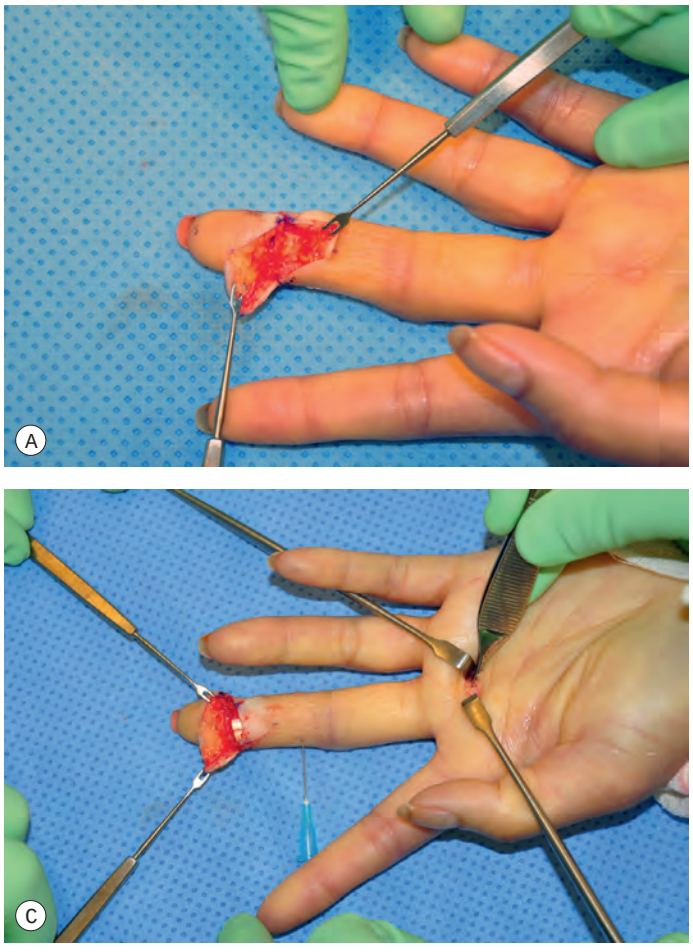

Fig. 9.13 A separate incision in the distal palm is often necessary to find retracted flexor digitorum profundus tendon and advance it distally. **(A)** An incision in the distal palm to find the proximal stump. **(B)** Feeding the retracted proximal tendon forward to the surgical field in zone 1 bit by bit using forceps without traumatizing the tendon stump, which the author often uses. **(C)** A needle was inserted transversely through the sheath and proximal tendon to temporarily fix the proximal tendon to ease tension during repair.

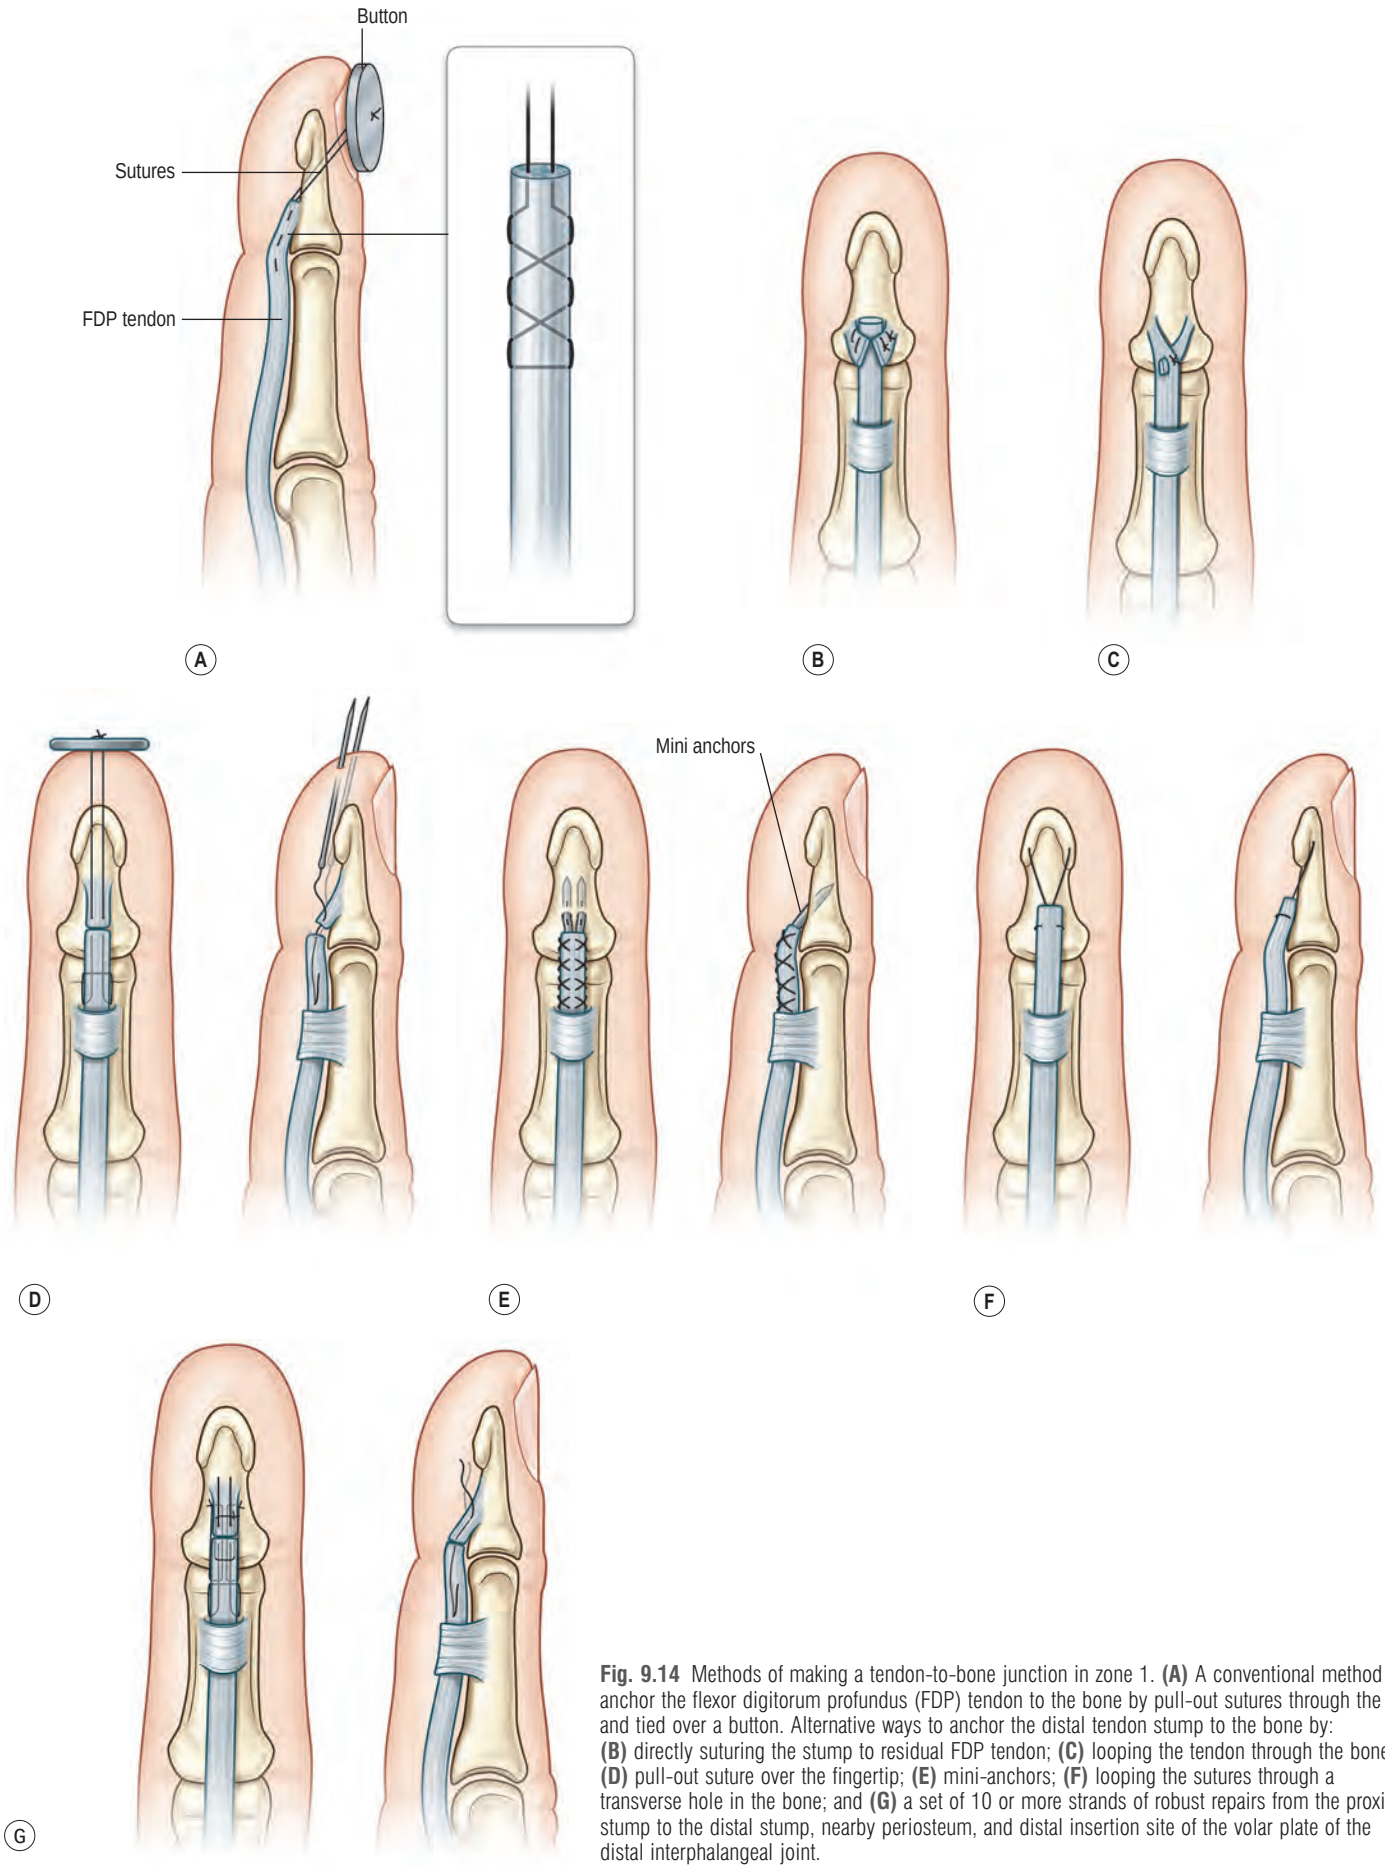

Fig. 9.14 Methods of making a tendon-to-bone junction in zone 1. **(A)** A conventional method to anchor the flexor digitorum profundus (FDP) tendon to the bone by pull-out sutures through the nail and tied over a button. Alternative ways to anchor the distal tendon stump to the bone by: **(B)** directly suturing the stump to residual FDP tendon; **(C)** looping the tendon through the bone; **(D)** pull-out suture over the fingertip; **(E)** mini-anchors; **(F)** looping the sutures through a transverse hole in the bone; and **(G)** a set of 10 or more strands of robust repairs from the proximal stump to the distal stump, nearby periosteum, and distal insertion site of the volar plate of the distal interphalangeal joint.

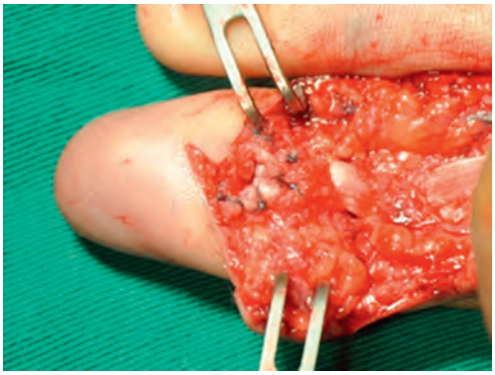

Fig. 9.15 A tendon-to-bone junction made through splitting the short distal stump and reinforced suture repair to the proximal stump or a graft using a 4-0 suture.

sutured, the suture is led through the hole and tied to the other end, through an open approach or percutaneously.[159]

Other methods include: (1) reinforced suture repair of the proximal FDP tendon stump to the distal stump with 4-0 or 3-0 sutures, after the distal stump is split along the midline and the proximal stump is placed between the two slips of the split distal stump;[160] and (2) an extremely robust end-to-end repair, with 10 or 12 strands with 4-0 sutures to connect the proximal tendon to the distal stump, periosteum of the distal phalanx, and the distal anchoring part of the volar plate of the DIP joint (see Fig. 9.14). The author uses both methods (Figs. 9.15 & 9.16) and finds that they have sufficient strength.

Injuries in zones 1B and 1C usually create tendon stumps of sufficient lengths for a more common end-to-end repair, which can be treated by methods similar to treatment in zone

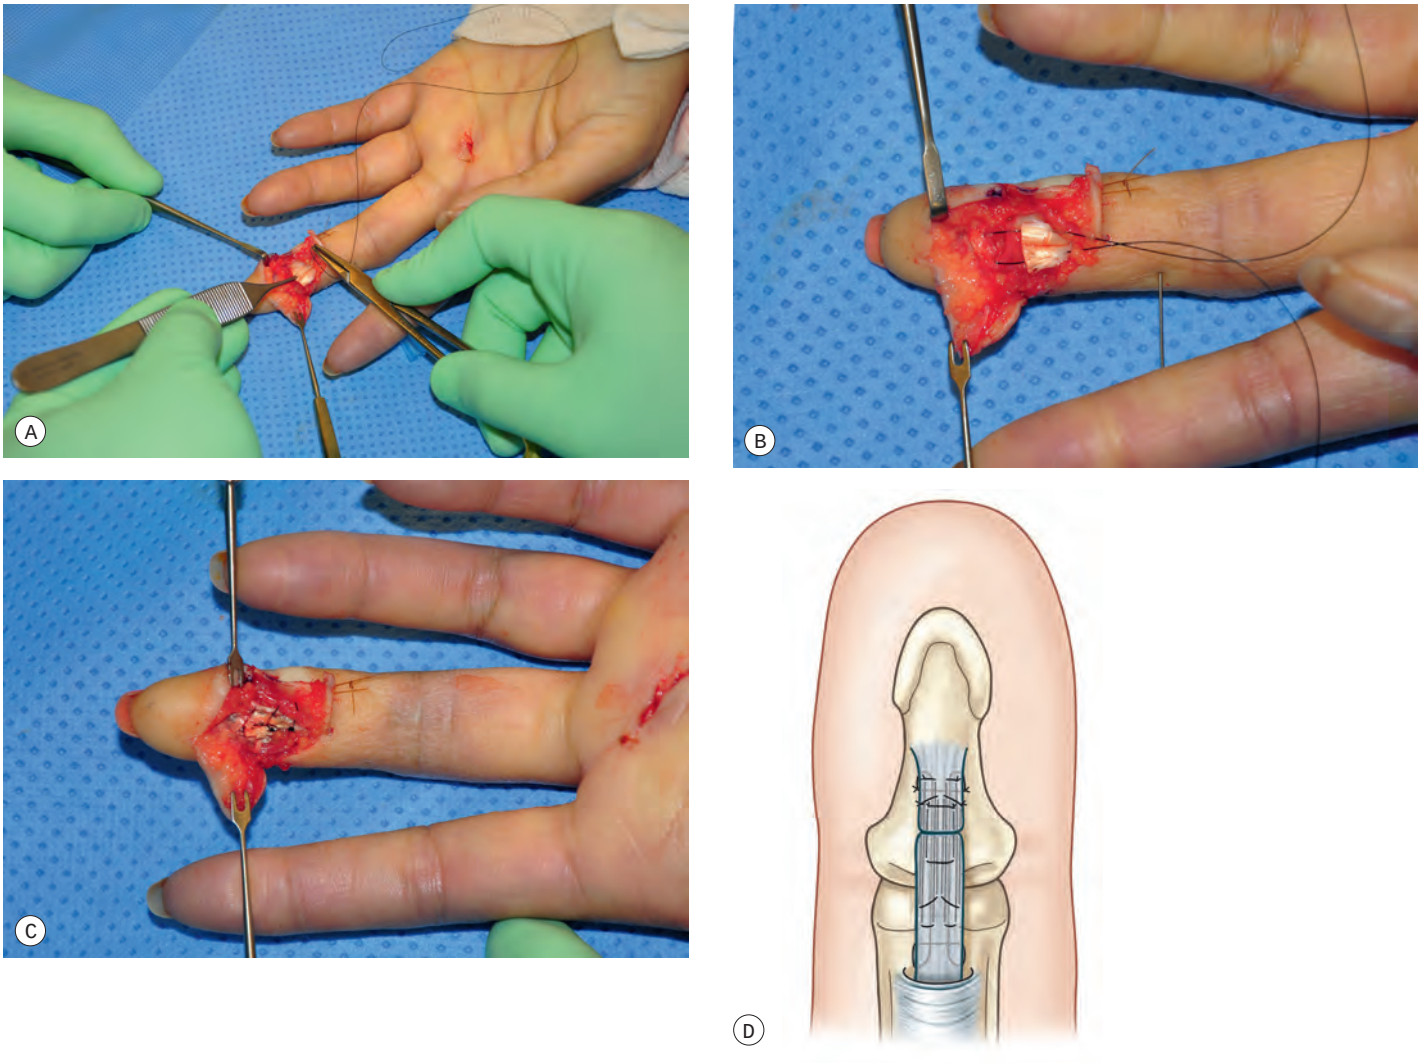

Fig. 9.16 A case of direct suture repair of the proximal stump to the short distal stump with a set of robust 12-strand core sutures made with 4-0 suture. **(A)** In making the first set of repairs: two-strand Kessler, the first bit is in the proximal stump; **(B)** the suture was placed to both stumps; **(C)** after completion of all 12-strand core sutures the repair consists of a Kessler repair in the tendon and a few two-strand repairs with rectangle configuration of different lengths extending to other tissues as shown in **(D)**; and **(D)** drawing depicting this robust direct attachment. The sutures placed after the first Kessler were extended to the periosteum and the other adjacent tissues to help anchor the sutures.

2. Core tendon sutures, such as the cruciate, modified Becker, Strickland, double Kessler repairs, six-strand triple Kessler, or M-Tang, can be placed to the proximal end through a window opening in the proximal sheath. The proximal end is brought underneath the intact sheath between the wound and the proximal opening to approximate the distal end.

Zone 2 injuries (Videos 9.1–9.5 ▶)

Tendon injuries in this area are often exposed through a Bruner skin incision and a window opening in the synovial sheath, a release, or local excision of a short part of the annular pulleys. If the tendon ends have not retracted far proximally, flexion of the MCP or PIP joint can effectively bring the proximal end into sight. Sometimes the proximal tendon end is found retracted even to the middle of the palm. In this instance, an additional incision of 1–1.5 cm is made in the distal or middle of the palm around the MCP joint level to expose the tendons. By loosely suturing the proximal tendon end to a catheter, the proximal tendon end is then pulled distally within the synovial sheath, or the proximal tendon is advanced underneath the intact sheath tunnel by alternately feeding the tendon with two pairs of forceps from the palm incision (see Fig. 9.13). The end is brought out of the distal opening in the sheath to approximate the distal end. While the finger is held in slight flexion, a 25-gauge needle is then inserted at the base of the finger through the proximal tendon to hold the tendon temporarily and to release the tension at the surgical suture site.

During surgery, tendons should be handled atraumatically, and ragged tendon tissue at the cut ends should be removed with a scalpel or fine scissors. Stronger suture materials are preferred; 3-0 or 4-0 sutures (nylon or coated nylon) are common choices. Basic requirements of a tendon repair are: (1) sufficient strength; (2) smooth tendon gliding surface, with minimal suture (and knot) exposure; (3) no gapping of the repair site under tension; and (4) ease to perform.

Surgical suture techniques used vary among surgeons. Some of core suture methods are shown in Fig. 9.17. The modified Kessler and cruciate techniques are further detailed in Fig. 9.18. The Bunnell method is no longer popular for end-to-end repair. The two-strand modified Kessler method and Tsuge method are among the most widely used over the past 40 years. In the last 25 years, a number of multistrand repair techniques have emerged,[14–19,65–69] which include four-strand repairs such as cruciate, modified Savage, Strickland,

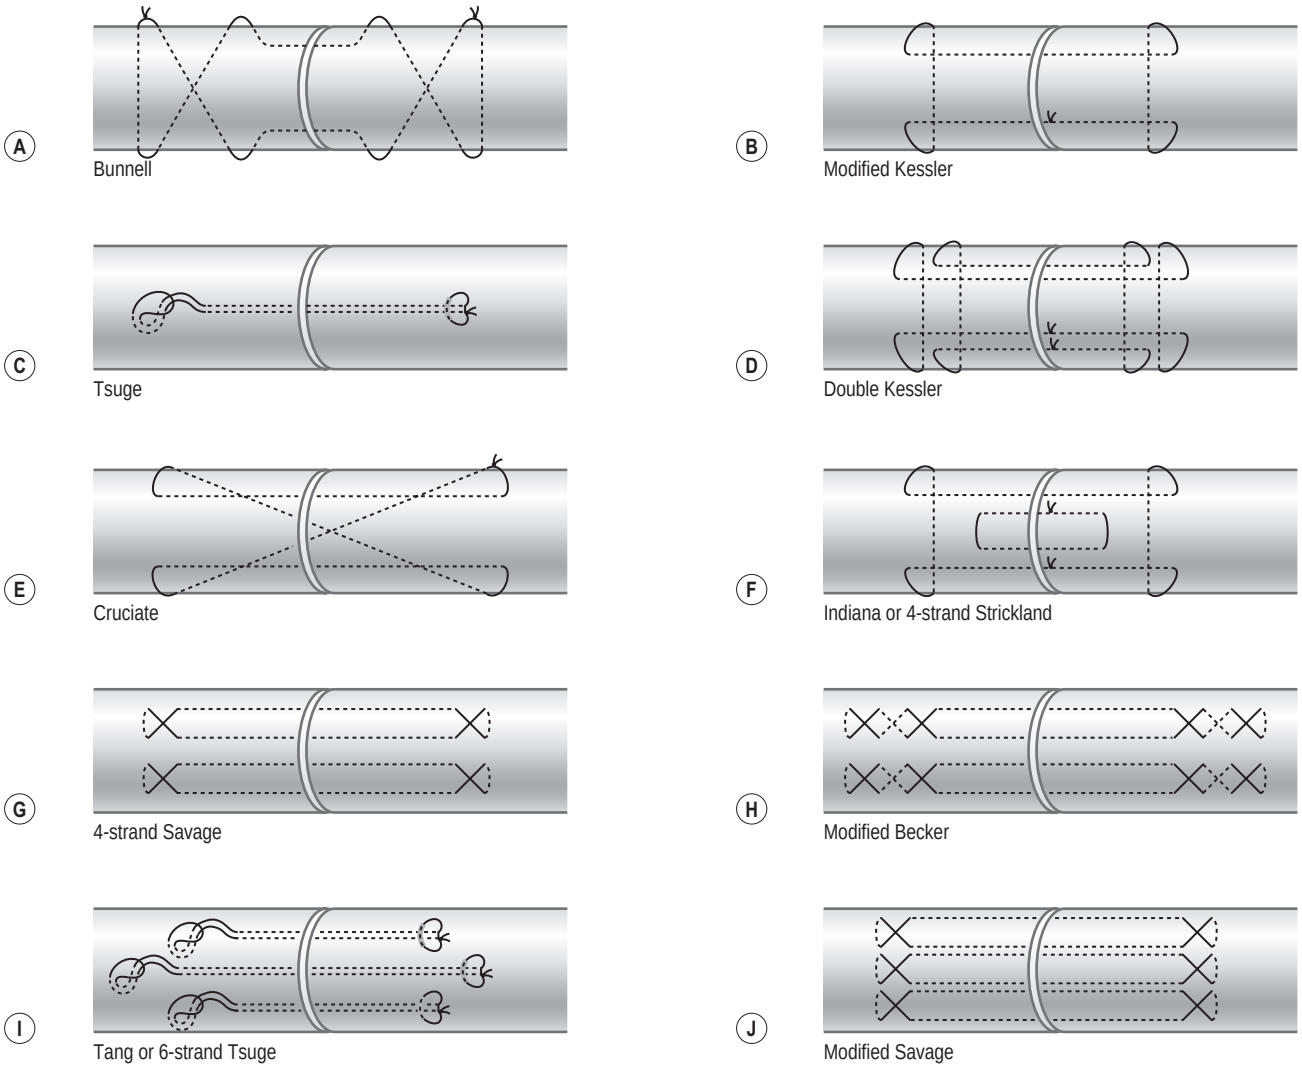

Fig. 9.17 Summary of some methods used to make core sutures in flexor tendon repairs.

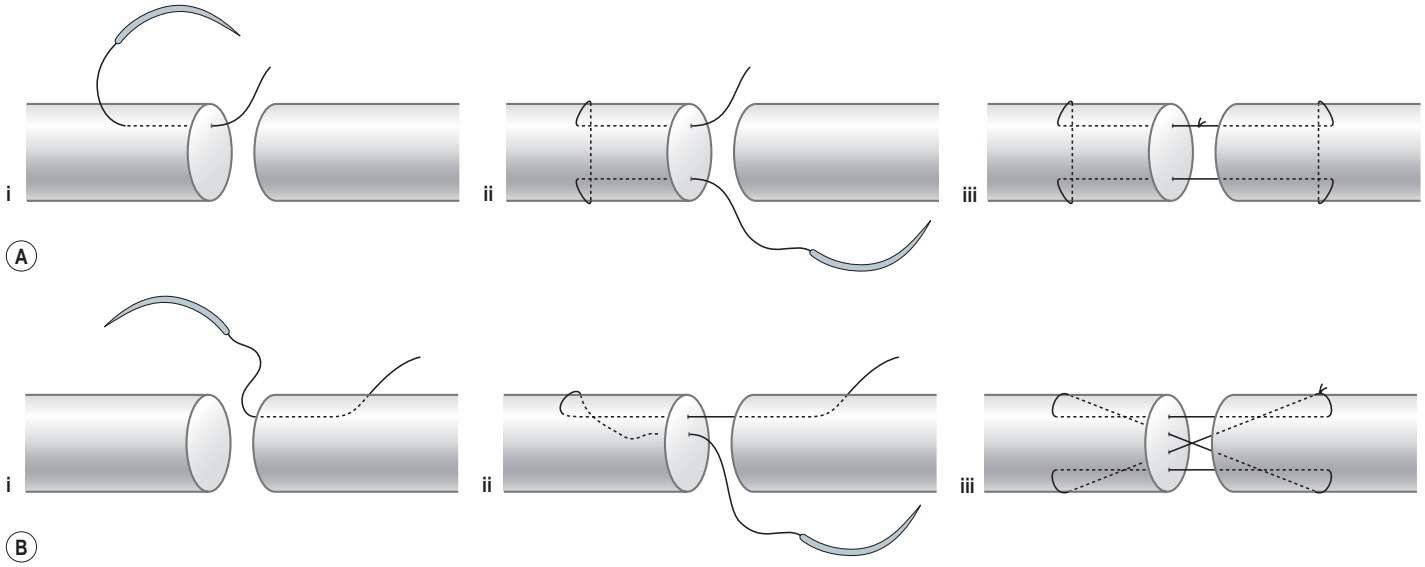

Fig. 9.18 Two common techniques in flexor tendon repairs. **(A)** Modified Kessler method. **(B)** Cruciate method.

and double Kessler; six-strand repairs such as Savage, Lim–Tsai, Tang, and M-Tang; and eight-strand Winters–Gelberman methods. Most surgeons now prefer a multistrand repair. The author uses multistrand methods, typically a six-strand repair method, in repairing lacerated FDP tendons in zone 2.

In the author's practice, the double Tsuge method or six-strand methods have been used in the past 25 years. In the past 15 years, the author and colleagues have used modifications of the original methods to repair tendons using fewer looped lines and knots, but maintaining suture strands and repair strength across the repair site identical to those of the original methods (Fig. 9.19). These methods are relatively easy, and surgical repair strength is very reliable (Figs. 9.20–9.26).

Surgeons use many variants of multistrand repairs in an FDP tendon repair: a variant of the Strickland method is used at Stanford University, a locking cruciate repair at the Hospital for Special Surgery in New York (Fig. 9.27), and an eight-strand core suture is used at Washington University in St. Louis, Missouri. The six-strand Lim–Tsai method is used at the University of Bern, Switzerland and a six-strand Tang method at Broomfield Hospital in Chelmsford, England. The author has also used an asymmetric six-strand Kessler repair, a method of three groups of two-strand Kessler repair made with different purchase lengths in two tendon stumps to better resist gapping (see Fig. 9.27). For FDS tendon cut proximal to bifurcation, I also used a four-strand repair carrying a looped suture or two separate suture lines (see Fig. 9.27).[72] To make a successful repair, surgeons should follow some universal principles, such as ensuring strong core suture repair, sufficient suture purchase, secure anchor of the suture to the tendon and knot security, and creating tighter tension over the repair site. Once such principles are followed, suture configuration itself is not vital. The multistrand methods described – preferred in different centers – may be likewise reliable.

Epitendinous stitches smooth the approximation of the tendon ends and resist gapping during tendon movement. Simple running peripheral, locking running peripheral, cross-stitch peripheral, and Halsted horizontal mattress sutures are among those most often used, with the first two more popular (Fig. 9.28). Some surgeons prefer "deep-bite" peripheral stitches to add strength to repairs.[156] An epitendinous suture is usually added after completion of core sutures, but it can also be added first.[161] Peripheral stitches can be unnecessary given a strong multistrand core suture.[25] Clinically, peripheral repairs vary from complex stitches to none. The author's preference is to use a simple running peripheral suture with 6-0 nylon after completion of a four- or six-strand core suture repair.

Technically, to make an optimal surgical repair, the length of core suture purchase in each tendon end should be at least 7 mm to 1.0 cm. Surgical repair strength decreases as the length of the suture purchase decreases (Fig. 9.29). In addition, a certain tension across the repair site is beneficial to resist gapping. In the author's experience, a certain tension (that results in about 10% shortening of the encompassed tendon, when the proximal tendon is temporarily fixed during surgery) appears beneficial, because a small amount of baseline tension in the repair would counteract the tension of the locomotor system during resting or active motion. When locking suture-junction in the tendon is incorporated in the core sutures, the locking circles of the suture in the tendon should be of a sufficient diameter (approximately 2 mm). After completing the repair, the cut tendon ends should align well, and no gapping between the tendon ends should be observed (Box 9.4).

In the past 15 years, novel repair concepts have emerged and novel materials have been used. For example, of potential clinical merit are techniques involving a single passage of the needle carrying double or even triple strands into the tendon;[69,155,161–163] FiberWire also offers a strong suture material for tendon repairs.[95,155] These methods are effective in enhancing strength with a minimal suture passage in the tendon.

Closure of the synovial sheath is no longer considered essential for tendon repairs after hot debate in the 1980s and early 1990s.[164–171] Closure may be attempted in clean-cut injury when sheath defects or abrasions are absent. It is now agreed that avoiding compression or constriction to the edematous

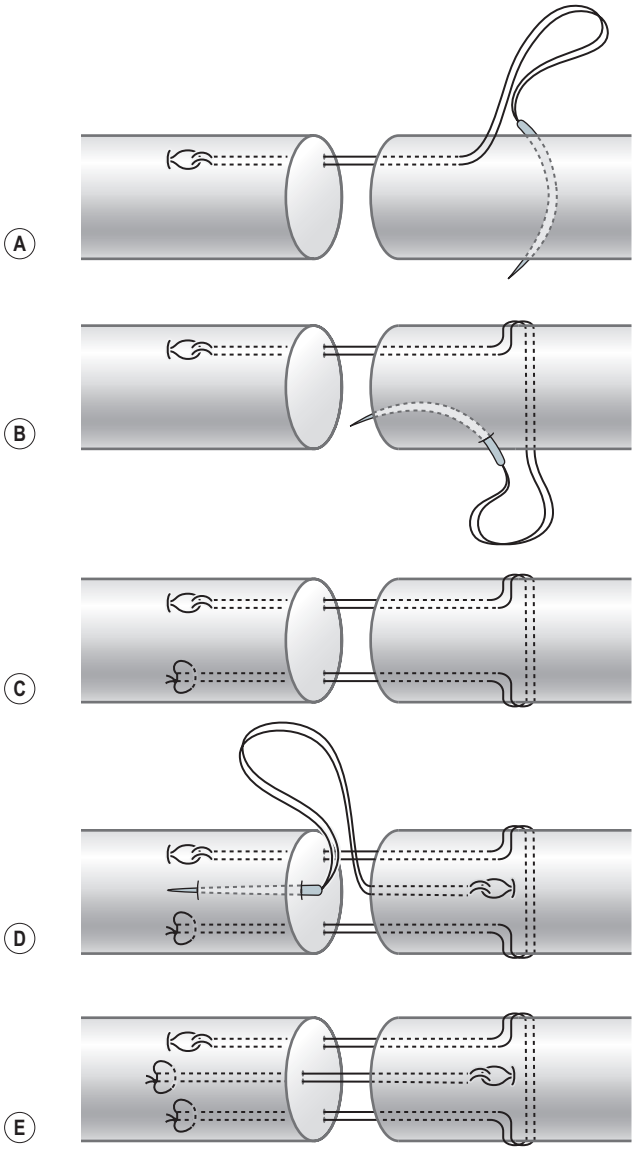

Fig. 9.19 The technique for making a six-strand M-Tang tendon repair. Two separated looped sutures are used to make an M-shaped repair within the tendon. **(A–C)** A U-shaped four-strand repair is completed, which can be used alone for tendon repair. **(D,E)** An additional looped repair is added at the center, to complete the six-strand repair. In tendon cross-sections, three suture groups are placed at points of a triangle to avoid interference to the dorsal center of the tendon where the vascular networks converge. The dorsolateral sutures may act as tension bands to resist gapping of the tendon.

tendons by the sheath or annular pulleys after surgery is very important to tendon healing. With major pulleys and a majority of the sheath intact, leaving a part of the synovial sheath open has no significant adverse effect on tendon function and healing. On the other hand, incision of one single annular pulley (A1, A3, or A4) or a critical part (up to two-thirds of its length) of the A2 pulley does not significantly affect tendon gliding when all other pulleys or the synovial sheath are intact. Such a release can in fact be beneficial to tendon healing and gliding: as healing responses and adhesions arise, it releases constrictions on edematous tendons.

Clinically, the A4 or A2 pulley sometimes constitutes an obstacle for the edematous tendon to glide through, which

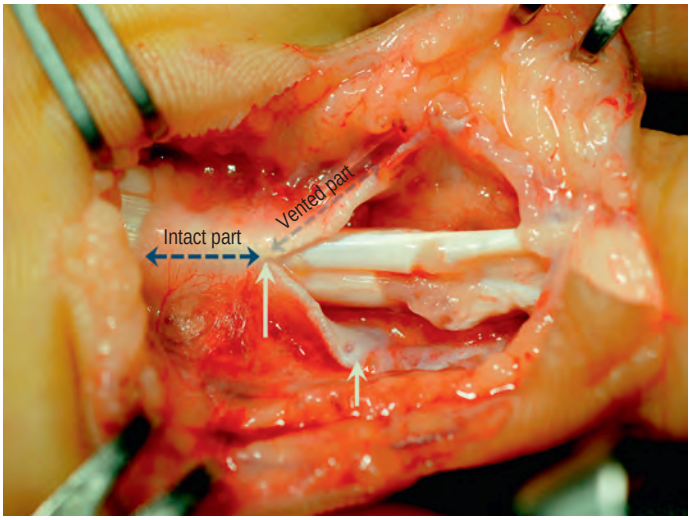

Fig. 9.20 A case with complete laceration of the flexor digitorum profundus tendon and partial flexor digitorum superficialis tendon laceration in zone 2B. The surgery was performed 10 days after injury. The wound was exposed through a Bruner incision, and the distal half of the A2 pulley was incised through the volar midline.

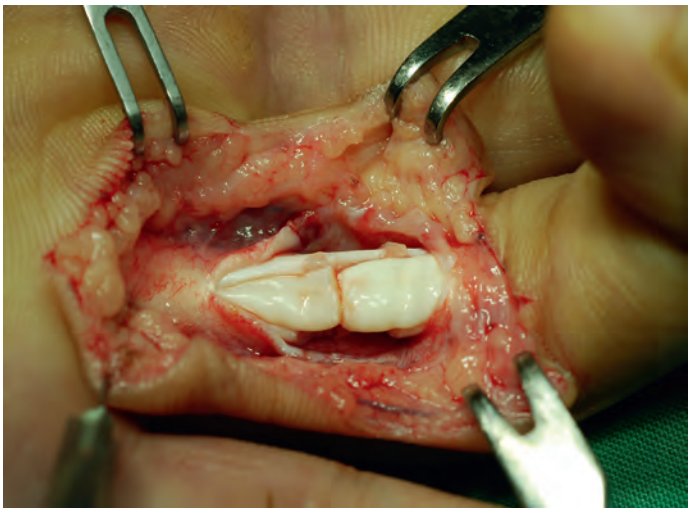

Fig. 9.21 The lacerated flexor digitorum profundus tendon was found through a separate incision in the palm and was led underneath the sheath and pulleys to the operation field distal to the A2 pulley, to approximate the distal stump.

may cause repair rupture during tendon motion exercise. The perceived need for complete preservation of the A4 and A2 pulleys during primary repairs is "borrowed" from the surgery pertaining to secondary tendon reconstructions, and does not hold true when the tendons are cut through a single wound and other sheaths or pulleys are intact. Contrary to the practice of 10 or 20 years ago, releasing the A4 pulley entirely and releasing a part of the A2 have become accepted clinical practice in recent years.[19,23,150,172,173] In the author's clinic, when the repaired FDP tendons are found tightly entrapped by the A4 pulley after testing during surgery, the A4 pulley is completely released (Figs. 9.30–9.32) (Box 9.5). A

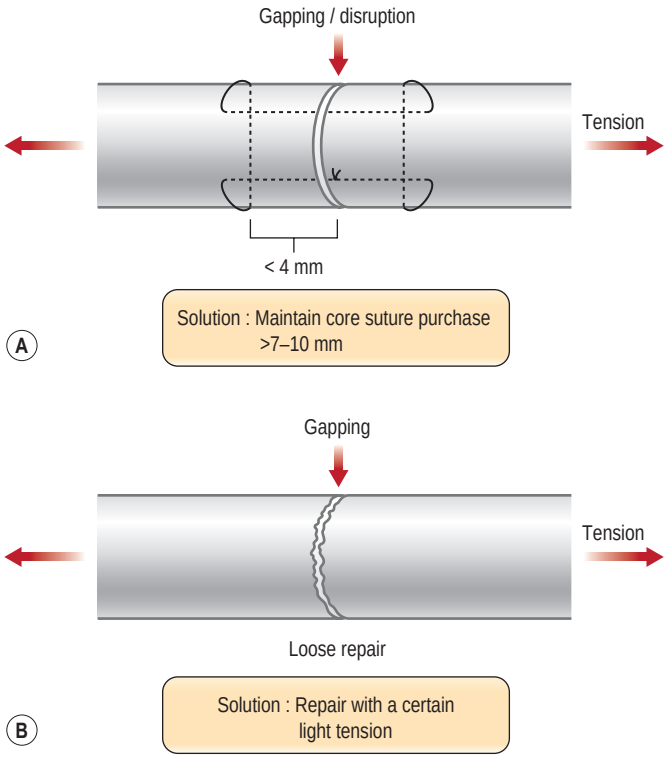

Fig. 9.29 Two bad repairs decrease the strength: **(A)** a repair with short core suture purchase and **(B)** a loose repair. Sufficient core suture purchase and a certain pre-tension favor resisting gapping and decrease the chance of repair failure during tendon motion after surgery.

BOX 9.4 **Recommended surgical tendon repair requirements**

- More than 2 strands as the core repair – four- or six-strands recommended.
- Certain tension across the repair site – 10% shortening of tendon segment after repair.
- Core suture purchase: 7–10 cm.
- Locking tendon-suture junctions in core suture.
- Diameter of the locks: 2 mm or over.
- Suture calibers: 3-0 or 4-0 for core suture.
- A variety of nylon sutures, or a FiberWire suture.
- A simple running or locking peripheral suture.
- Minimal separate stitches of peripheral suture if core repair is extremely strong.
- Avoid extensive exposure of sutures over the tendon surface.

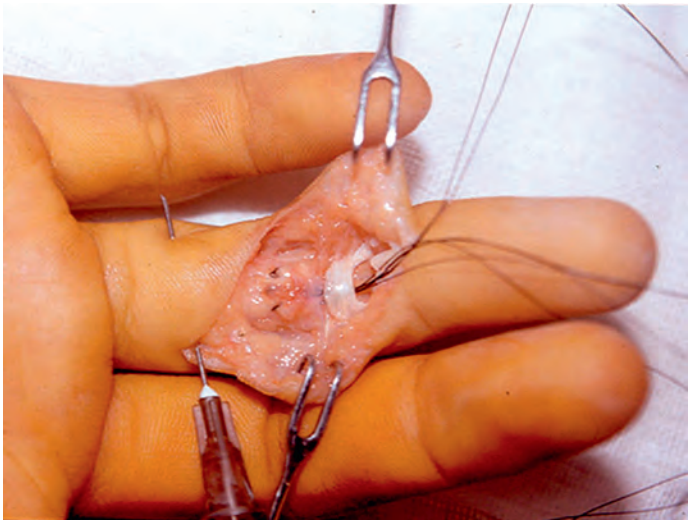

Fig. 9.30 The constricting A4 pulley sometimes presents an obstacle for the passage of the flexor digitorum profundus tendon.

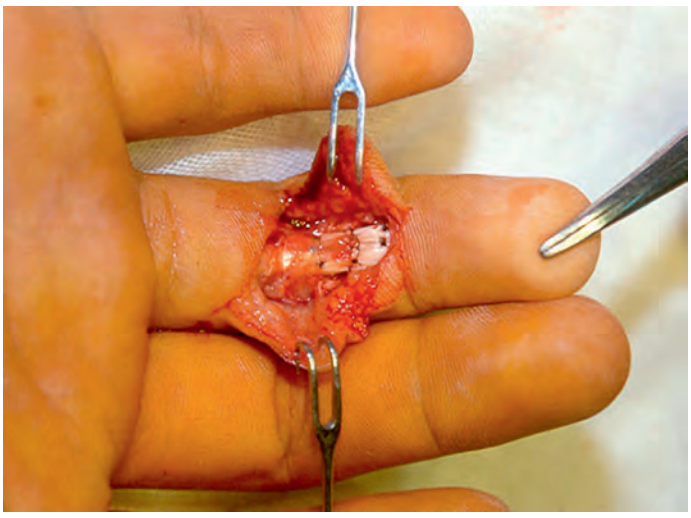

Fig. 9.31 The A4 pulley and a part of its adjacent sheath were vented to allow tendon passage in this patient. Other parts of the sheath were not violated. In this case, the flexor digitorum profundus tendon was repaired with a six-strand original Tang repair with three groups of looped sutures.

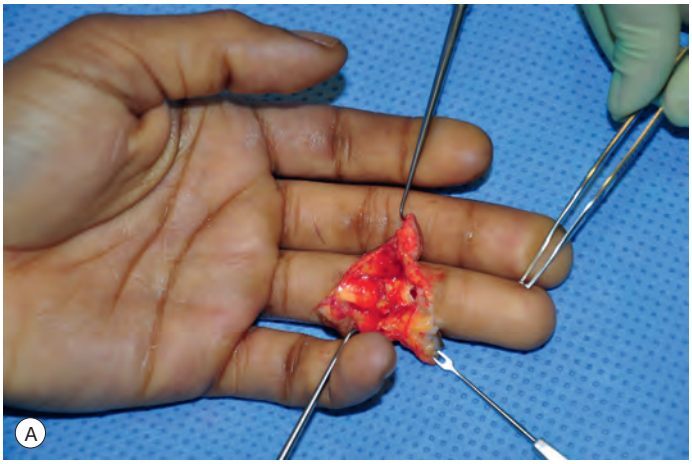

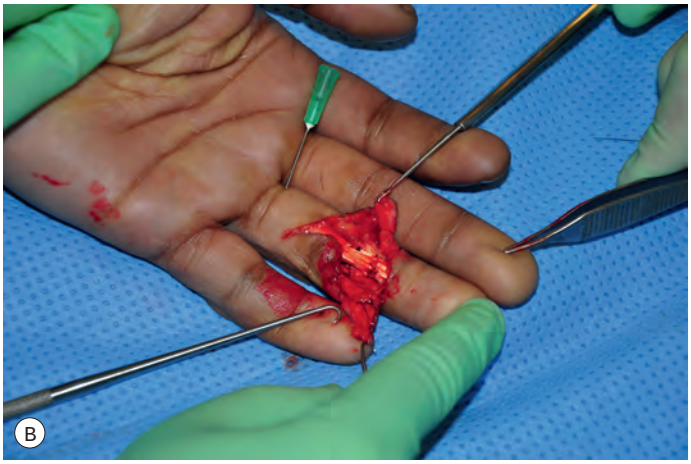

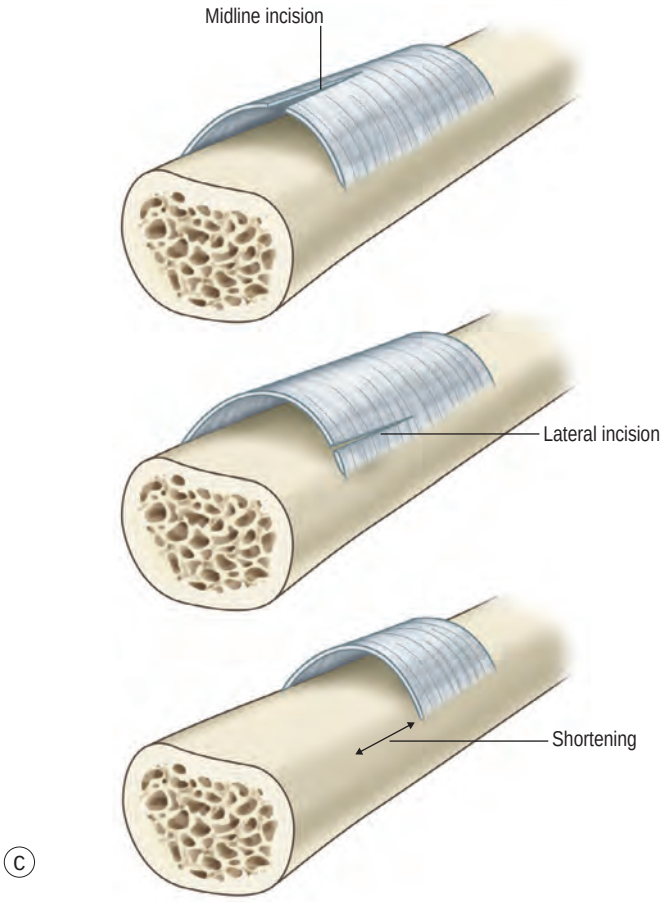

Fig. 9.32 A case of delayed primary repair. **(A)** An intact A4 pulley was seen. **(B)** The A4 pulley was cut open entirely to allow tendon repair. The flexor digitorum profundus tendon was repaired with a six-strand asymmetric Kessler repair (see Fig. 9.27C). **(C)** Methods of venting a pulley: midline cut, lateral cut, or shortening.

part of the A2 pulley, either proximal or distal (about one-half to two-thirds length of the A2 pulley; see Figs. 9.20–9.24), is cut when both the FDS and FDP tendons are repaired in the area of or distal to the A2 pulley. When the repair is considerably delayed (3 weeks after injury), the A2 pulley usually collapses or is even embedded within scars. A portion of the A2 pulley is excised to shorten this pulley (Figs. 9.33–9.37).

The release usually needs to include a part of adjacent synovial sheath. The total length of the sheath–pulley release is about 2 cm in adults, which amply decompresses tendon gliding, but does not lead to functional disturbance. The areas of the release are shown in Fig. 9.38.

Over the years, release of the pulleys has been achieved differently: (1) incision of the entire or a critical part of the major pulley;[19,22,23,150] (2) excision of a part of the major pulley;[19] (3) Omega pulley plasty;[174] and (4) sheath enlargement plasty.[175,176] My current pulley release is a simple procedure: incising the A4 or a portion of the A2 pulley, or partially excising the A2 pulley, while obviating complicated sheath- or pulley-plasty surgeries.

Whether or how to repair the FDS tendon when both flexor tendons are injured is a subject of diverse opinions, particularly in the areas covered by the A2 pulley or distal to it. A few reports have discussed it specifically.[21,177,178] Repair of one

BOX 9.5 When and how to vent the A4 pulley for tendon repair

1. The A4 pulley is located at the middle part of the middle phalanx, about 5 mm long.
2. The A4 pulley is rigid, constrictive, and narrow.
3. When this pulley prevents smooth passage of the retracted FDP tendon underneath, or when the pulley is found to prevent smooth gliding of the repaired FDP tendon during digital extension–flexion test (see Box 9.6 for method detail), this pulley can be entirely vented after the surgeon confirms that all other annular pulleys are intact.
4. The A3 pulley should usually be preserved. In the rare case when the A3 pulley has to be vented, any synovial sheath proximal to the A3 should be entirely preserved.
5. The entire length of the sheath–pulley venting should be less than 1.5–2 cm over the middle phalanx area.
6. The method of venting is (1) direct cut along the palmar midline of the pulley, or (2) direct cut along the lateral side of the pulley, or (3) resection of this pulley if it has been embedded inside adhesions and fibrosis.

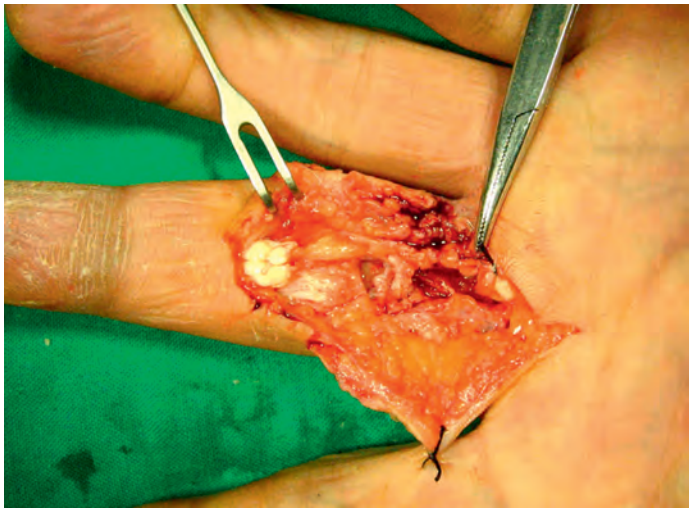

Fig. 9.33 A case of ruptured primary repair referred to the author. Direct repair of the ruptured flexor digitorum profundus tendon was performed 3 weeks after the first tendon repair. The flexor tendons and the A2 pulley were found embedded within scars.

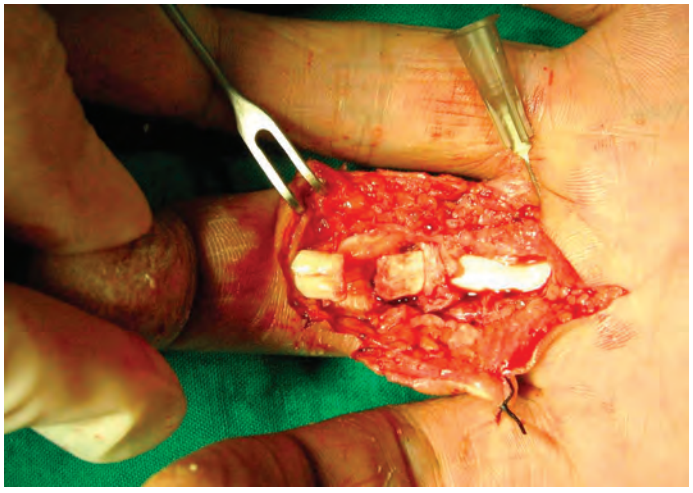

Fig. 9.34 The A2 pulley was partially excised and the intact part of the A2 pulley was released from the scar. The ragged tendon ends were trimmed to fresh tendon surfaces.

Fig. 9.35 The proximal tendon stump was passed underneath the preserved portion of the A2 pulley. The tendon was repaired with the six-strand M-Tang technique.

slip of the FDS is also feasible.[100,108] In the area of the A2 pulley (zone 2C), the author prefers to locally excise the FDS in cases with severe peritendinous injuries, when the tendons appear edematous, and in cases with delayed primary repairs. In performing the delayed repair, the author finds it almost impossible to repair the FDS tendon in zone 2C, because some degree of collapse or narrowing of the A2 pulley is inevitable, and the tendons are often edematous. In zone 2B, where the FDS tendon is bifurcated into two slips, the author uses two Tsuge repairs separately in each tendon slip; when the laceration is close to the insertion, the tendon slips are anchored to the phalanx. Treatment of the FDS tendon in zone 2D is straightforward, similar to the FDP tendon except that the FDS is flatter and four or fewer strands are used.

Fig. 9.36 Follow-up 6 months after surgery. Full flexion of the finger, with no loss of digital flexion and no tendon bowstringing.

Fig. 9.37 Full extension of the fingers, without extension deficits of the finger joints.

In deciding surgical options relating to both the FDS and the pulleys, the author generally seeks to appropriately decrease the gliding contents (by not repairing or excising the FDS tendon) or enlarge the sheath (when both tendons are repaired primarily or only the FDP tendon is repaired at the delayed stage). The underlying idea is that the fibro-osseous digital flexor sheath tunnel is comparable to a tight fascia compartment of extremities; the edematous and healing tendons are compromised easily. Release of compression of the tendon to avoid overloading it during motion can be more vital to the success of treatment than providing it with sufficient surgical strength.

Surgical options currently advised to deal with the tendons and pulleys in the most complex areas of finger flexor tendons are summarized in Table 9.1.

Once surgeons have completed surgical repair of the tendon, and vented the pulleys in case of need, an intraoperative test – "digital extension–flexion test" – should be performed before closure of surgical incisions.[149] Detailed in Box 9.6, this test consists of three parts: full extension of the operated digit, flexion of the digit from full extension to flexion, and finally maximal digital flexion (Fig. 9.39). If the repair fails this test, the repair should be either redone or enhanced, or the annular pulley proximal to the repair vented further, depending on the circumstance. If the repair is a wide-awake surgery, the patient should move the digit actively on

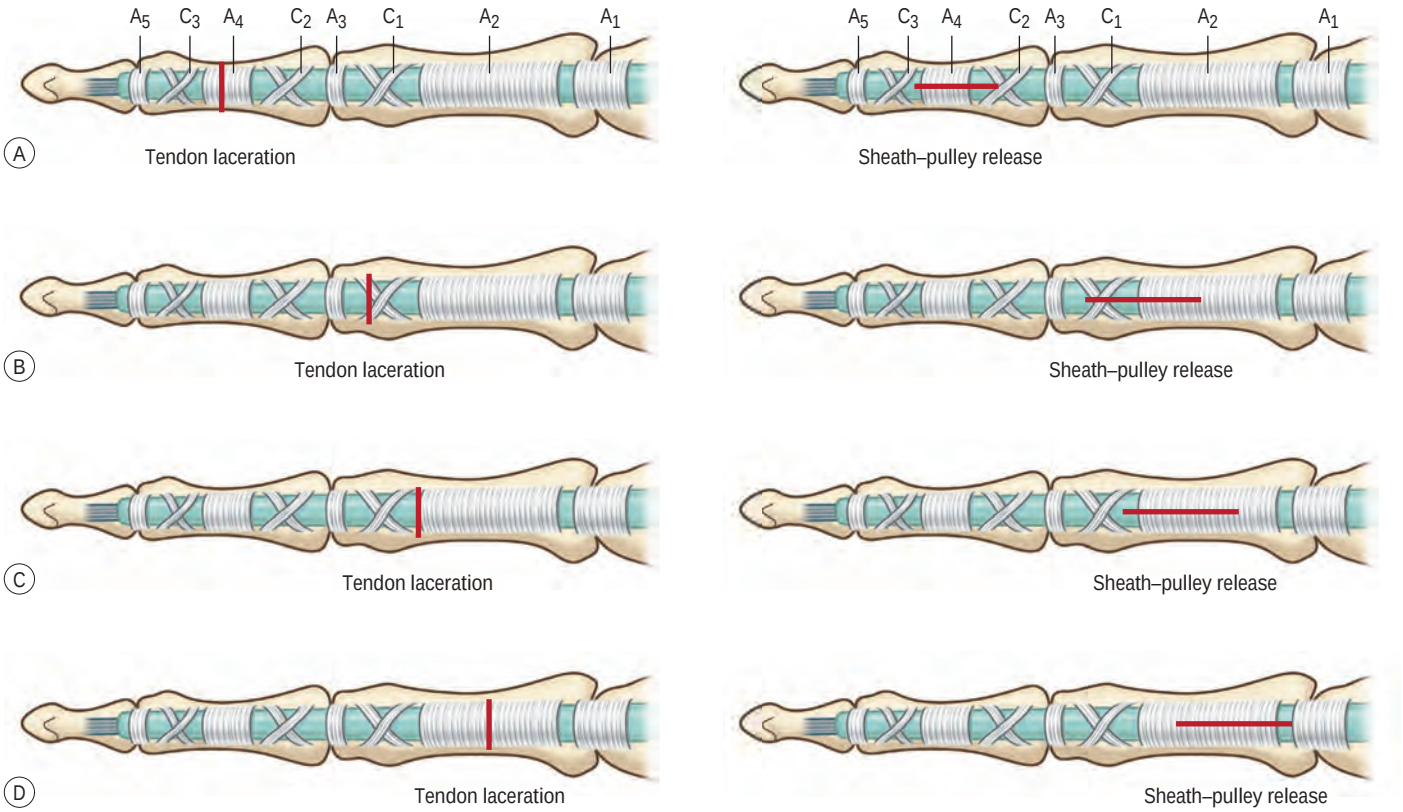

Fig. 9.38 Drawings depicting the length and areas of release of the pulley–sheath complex to decompress the repaired tendons, without bowstringing or loss of tendon function. **(A)** Release of the entire A4 pulley when the flexor digitorum profundus tendon has been cut around the A4 pulley and the tendon cannot pass easily beneath this pulley during surgery. **(B)** Release of a part of the sheath distal to the A2 pulley and the distal half of the A2 pulley, when the tendons are cut a little distal to the A2 pulley. **(C)** Release of a short part of the sheath distal to the A2 pulley and the distal two-thirds of the A2 pulley when repairing tendons cut at the edge of, or in the distal part of, the A2 pulley. **(D)** Release of the proximal two-thirds of the A2 pulley when repairing a cut in the middle, or proximal part of, the A2 pulley.

Table 9.1 Summary of mechanical basis and surgical options advised to deal with the flexor digitorum superficialis (FDS) tendon and pulleys in zone 2 of the finger

Investigations	Area of FDS insertion (2A)	Distal to A2 pulley (2B)	Beneath A2 pulley (2C)	Proximal to A2 pulley (2D)
Anatomic				
FDS tendon	Insertion	2 slips, dorsal to FDP, with vincula	Bifurcation	One single band, flattened palmar to FDP
Pulleys	A4, C2, narrow	A3, C1	A2, narrow	A1, PA
Biomechanical				
FDS tendon	No gliding	Not constricting FDP	Constricting FDP, as a moving and second "pulley"	Little constriction
Pulleys	A4 release is feasible[112]	May incise one pulley[107]	Partial release is feasible[22,111,112]	
Clinical options				
FDS tendon		Repair[174,214]	Resection or do not repair[21,23,150] Resect one slip[101]	Repair both tendons when possible
Pulleys	A4 venting[19,23,172]		Partial release[19,23,150,172] Pulley shortening or plasty[100,175]	

FDP, Flexor digitorum profundus; PA, palmar aponeurosis.

the operating table, which offers the most objective measure of quality of the repair (Fig. 9.40). If a repair fails the test intraoperatively, this poor repair is bound to gapping or disruption in later early active motion; therefore it should be revised before leaving the operating table.

Zone 3, 4, and 5 injuries

The repair techniques for injured flexor tendons proximal to zone 2 are almost identical to those used in zone 2. These zones have a better prognosis because of richer vascularity around the tendon and lack of constricting pulleys over the tendons. Adhesions in these areas are less likely to impede tendon motion. Zone 4 tendon injuries are frequently accompanied by lacerations to the median nerve. The transverse carpal ligament may be partly or entirely opened to facilitate repairs and left partly open after tendon repairs. Zone 5 tendon injuries usually present as multiple tendon lacerations with neurovascular injuries. A wrist with transection of a majority of tendons, vessels, and nerves (at least 10 out of 15 of these structures, excluding palmaris longus) is called a "spaghetti" wrist.[179–183] A "spaghetti" wrist was reported to have an adverse effect on the recovery of the independent FDS action but not on the recovery of digital range of motion.[183] In zone 5, repair of the FDS tendon is preferred, and early postoperative tendon motion is advised,[183–185] which favors independent movement of the superficialis. However, the FDS tendon to the little finger may be absent or too slender to repair.

BOX 9.6 When and how to perform an extension–flexion test

- This test should be performed after any kind of primary repair of flexor tendons in the digital and palm area, to make sure the repair is strong and that tendon gliding is smooth before closure of surgical incisions.
- There are three parts to this test. *Part 1*: Full passive extension of the digit that has undergone surgery by the operator, to confirm that the tendon repair site has no gapping.
- *Part 2*: From the fully extended position, the operated digit is passively flexed to moderate degrees, to confirm that the tendon and the repair site can glide smoothly.
- *Part 3*: Further pushing the digit to full or almost full flexion, to confirm that the tendon repair site does not impinge against rigid annular pulleys.
- If tendon gapping is found with digital extension, the repair should be reinforced, or if annular pulleys block tendon gliding with digital flexion, the pulleys should be vented, according to guidelines for treatment of pulleys.
- The results of the above tests are included in the operative notes and the therapists are informed.

FPL injuries

Repair of the injured FPL tendon in the thumb usually follows the same principles and methods of repairs of the FDP tendon in fingers. Multistrand repairs are advised, and one or two pulleys can be vented to free tendon motion. Reports have shown that conventional two-strand repairs have a risk of rupture as high as 17%.[25,172] In a report from David Elliot's hand center, Giesen *et al*.[25] reported no ruptures and good function after use of a six-strand Tang method without peripheral sutures in repairing 50 FPL tendons. In this case series, which reported the best outcomes of FPL tendon repairs thus far, the pulleys were vented and the sheath was not closed. The authors found that this six-strand repair was safe for early active mobilization and easier to perform than Kessler core sutures and elaborate Silfverskiöld sutures.

In repairing the FPL tendon, the proximal cut end of the tendon frequently retracts into the thenar muscles. This end can be retrieved with the techniques described for retracted FDS and FDP tendons (Figs. 9.41 & 9.42). If the proximal stump of the FPL tendon has retracted proximal to the thenar

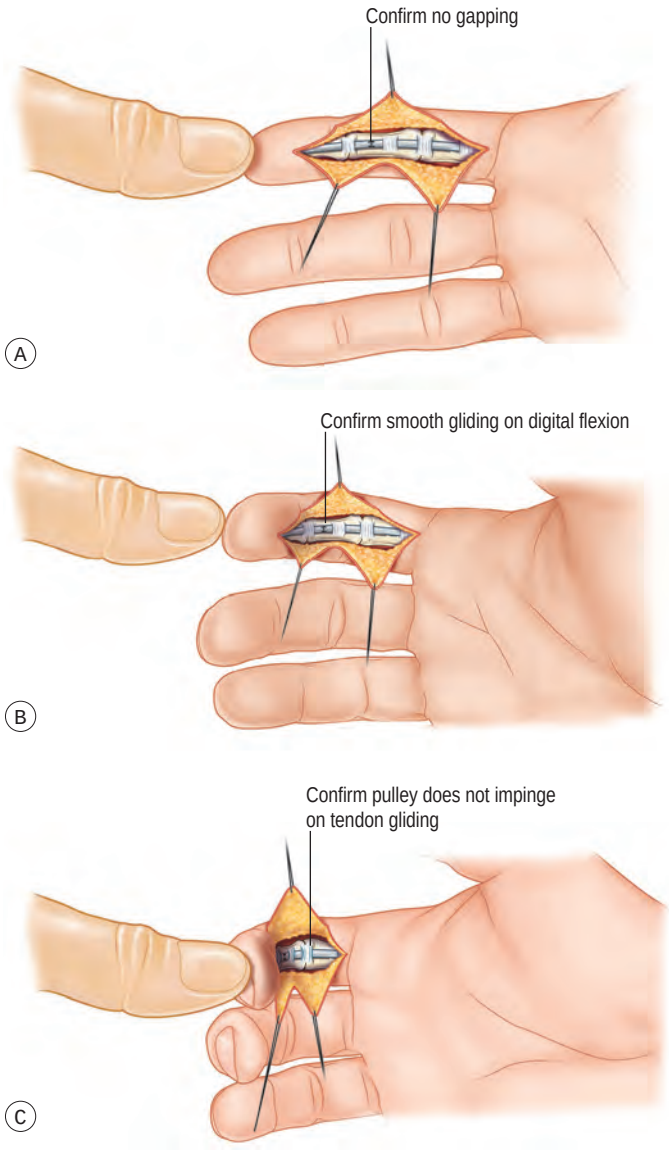

Fig. 9.39 Extension–flexion test of the repaired tendon before closure of surgical incision. **(A)** Full extension of the digit. **(B)** Motion from full extension to flexion. **(C)** Completing the maximal flexion. In wide-awake surgical settings, the digital motion is active, providing the best measure of quality of surgical repair.

muscles, a separate incision in the forearm is required to locate the stump. The FPL stump usually lies deep to the FCR tendon and the radial artery.

Injuries in children

Flexor tendon repairs in children have a better prognosis than those in adults.[186–190] As children may be less compliant with instructions to limit movement, the repaired digits are usually immobilized for 3–3.5 weeks after surgery. Either a two-strand or a four-strand repair can be used. In practice, many surgeons use a two-strand repair and achieve good return of function. The outcomes appear unaffected by whether a two- or four-strand repair is used or whether the tendon is moved or immobilized early after surgery.[188,189] Navali and Rouhani[188] reported that both a two-strand and four-strand repair achieved good functional return, with no difference in range of active digital motion between the two methods. Elhassan *et al*.[189] reported that early postoperative motion and immobilization did not affect outcomes in children aged 2–14 years with injuries in zones 1 and 2.

Partial tendon lacerations

Laceration through less than 60% of the diameter of the tendon does not necessitate a repair by core sutures. An increased risk of triggering, entrapment, or ruptures is associated with partial laceration over 60%.[191–195] For lacerations less than 60%, the tendon wound can be trimmed to lessen the chance of entrapment by pulley edges and friction against the sheath. Alternatively, the cut portion of the tendon can be repaired with epitendinous stitches to smooth the tendon surface and to strengthen the tendon. Laceration of 60–80% requires at least an epitendinous repair[196–199] and is better repaired using a two-strand core suture through the cut portion. Laceration of 80–90% is treated identically to a complete laceration.

Closed rupture of the flexor tendons and pulleys

Traumatic FDP tendon avulsion from the tendon–bone junction accounts for a major portion of closed rupture cases.[200–203] The injury mechanism is hyperextension of the DIP joint, which subjects the FDP tendon to excessive load. The tendon disrupts at its insertion to the distal phalanx. Athletic injuries can lead to this type of injury. In football, wrestling, or rugby, when one player grabs another's jersey, a finger gets caught and pulled, resulting in disruption of flexor tendons. This injury ("jersey finger") is seen most commonly in the ring finger. Closed tendon ruptures at the wrist can be associated with fractures in carpal bones.[203] Flexor pulleys are prone to sprains and ruptures during climbing. Rupture of the pulleys occurs in up to 20% of climbers.[204] The A2 pulley of the ring finger is the most often injured. Closed pulley ruptures are treated conservatively or by surgical reconstruction.

Leddy and Packer[200] classified close tendon ruptures into following types:

I. The FDP tendon is avulsed from the phalanx and retracts into the palm. The vincula of the FDP tendon are disrupted. There is no active flexion of the DIP joint. A tender mass is present in the palm. The tendon should be reinserted within 7–10 days before the sheath collapses, which may prevent advancing the tendon distally. Muscle contracture may also prevent tendon advancement.
II. The FDP tendon retracts to the level of the PIP joint. This is the most common type. The sheath is not compromised, and muscle contracture does not develop easily. Repair may be attempted 1 month after injury.
III. A large bone fragment is attached to the FDP tendon. This bone fragment frequently prevents the tendon from retraction proximal to the A4 pulley. Bony fixation using a K-wire or a screw usually suffices.
IV. The FDP tendon avulses from the bony fragment. This type was added by Smith.[200] The avulsed tendon retracts beyond the middle phalanx and even into the palm. In treating type IV injuries, the bony fragment is attached into the distal phalanx first; then the avulsed tendon is

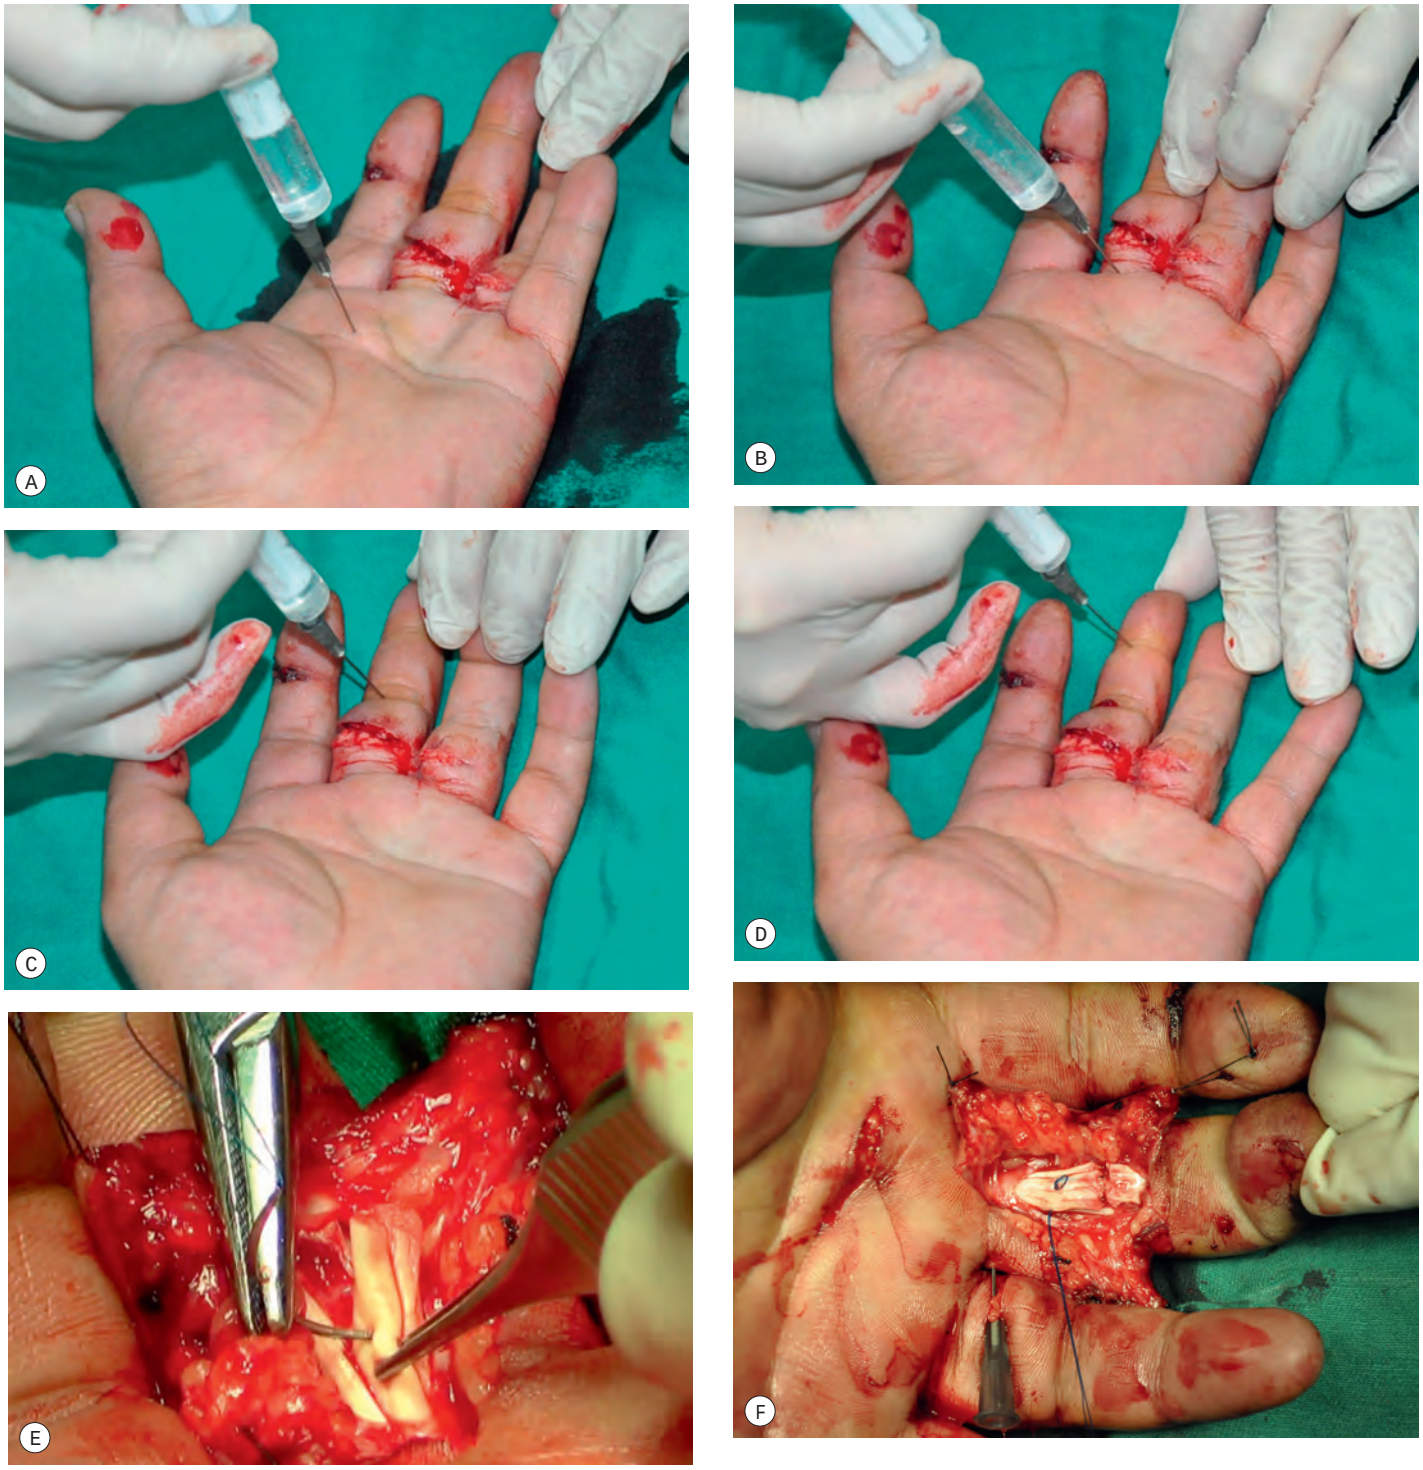

Fig. 9.40 Primary tendon repair of the tendon in the A2 pulley area (zone 2C) under a wide-awake setting. **(A)** The first injection of 5 ml of the 1% lidocaine with 1 : 100 000 to the palm 30 minutes before surgery. **(B)** The second injection was given 15 minutes later, to the proximal part of the digit, followed immediately by injection to the middle and distal parts of the digit **(C,D)**. **(E)** A close-up view of making the first anchor of the looped suture to the tendon in the six-strand M-Tang repair. Note that the site of needle entry is 1 cm away from the cut end and the size of the lock is large. **(F)** The U-shaped repair with the first looped suture was completed. Two strands of centrally placed looped sutures was added later to complete the 6-strand core repair.

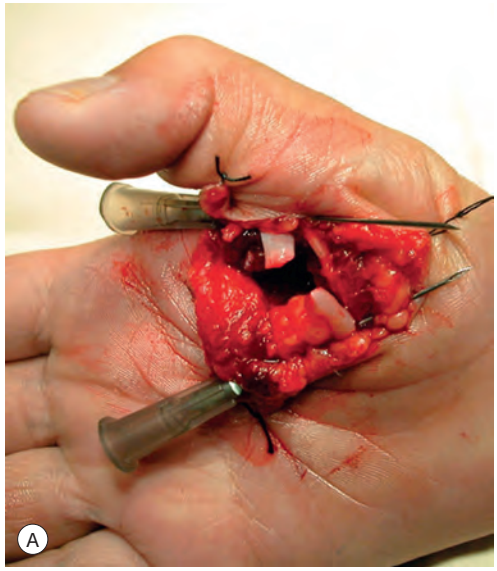
Fig. 9.40, cont'd (D) After completion of the six-strand repair and simple peripheral suture, the patient actively extended **(G)** and actively flexed **(H)** the digit to check quality of the repair. **(I)** Pictures taken 5 months later showing full recovery.



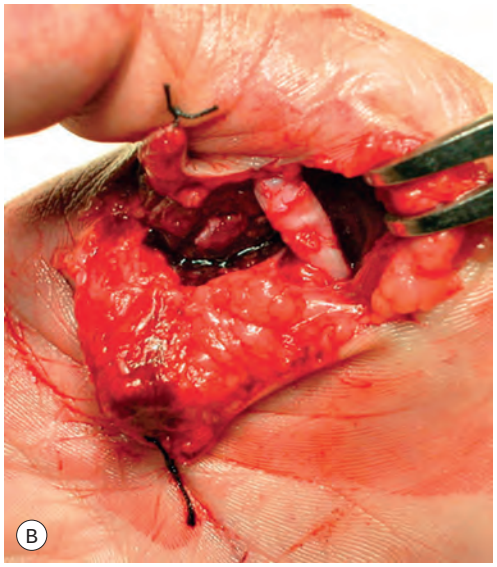


Fig. 9.41 A 9-year-old boy with a complete flexor pollicis longus tendon cut. The retracted proximal tendon end was found and was temporarily fixed with a needle to accommodate tendon repair **(A)**. The FPL tendon was repaired with the six-strand M-Tang technique **(B)**.

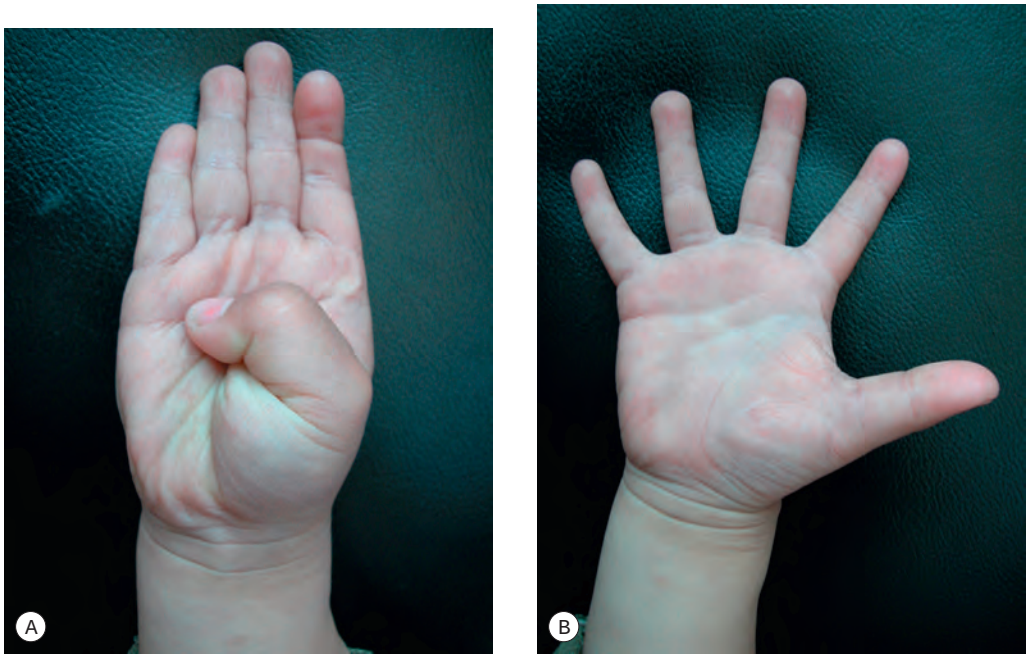

Fig. 9.42 Follow-up 8 months after surgery. **(A)** Full flexion of the repaired thumb. **(B)** Full extension of the thumb.

advanced. Postoperatively, the DIP joint is immobilized for 4–5 weeks, or a gentle motion regime is prescribed.

Early recognition of closed tendon ruptures is of paramount importance. In the cases of late diagnosis, primary repair is difficult or even impossible. Chronic cases require free tendon grafting.

Postoperative care

With the exception of a few instances – such as tendon repairs in children, adults who are unable to follow through the protocol, or associated with complex fractures – motion of repaired tendons should be initiated from the early postsurgical period. From the 1970s to 1990s, the Kleinert and Duran–Houser protocols were most popular. In recent years, a variety of combined passive–active flexion protocols have been developed, replacing passive flexion protocols. The protocols have evolved and the methods presently used in many clinics are combined passive–active digital flexion regimes.

In the 1960s, Kleinert and associates introduced a controlled active extension–passive flexion protocol, which was a conceptual breakthrough.[205] They placed the wrist in palmar flexion of 30° to 40° and 60–70° MCP joint flexion with a dorsal protective splint. Rubber bands were attached to the volar forearm and to the tip of the finger. The patients were allowed to actively extend the fingers and the fingers were brought back to flexion passively by the tensed rubber bands. This traction was found to lead to flexion contractures of the finger, with the original protocol as well as after a pulley for the rubber band added at the MCP joint level in 1990s.[206,207] Therefore, the rubber band traction has mostly been abandoned.

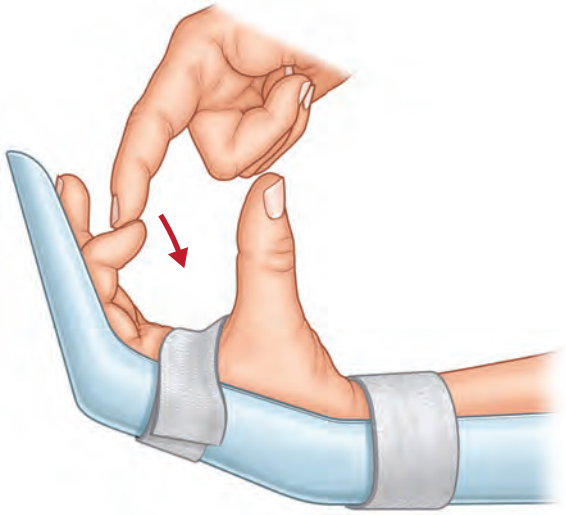
Duran–Houser method

This was a controlled passive finger flexion protocol introduced by Duran and Houser in the 1970s.[208] A dorsal splint was applied with the wrist in 20° flexion, the MCP joint in 50° flexion, and the IP joints were allowed full extension (Fig. 9.43). Within the first 4.5 weeks, the patients performed 10 passive DIP joint extensions with PIP and MCP joint flexions, and 10 passive PIP joint extensions with MCP and DIP joint flexions hourly within the splint (see Fig. 9.43).

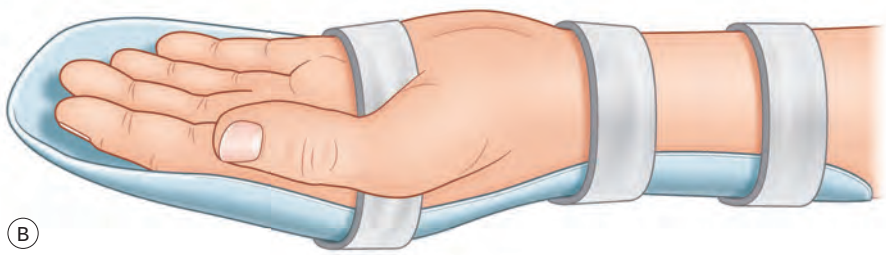
Strickland and Gettle modified this protocol by adopting a Duran-like protocol for a four-strand tendon repair,[209] later known as the "Indianapolis method". This protocol consisted of two splints, the dorsal-blocking splint (used during periods of rest and passive motion, with the wrist at 20–30° of flexion, MCP joints in 50° of flexion, and IP joints in neutral position) and a tenodesis splint (used when performing place and hold exercise). The latter hinged wrist splint permitted the wrist position to be varied between flexion and extension. With the tenodesis splint, the patient passively flexed the digits while actively extending the wrist. The patients passively pushed their fingers into a passive composite fist with the wrist extended and hold for 5 seconds. The patients relaxed the wrist and let it descend into flexion. Patients were instructed to exercise 25 times per waking hour. Four weeks after surgery, active digital flexion and extension was instituted with the dorsal blocking splint still on and the tenodesis splint was discontinued. One week later, active composite fist followed by active extension of the wrist and digits was added to the program. When both flexor tendons are repaired in the digital sheath, differential motion of the two tendons could be practiced. Shifting the finger postures from straight, hook, and fist positions generated differential gliding of the two tendons.

Early active motion

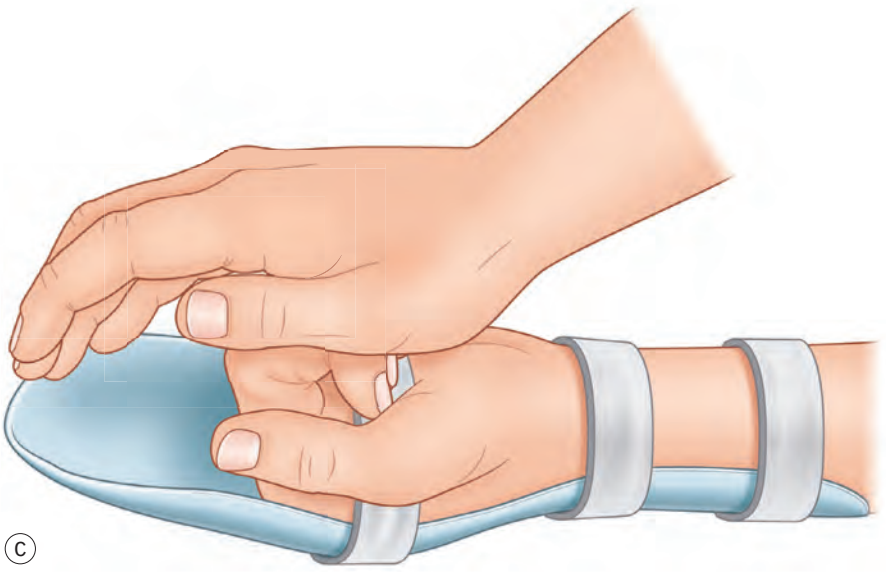
In the late 1980s and early 1990s, protocols containing early active tendon motion components emerged. One requirement is that the tendon repairs be strong enough to tolerate the tension during the motion. In 1989, Belfast surgeons devised an active motion protocol,[210] which was later known as



(A) Duran and Houser passive motion regime



(B)



(C)

(D)

Fig. 9.43 **(A)** Duran passive tendon motion protocols. **(B)** Nantong regime. Passive flexion of the fingers over 20–40 times, followed by partial active digital motion to one- or two-thirds of the entire arc of finger flexion.

"Belfast method". Postoperatively, a splint is applied from the elbow to the fingertips with the wrist in mid-flexion, the MCP joint at slightly less than 90° flexion, and the IP joints straight. The light dressing is removed from the digits and exercises commences 48 hours after surgery. Under supervision, the exercises consist of two passive movements followed by two active movements and are performed at 2-hour intervals. The hand is rested in elevation overnight. During the first week, the PIP joint is actively flexed through about 30° and the DIP joint through 5–10°. In subsequent weeks, the range of active motion is gradually increased. The splint is removed by the 6th week and blocking exercises of the IP joints are initiated when necessary. Variants of the Belfast method have been reported. In one of the variants, the "Billericay regimen", the wrist and the MCP joint are kept in a splint at 30° flexion, respectively, and the splint is removed by the fifth week. The patient is instructed to perform 10 repetitions of exercise hourly.[211]

Author's preferred combined passive–active method (Nantong regimen)

After surgery, the hand is protected in a dorsal thermoplastic splint, with the wrist at 20–30° flexion, MCP joint at slight flexion, and the IP joints in extension for the initial 2.5 weeks (3 weeks or slightly longer when the trauma is severe or digital edema is remarkable) (see Fig. 9.43).[19] The wrist can be placed at neutral position instead. We do not encourage the patients to move the finger in the initial postoperative days; exercise starts at 3–5 days after surgery. The patient is instructed to perform at least 4–6 sessions of combined passive–active motion daily across the morning, noon, evening, and before sleep. More sessions can be implemented as needed, while hourly exercises are not required. At beginning of each exercise session, the finger is passively flexed 10–30 times to lessen the overall resistance of finger joints and soft tissues during subsequent active flexion. The passive motion is followed by actively flexing the finger with gentle force 20–30 times up to the range the patients feel comfortable with (usually from full extension to one-third or one-half of entire flexion range, and may even increase to two-thirds if achieved with ease). Active flexion over full range is not encouraged, unless it can be achieved very easily. In this 2.5-week period, full active extension is particularly encouraged, and prevention of extension deficits rather than achieving full range active flexion is emphasized.

After 2.5 weeks (or 3 weeks, or slightly later), a new thermoplastic splint is made, and the wrist is splinted at 30° extension (Fig. 9.44). Exercise of finger flexion, both passively and actively, is emphasized in this period. Active motion up to the midrange is required, and can proceed up to two-thirds (or full range). However, digital flexion from the mid-range to full range, in particular over the final one-third of the flexion range, usually is achieved passively. In this period, we ensure passive flexion over a full range to prevent joint contracture and active flexion over an increasingly greater range gradually approaching full flexion range, but discourage active forceful flexion of the finger over the final range where the tendon is subjected to the greatest load and is more vulnerable to rupture (see Figs. 9.8 & 9.43). Differential FDS and FDP motion exercise is encouraged throughout the first 5 weeks. From the sixth week, full active finger flexion is encouraged (which can be started earlier when the flexion is judged to have less resistance). From 6 or 8 weeks, the splint is removed or used only at night or when going out.

Delayed motion exercises

Delaying motion exercises, i.e., immobilization over the first 2 weeks, can be a right choice for some patients. A patient with distal zone 1 direct end-to-end repair, the terminal part of the FDP tendon has little need of gliding and adhesions have almost no impact on digital motion. The author immobilizes the wrist in 20–30° of flexion and the MCP joint in slight flexion for 2 weeks with a short dorsal splint. From the third week, the digit is passively moved within the splint. From the fifth week, the patient performs active digital flexion with the splint removed; the splint is not discarded until week 7.

A severely traumatized hand after repair of multiple structures also merits from such delayed exercises. The above-described protocols represent several distinct categories of exercise. While the key points of the passive–active motion regime are respected currently (Box 9.7), upon applying to individual patients, surgeons or therapists should incorporate refinements. In patients with severe edema of the hand or trauma to multiple digits, motion exercise can be delayed for a few days, and more sessions of passive digital motion should be integrated. Table 9.2 is the straightforward scale that I use to record the severity of digital edema for setting timing and intensity of exercise. Other factors such as joint stiffness, soft-tissue conditions, and extensor tethering should also be considered in adjusting the regime.[212]

Strong surgical repairs together with necessary venting of the pulleys have bestowed greater freedom in wrist positions after surgery. Often the wrist is put in a neutral position and a shorter splint is used (to about 10 cm above the wrist)

BOX 9.7 When to begin and how to perform early active motion

- Early active motion of the surgically repaired digit is a component of an early passive–active motion regime, which should be performed together with passive motion in each exercise session with the protection of a dorsal splint (or out-of-splint exercise in very compliant patients).
- Early active motion should be initiated on day 3, 4, or 5 after surgery, not necessarily starting on day 1. Delaying the early motion for a few days decreases pain and avoids peak digital edema.
- Early active motion can be delayed to around the end of week 1 if remarkable digital edema is drastic and wound conditions do not allow earlier motion. However, passive hand motion should be implemented earlier to decrease the risk of joint stiffness and edema.
- At least 4–6 sessions of exercise are necessary, distributed across the day and evening. More exercise sessions should be added if possible.
- In each session, passive motion always precedes active digital flexion. The finger should be flexed passively and extended 20–30 times (or more) before starting active finger flexion.
- In performing active finger flexion, the patient should be instructed to perform partial range active flexion in the first 2.5 or 3 weeks, i.e., active flexion over the first one-half or two-third parts of the entire flexion arc, avoiding the final part of active flexion or making a fist.
- Full range of active flexion is allowed 3–4 weeks after surgery.

Fig. 9.44 The author's combined passive–active tendon motion protocol. This protocol is divided into two 2.5-week periods, or into two 3-week periods when trauma to the digit is severe or edema of the hand is remarkable. In the first 2.5 weeks, with wrist in slight flexion, finger extension is emphasized. Only partial active digital flexion is allowed, but full range of passive motion is implemented. In the second 2.5 weeks, with wrist in extension, full active finger flexion is encouraged. This protocol incorporates the concept of synergistic wrist and finger motion. When the wrist is flexed, finger extension is less tensed; when the wrist is extended, finger flexion is less tensed.

to protect zone 1 and 2 repairs (Fig. 9.45). Because tendon repairs are strong, out-of-splint active motion is performed regularly.

From communications with many hand surgeons and therapists, the author has found that hand centers around the globe actually use some kinds of variants of these protocols.[149,213] Motion regimes for zone 4 and 5 repairs are generally not as complex as those described above. There is not yet universal agreement regarding the timing of initiating rehabilitation and frequency of motion. Theoretically, tendon adhesions develop from 10 days to 2 weeks after surgery. No studies have yet proven the necessity of starting exercise on the first day. It seems equally reasonable to commence exercise slightly later, though still within one week after surgery. Likewise, no studies have identified the optimal frequency of motion in each exercise episode.

Experimental evidence supporting later commencement of tendon motion were offered by Zhao *et al.*[118] of the Amadio group, and the author's colleagues Xie *et al.*[119] and Cao *et al.*[122] Digital edema increases resistance to motion, which peaks at 3 to 5 days.[120–122] Both Zhao *et al.*[118] and Cao *et al.*[122] suggest that motion be commenced later (5 days after surgery).

Table 9.2 Severity of digital edema

Grades	Descriptions
0 (none)	Swelling is absent
1 (slight)	Swelling is minimal or mild
2 (moderate)	Swelling is prominent, with increase in digital diameter
3 (severe)	Swelling with openings in skin incisions

Fig. 9.45 The postoperative protection and motion. **(A)** Neutral wrist position with a short forearm splint. **(B)** Out-of-splint motion exercise is allowed. **(C)** In later weeks, specific motion exercise of the distal interphalangeal joint is often necessary to correct mild to moderate stiffness, which develops 3 to 4 weeks after surgery.

Outcomes, prognosis, and complications

Review of outcomes reported over 25 years showed excellent or good active range of finger motion in more than three-quarters of primary tendon repairs.[14,17,19–21,25,210,211,213–232] Nevertheless, repair ruptures were documented in a majority of the reports. In the earlier part of this period, the rupture rates ranged from 4 to 10% in the finger flexors and from 3 to 17% in the FPL tendon of thumbs.[14,17,214–228] Adhesions remained the most common complication, preventing satisfactory return of active joint motion. Finger joint stiffness was reported fairly frequently as well. It is worth noting that most of these reports came from the finest hand centers in the world, and each team was supervised by at least one surgeon with expertise in treating tendon injuries. The outcomes in a general hospital setting may actually reflect a lower level of success. Flexor tendon repairs might have been unsuccessful in a larger proportion of patients, with a greater incidence of repair ruptures, adhesion formations, or digital joint contracture.

Nevertheless, the past 25 years have seen impressive improvements in outcomes of flexor tendon repairs. In the late 1980s and early 1990s, Small *et al*.[210] and Cullen *et al*.[213] used a two-strand repair and postoperative active motion and had repair ruptures in 6–9% of the repairs, with overall good or excellent results in 78% of the digits. Elliot *et al*.[211] reported a series of 233 patients with complete division of the digital flexor tendons, treated with a two-strand core repair with a controlled active motion regimen. Thirteen (5.8%) fingers and five (16.6%) thumbs suffered tendon ruptures during the mobilization. In the same period, multistrand core repairs were reported by Savage and Risitano,[14] and Tang *et al*.[17,214] together with active or passive–active motion therapies.

Trumble *et al*.[229] used a four-strand Strickland core suture and a running epitendinous suture to repair zone 2 flexor tendon lacerations in 119 digits (103 patients) and examined postoperative therapies in a multicenter prospective randomized trial. They documented significantly greater range of digital motion, smaller digital flexion contractures, and greater patient satisfaction in the active motion group than in the passive motion group. Associated nerve injury, multiple digit injuries, and smoking were factors leading to poorer outcomes. Patients treated by a certified hand therapist had better motion

BOX 9.8 Methods to optimize outcomes

1. Master tendon anatomy in detail and use atraumatic techniques throughout surgery.
2. To expose the tendons, open a window in the synovial sheath, or open the A2 partially or the entire A4 pulley if the repair site overlaps or is located just distal to these structures.
3. May release the distal two-third parts of the A2 pulley, where it is the most narrow and most constrictive to the tendons, when the FDP tendon is cut just distal or under the pulley.
4. Adopt a stronger and more secure core suture method.
5. Add peripheral sutures to smooth the repair and to prevent gap formation.
6. Properly combine passive and active finger motion into postoperative motion protocols. Fully extend and flex the finger passively, followed by active finger flexion over a certain range. Active motion over the final one-half or one-third is discouraged in the initial weeks to avoid tendon overload (rupture). Postoperatively, apply motion therapy for at least 5–6 weeks.
7. Passive finger motion before active motion substantially decreases the overall resistance to digital motion, lessening the chance of repair ruptures during active motion.
8. Surgical tendon repairs are performed by experienced surgeons, and the unit should have established postsurgical rehabilitation guidelines.

BOX 9.9 What are the most important factors during surgery?

1. Two essential goals must be achieved: maintaining sufficient purchase length (> 0.7–1.0 cm) of the core suture – most vital for the suture's anchor in the tendon, and maintaining tension in the sutures placed in the tendon – critical to prevent gapping between stumps.
2. The suture's holding – a grasp or a lock – in the tendon should be at least 2 mm or greater. Small grasps or locks are pulled out easily.
3. Increasing the diameter of suture from 4-0 to 3-0 can increase the core suture strength; but with sutures of either caliber, at least four strands are needed for any zone 1–3 repairs.
4. Even a robust repair may fail if the tendon impinges against a pulley or is tightly constricted by narrow pulleys. Therefore, properly venting pulleys when necessary is just as important as employment of a robust repair.

and less severe contractures. Two digits had tendon ruptures in each group. The study supports the combination of multistrand tendon repair and early active motion after zone 2 repairs. Reports over the recent years give further support to early active digital motion.[230–232] Rupture rates do not increase in tendons with strong surgical repair and early active flexion.[230–232] The wrist can be placed in a neutral position or may simply use a hand-based splint after tendon repairs in the digits. Robust tendon repairs and venting the narrow part of the annular pulleys actually result in greater freedom of hand position and motion, and minimize the risk of repair ruptures.

Of note, reports of multistrand core sutures in recent years documented minimal or zero repair ruptures. A stronger surgical repair combined with release of the pulleys offered great safety to the postoperative active motion exercise. After combined use of multistrand repairs and pulley releases, the majority of the cases had good to excellent active range of digital motion with zero tendon ruptures.[19,24,25] The author's own clinical outcomes also indicate that good-to-excellent return of function can be achieved fairly consistently by means of multistrand tendon repairs, venting of pulleys, and well-designed combined passive and active motion protocols (Boxes 9.8 & 9.9). Strickland and Glogovac criteria (Table 9.3) are the most commonly used methods in assessment of outcomes.[15] The Moiemen and Elliot criteria (Table 9.3),[20] which specifically evaluate the active range of flexion of the DIP joint, are favored by surgeons who record outcomes of zone 1 repair. The TAM (total active range of motion) method proposed by the American Society for Surgery of the Hand is also used, and the Buck-Gramcko method is used often by German-speaking hand societies.[153] Among the less popular methods currently used are White, Tubiana, and tip-to-palm distance methods. The author currently uses a criterion that implements a more stringent measure of range of active finger motion, as well as grip strength and quality of motion, into the grading system (see Table 9.3).[19]

Outcomes of flexor tendon repairs are affected by patient age, extent and zones of injuries, timing of the repairs, postoperative exercise, and the expertise of the surgeon. Results of tendon repairs in children are generally better than those in adults. Tendon repairs associated with extended soft-tissue damage or accompanied by phalangeal fractures are likely to have worse outcomes.

Secondary procedures

Secondary tendon repairs are achieved by free tendon grafting or staged reconstruction. These procedures are reserved for tendons that could not be repaired primarily or for lengthy tendon defects (Box 9.10). These techniques, developed by the early masters of hand surgery,[38–42,233–243] remain largely unchanged today despite refinements in tendon junction methods, use of novel suture materials, and widespread adoption of postsurgical rehabilitation in recent decades.[244–248]

BOX 9.10 Secondary surgery: grafting and staged reconstruction

Indications

1. Tendon injuries not treated within 1 month after injury
2. Rupture of the tendon repairs at primary or delayed primary stages
3. Tendon injuries not indicated for primary repair
4. Badly scarred digits

Essential requirements

1. Supple passive motion of the hand
2. Good soft-tissue condition
3. Sufficient time after initial tendon injury: at least 3 months

Contraindications

1. Limited joint motion
2. Presence of soft tissue wounds or defects, and fractures not well-healed

Table 9.3 Criteria of assessment of functional outcomes of flexor tendon repairs

% Return of motion*	Grip strength†	Quality of motion‡	Function grade
Strickland criteria (1980)			
85–100 (>150°)			Excellent
70–84 (125–149°)			Good
50–69 (90–124°)			Fair
0–49 (<90°)			Poor
Moiemen–Elliot criteria (2000) for zone 1 injuries, the distal interphalangeal (DIP) joint only			
85–100 (>62°)			Excellent
70–84 (51–61°)			Good
50–69 (37–50°)			Fair
0–49 (<36°)			Poor
Tang criteria (2007)			
90–100	+ –	Excellent or good Poor	Excellent + Excellent –
70–89	+ –	Excellent or good Poor	Good + Good –
50–69			Fair
30–49			Poor
0–29			Failure

Function is graded as excellent or good when either the grip strength is – or quality of motion is "poor".
*Percentage return of the normal (contralateral) hand. Strickland and Tang criteria use sum of active range of motion of the DIP and proximal interphalangeal joints. Moiemen–Elliot criteria use motion of the DIP joint only.
†Grip strength is recorded as + when it is greater than that of the contralateral hand (the nondominant hand), or over 70% of that of the contralateral hand (dominant hand). Otherwise, grip strength is considered abnormal and recorded as –.
‡Quality of motion is rated on the basis of direct observation of finger motion by surgeons. It is recorded as "excellent" when all three aspects – motion arc, coordination, and speed – are normal; as "good" when any two are normal; and as "poor" when only one, or none, is normal.

Free tendon grafting

Indications and contraindications

Most traumatic lacerations of the digital flexor tendons are now treated with end-to-end tenorrhaphy primarily. Only some cases require secondary repairs by means of free tendon grafting. Tendon grafting is indicated (1) when the lacerated tendons are not treated during primary or delayed primary stage, (2) when the primary repairs have ruptured and cannot be re-repaired directly, and (3) in the cases with severe contamination, infection, lengthy loss of tendon substance, extensive destruction of the pulleys, or accompanying injuries. Patients who have serious scarring in the tendon bed or failed previous efforts at secondary flexor tendon procedures are appropriate for a staged tendon reconstruction, rather than one-stage tendon grafting. Surgeons sometimes need to decide according to intraoperative findings.

Before surgery is attempted, the soft tissue wound should be well-healed, with supple passive motion of the hand. Physical therapy is prescribed to improve the range of motion of the digits if passive joint motion is limited substantially. Boyes[42] classified the conditions associated with the cases of tendon grafts and surgical prognosis is worsened by poor hand condition. Lack of passive range of joint motion is contraindicated for one-stage tendon grafting, but may be suitable for staged tendon reconstruction. The timing of tendon grafting is usually 3 months after injury.

Donor tendons

The donors are palmaris longus, plantaris, long toe extensors, or in rare instances the FDS tendon from a normal finger (Figs. 9.46 & 9.47). The palmaris longus tendon (about 15 cm) from the ipsilateral limb is a frequently used donor and is appropriate for a palm-to-fingertip graft. It can be easily harvested through a short transverse incision over the tendon just

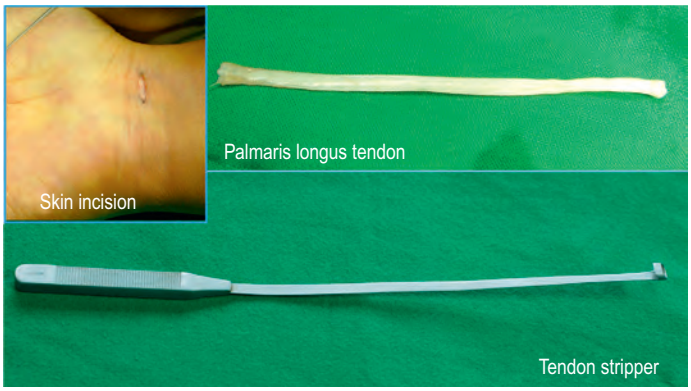


Fig. 9.46 Harvesting a tendon graft through a small skin incision, using a tendon stripper.

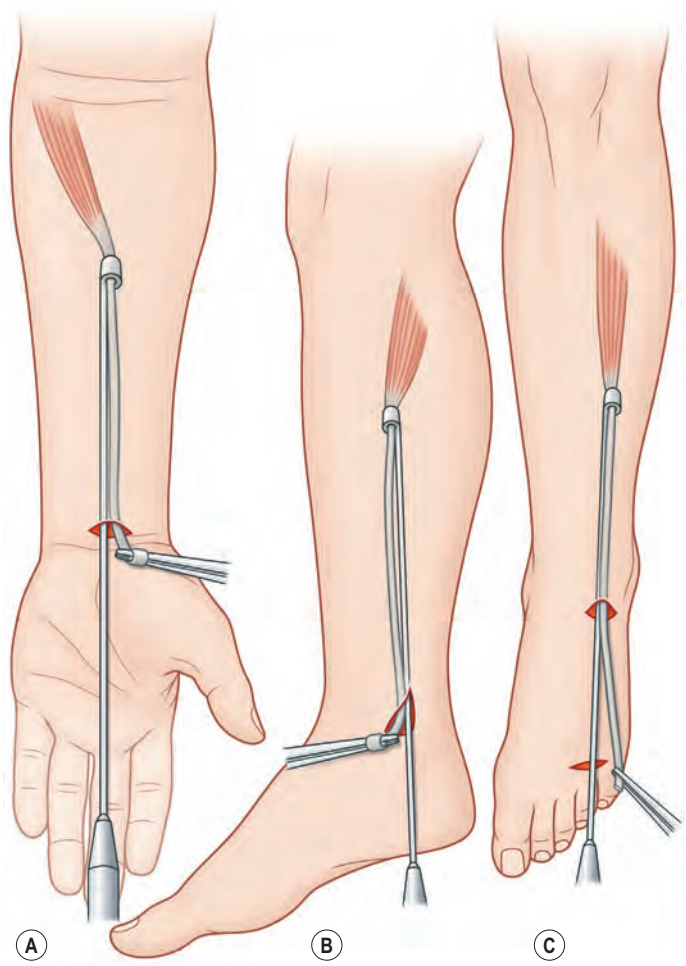

Fig. 9.47 Three common donors of tendon grafts: **(A)** palmaris longus tendon; **(B)** plantaris; and **(C)** toe extensors.

proximal to the flexion crease of the wrist. The tendon is divided and grasped with a hemostat, while a tendon stripper is advanced slowly into the proximal forearm. Care must be taken to protect the median nerve trunk lying beneath the tendon and its cutaneous branch of the median nerve.[249] Because this tendon is absent in about 15% of all hands,[250] examination to confirm its presence is essential before surgery. The plantaris tendon is equally satisfactory for a graft, which is obtained by an incision medial to the Achilles tendon and use of a tendon stripper. The length of this tendon (25 cm) is well-suited for a long distal forearm–fingertip graft. However, this tendon is absent in 7–20% of limbs, and its presence cannot be predicted preoperatively.[251,252] Extensor digitorum longus tendons to the second, third, and fourth toes, the extensor indicis proprius, the extensor digiti quinti proprius, and the FDS tendon to the fifth finger can be used as well. In my clinic, I use the palmaris longus tendon most frequently and place the proximal junction in the palm.

Operative techniques

The flexor tendon is exposed through a volar Bruner's incision or the midaxial approach.[253–257] Integrity of the major annular pulleys is important to the function of the graft. At least the A2 and A4 pulleys should be preserved. If possible, other annular pulleys such as A1 or A3 and a part of the synovial sheath are preserved to foster better gliding of the grafted tendon. If a series of annular pulleys are found to be destroyed, reconstruction of pulleys is necessary. Most cases requiring the reconstruction need to be preceded by staged tendon reconstruction.

The distal junction of the graft is placed at the fingertip. The common method is to suture the graft directly to the residual FDP stump or to bury it under an osteoperiosteal flap in the volar phalanx (see Fig. 9.14).[257–259] In the latter case, straight Keith needles are passed through the distal phalangeal drill hole and exit over the proximal portion of the nail. After emerging from the nail surface, the needles are passed through a gauze pad or a sponge, and through the holes of an overlaying button. The sutures are tied over the button to anchor the graft. Additional sutures are used to secure the FDP tendon stump to the graft. Alternative methods are available, as shown in zone 1 repair (see Fig. 9.14).[157,159,160,243] In children, because drill-holes in the distal phalanx may damage the open epiphyses, the graft is sutured directly to the stump of the profundus instead. Either at the palm or in the forearm, the proximal junction of the graft is achieved by a Pulvertaft weave suture to the proximal stump of the flexor tendon (Fig. 9.48). Placement of the junction at the palm requires a shorter graft and preserves the function of lumbrical muscles. Care is taken to avoid suturing the tendon to the lumbrical muscle, because this tends to increase the tension in the muscle. Placement of the junction distal to the wrist allows easy adjustment of the tension of the graft, and the scar may be less severe. In the author's experience, a Pulvertaft weave suture is appropriate for the proximal junction in both areas (Fig. 9.49), and the finger is held in slightly greater flexion than in the resting position when the proximal stump is sutured (Fig. 9.50).

Postoperatively, the wrist is held in a position of 30–40° flexion, the MCP joints flexed to 60–70°, and the IP joints at rest in almost full extension. The traditional recommendation is 3 weeks of immobilization within a dorsal splint applied from the fingertip to below the elbow, followed by active exercise of the digits with the protection of a dorsal blocking splint. Some surgeons advocate passive or active finger motion under cautious supervision from a few days after surgery if the graft junctions are strong. Most surgeons still prefer to immobilize the grafted digits for at least 3 weeks to avoid tension on the tendon and to allow some revascularization of the graft. More vigorous exercise can be instituted at 6 weeks after surgery.

The need for tendon graft or reconstruction is controversial when the superficialis tendon is fully functional, but the FDP tendon is cut and has not been repaired directly within 3 to 4 weeks after trauma.[260–266] There is a risk of losing function if a profundus graft fails. However, such operations are worth the risk in selected cases, such as in young people with a reasonable need for active DIP joint flexion. The procedures are similar to those described above. A thinner donor tendon is preferable and the A2 pulley can be shortened, but a series of pulleys are preserved (Fig. 9.51). Alternatively, one slip of the FDS tendon can be removed to favor passage of the graft. During the procedure, while passing the graft through the FDS tendon, injury may occur that results in formation of adhesions and a loss of finger function. Overall, caution must be exercised with patient selection. Patients with intact

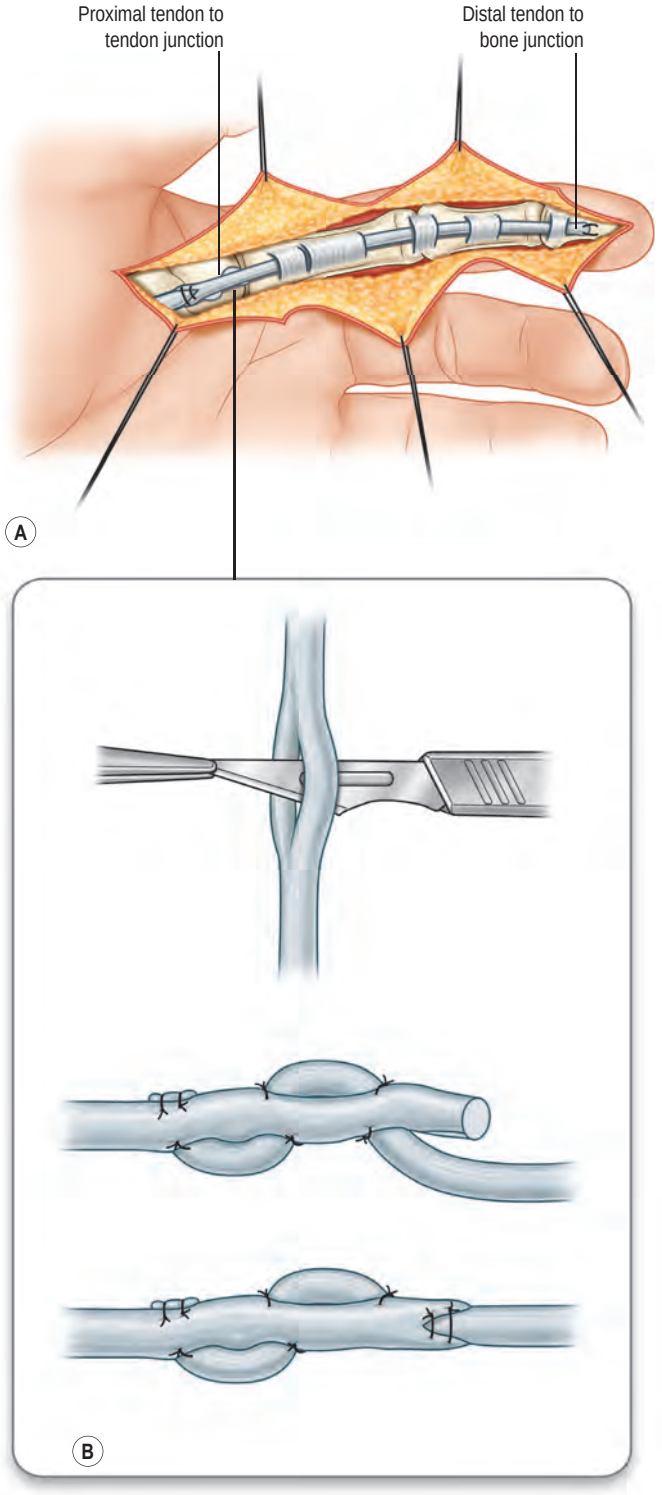

Fig. 9.48 Skin incision and the method of free tendon grafting to reconstruct the function of digital flexion. As many annular pulleys as possible are preserved. **(A)** The tendon junctions are placed outside of the flexor sheath region. To make a proximal junction of the graft with the end of a digital flexor tendon, the Pulvertaft weave technique is commonly used (shown in detail in **B**). The junction is placed at either palm or distal forearm. The graft was woven with the digital flexor through holes in the tendons created by a knife (**B** – top to bottom).

superficialis tendon may adapt nicely and require no treatment. Surgeons should fully inform patients about expected gain of function versus risks of this operation.

When the superficialis tendon is intact and the DIP joint is not stable, the DIP joint can be fused or tenodesed in slight flexion. In the presence of a functional FDS tendon, the combination of MCP and PIP joint motion produces approximately 85% of the arc covered by the finger in flexion.

Staged tendon reconstruction

Indications

This operation is indicated in cases with badly scarred digits, as a result of injury or multiple failed attempts to restore tendon continuity and gliding. The techniques were developed in the middle of the 20th century by Bassett and Carroll, Hunter, Paneva-Holevich, Schneider, *et al*.[44,267–278] This operation consists of procedures in two stages. In the first stage, the tendon and scar from the tendon bed are excised, but the pulleys are preserved or reconstructed. A Dacron-reinforced silicone tendon implant is inserted into the tendon bed to maintain the tunnel and to stimulate the formation of a mesothelium-lined pseudosheath. Following maturation of the sheath, a tendon is grafted in lieu of the implant in the second stage.

Techniques

The first stage

The involved finger is exposed through a volar zigzag incision and the incision is continued to the lumbrical origin level of the palm (Fig. 9.52). The tendons and sheath (pulleys) are usually found embedded within scars. The tendons are excised with a 1-cm stump of the profundus tendon retained at its distal insertion. The critically located annular pulleys are carefully dissected out of scars. All potential useful pulley materials are preserved. When a series of pulleys are damaged, critically located pulleys (A2 and A4) should be reconstructed, which is an important part of the reconstruction. One method is to use a tendon graft, either a portion of an excised flexor tendon or the palmaris longus tendon, and wrap it around the phalanx twice to obtain sufficient width, but place it deeper than the extensor mechanism in the proximal phalanx or superficial to the extensors in the middle phalanx (Fig. 9.53). Another method is to make use of one rim of a residual pulley, and a tendon graft or a part of the extensor retinaculum is woven back and forth to form a volar part of the residual pulley. A slip of the FDS tendon can be used to make a pulley as well. In the presence of flexion contracture of the finger joint, check-rein extensions of the palmar plate and the accessory collateral ligaments are divided to release the contracture. The profundus tendon is transected at the midpalm.

A set of tendon implants is then tried to determine the appropriate size of the implant, which is judged by the tightness of the digital pulleys and the expected size of the tendon graft in the second stage. In adults, 4-mm implants are often used, which are close in size to the tendon graft. After insertion of the implant underneath the pulleys, the implant should be movable in the tendon bed with minimal resistance. The distal anchor of the implant can be created in several ways (Fig. 9.54). A second incision is made in the distal forearm.

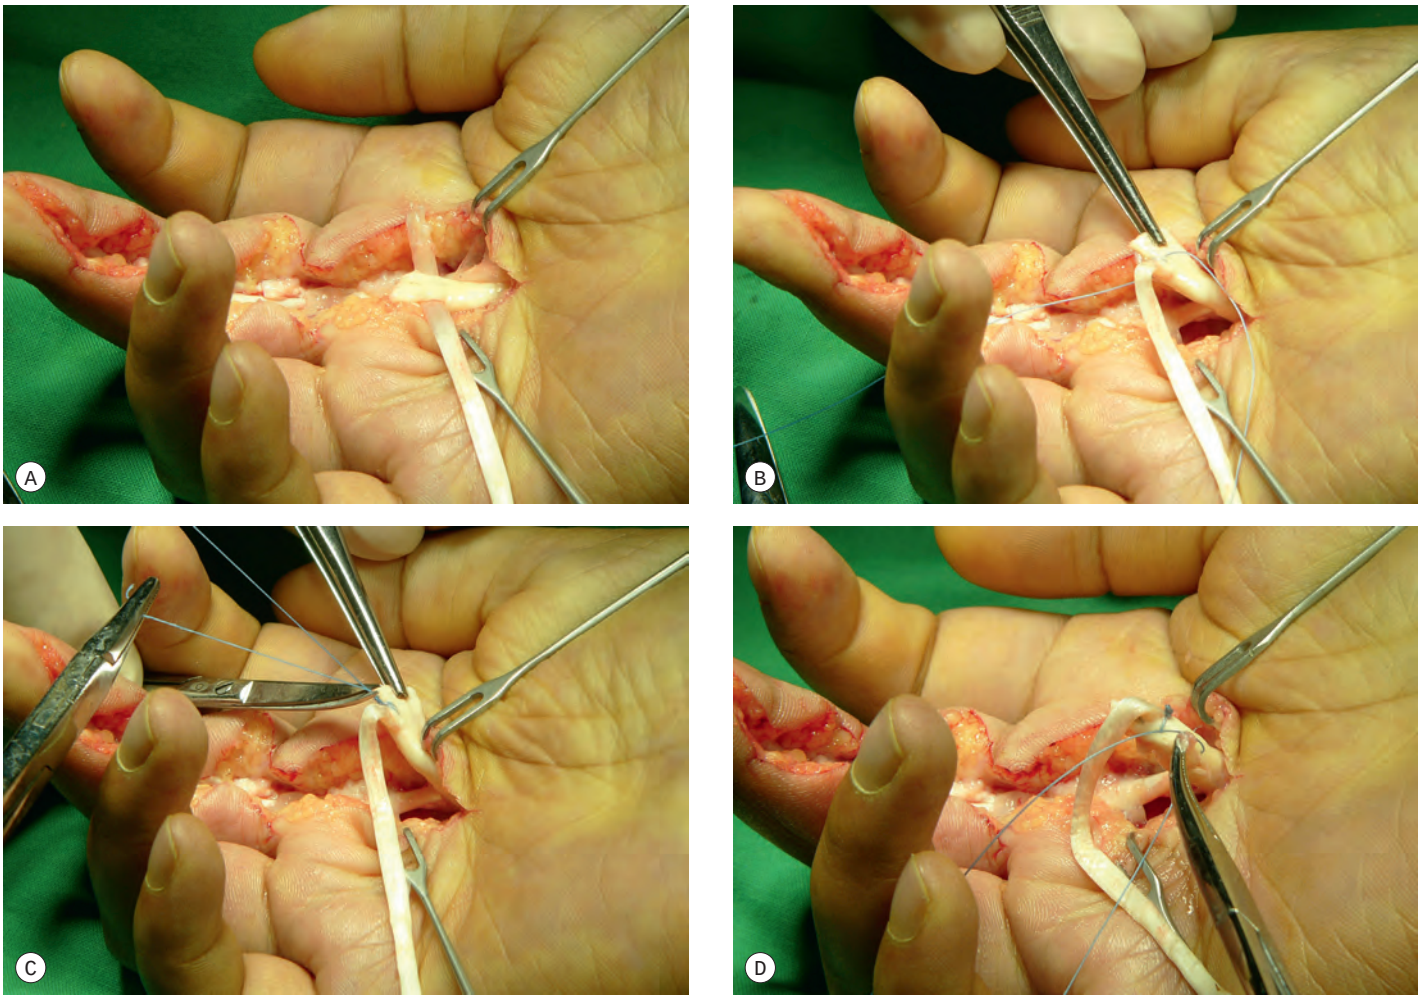

Fig. 9.49 A case of free tendon grafting with a Pulvertaft weave junction of the graft with a digital flexor tendon in the palm. **(A)** The graft was woven into the digital flexor tendon. **(B,C)** Two sutures were added in either side of the graft and the digital flexor. **(D)** Completion of the weave tendon repair.

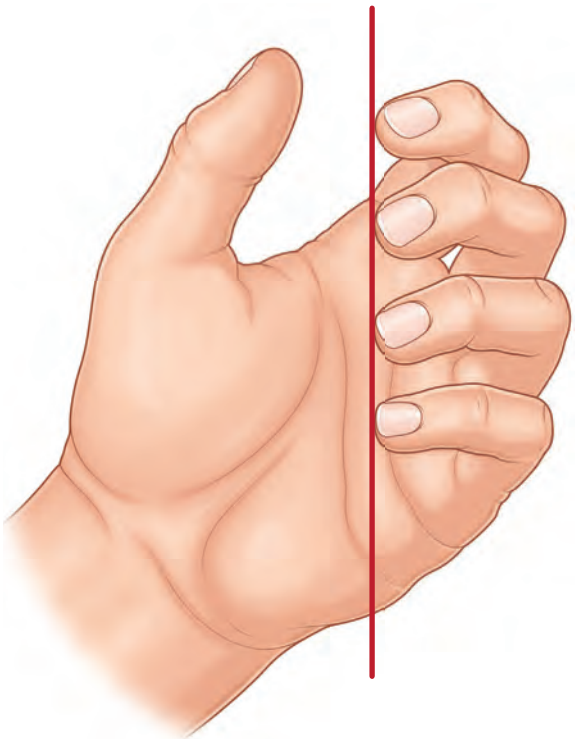

Fig. 9.50 Tension status of the fingers at the time of suturing the proximal tendon junction of a graft. With the wrist in neutral position, the fingers are slightly more flexed than at the resting position, with each finger falling into slightly more flexion than its radial neighboring fingers.

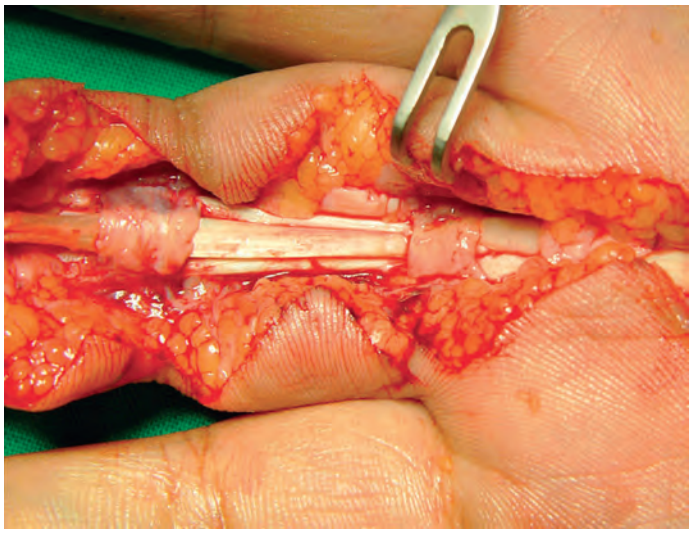

Fig. 9.51 A case of reconstruction of the flexor digitorum profundus tendon in the presence of an intact flexor digitorum superficialis (FDS) tendon. A palmaris longus tendon was harvested as a graft. A series of pulleys (A4, a part of the A2, and A1) were preserved. The thin palmaris longus tendon fits well within the pulleys and intact bifurcating FDS tendon in the finger.

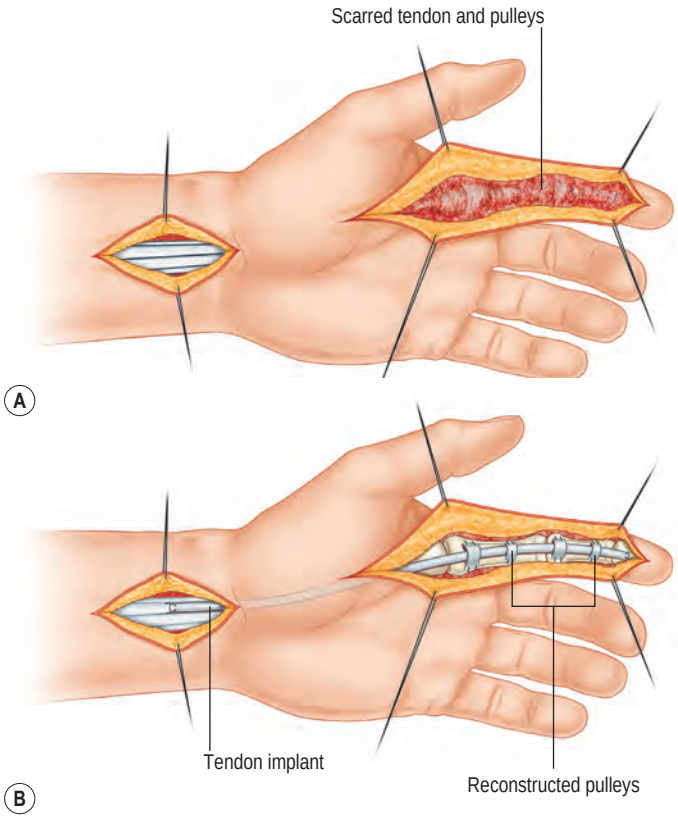

Fig. 9.52 (A) In stage 1, extensive scars are found after exposure. The scar and the tendon are excised. The annular pulleys were preserved. **(B)** A tendon implant is placed into the scarred tendon bed. Proximal end of the tendon implant is not sutured and left free.

The implant then is passed from the proximal palm to the distal forearm using a tendon passer. After the implant is seated, traction is placed on the proximal end of the implant to make sure that it glides freely. A tunnel is created with blunt dissection proximally over the profundus muscle in the proximal forearm. The implant is laid into this tunnel and a space proximal to the implant is ensured for implant migration during exercise.

Postoperatively, the wrist is held with a short arm posterior splint in slight flexion (30°) and the MCP joint in marked flexion. Passive wrist and digital motion can be started one week later. By 8 weeks, full activity is permitted, except powerful grip until 12 weeks. In cases with pulley reconstruction, the fingers must be protected by circumferential taping or orthoplast rings.

The second stage

The second stage operation is planned approximately 3 months later. A small incision is made adjacent to the distal implant–tendon junction (Fig. 9.55). A portion of the previous incision can be used. After disconnecting the implant from the tendon, the implant is tagged. A free tendon graft is harvested and inserted into the pseudosheath tunnel. Care is taken not to open the pseudosheath proximal to the DIP joint and to avoid injury to any pulleys. The appropriate motor tendon is then selected. The profundus mass is chosen for grafts to the middle, ring, and small fingers. For index finger reconstruction, the profundus tendon to the index finger is chosen as a motor. For thumb reconstruction, the FPL or one of the FDS muscles is used. The proximal junction can be placed in the palm, but in most cases, it is located in the distal forearm. The tendon graft is attached to one end of the implant. The implant is pulled out through the pseudosheath from one end. The distal tendon junction is secured as previously described for free tendon grafting. Placement of the proximal juncture in the forearm offers the graft a favorable environment for tendon gliding. Proper tension on the graft is essential for function.

Paneva-Holevich[267] advocated that the FDS tendon should be used proximal to the injury from the same finger as the graft source. This procedure evolved to include placement of a tendon implant together with suturing the proximal FDS to the proximal FDP tendon end at the first stage, and implant removed, grafting the FDS into the finger at the second sage, which yielded favorable results.[244,279]

Postoperatively, the wrist is held in a position identical to that for a tendon graft.

Some surgeons immobilize the hand for 3–4 weeks; others favor an early protected motion program initiated days after surgery. Therapy proceeds carefully through passive and light active motion until at least 6 weeks, when the tensile strength of the tendon and its junctures are sufficiently strong to tolerate more vigorous motion.

Tenolysis

Indications

Tenolysis is indicated when the passive range of digital motion greatly exceeds the range of active flexion several months after direct end-to-end tendon repair or tendon grafting.[234,280–286] Tendon trauma with severe damage to peritendinous tissues or compound injuries (such as digital or palm replantation) have greater chances of adhesion formation, thus are more likely to require tenolysis as a later surgery.[282] Children can also be candidates for this surgery.[282] The prerequisites for this operation are: (1) all fractures are healed; (2) wounds have reached equilibrium with soft, pliable skin and subcutaneous tissues, and minimal reactions around the incision scars; and (3) joint contractures must have been corrected and a normal or near-normal passive range of digital motion has been achieved. The optimal timing of tenolysis remains controversial.[233,284–287] It is reasonable to consider tenolysis if the desired range of motion is not achieved after 3 months of therapy. At least 3 months should have passed since the direct repair or graft, to allow necessary healing and revascularization of tendons, so as to avoid endangering tendon strength. To assess the patient's final function reliably, 4–6 months are usually required. However, there is no absolute criteria for how poor the range of motion must be to indicate tenolysis. Surgeons should consider the patient's age, occupational requirements, and functionality of the hand in making a decision. Preoperatively, the patients should be informed that intraoperative findings may be incompatible with tenolysis; thus the surgeons need to proceed to the first step of staged reconstruction on finding serious destruction of pulleys or a lengthy lysed tendon segment.

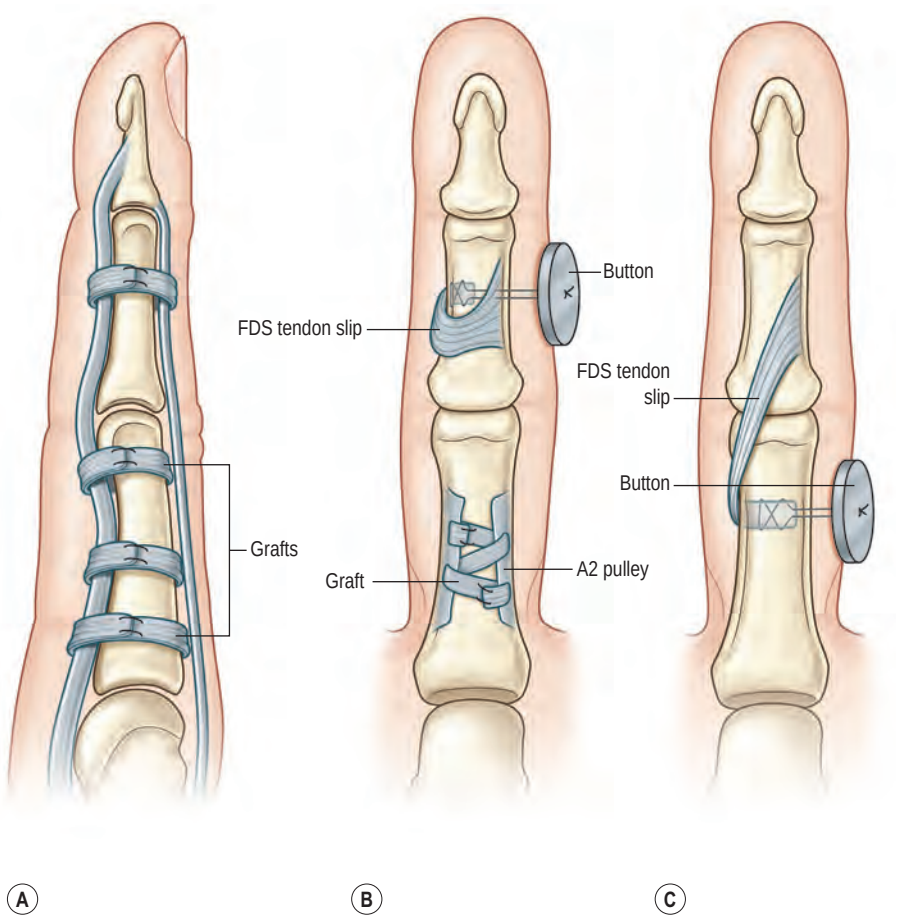

Fig. 9.53 Methods of flexor pulley reconstruction. **(A)** Reconstruction of the A4 and A2 pulleys using flexor tendon grafts passed circumferentially around proximal and middle phalanges. The tendon graft passes deeper to the extensor apparatus at the proximal phalangeal level and superficial to the extensors at the middle phalangeal level. **(B)** A tendon graft is woven through remnant of the A2 pulley to reconstruct the A2 pulley. **(C)** Use of a slip of flexor digitorum superficialis (FDS) tendon for middle digital pulley reconstruction. **(D)** An operative picture showing the FDS tendon slip as a source of graft for reconstructing multiple pulleys. The FDS was sutures to the remnants of the pulleys and periosteum.

Anesthesia

Active involvement of the patient in assessing tendon mobility and adequacy of release is a key step of surgery. This is achieved by using sedative anesthesia, combined with local anesthesia at the operation area,[234,288] or only local anesthesia (no sedation) with the patient awake during the entire surgical period.[123,124] The author uses 2% lidocaine infiltrated locally in the subcutaneous tissues or as a digital nerve block at the metacarpal level if the patient does not want to be awake. To perform wide-awake tenolysis, the author injects 10 ml of 1% lidocaine with 1:100000 epinephrine to the surgical field in each digit and the palm. Axillary block or general anesthesia are used if the surgeon expects an extensive operation, such as tenolysis in more than 2–3 digits, a staged reconstruction procedure, or if the patient is unlikely to tolerate surgery with local anesthesia.

Operative techniques

Through either a Bruner or midlateral incision, dissection proceeds from the unaffected area to the affected area. Tenolysis requires wider surgical exposure. All limiting adhesions are meticulously divided and care is taken to define the borders of the flexor tendons. During dissection, some surgeons advise preservation of the sheath as much as possible, but others prefer to excise the synovial sheath. Regardless, the major pulleys should be maintained, and the synovial sheath imbedded within the scar is removed. It is necessary to maintain the A2 and A4 pulleys at a minimum. If possible, the A3 pulley and its adjacent sheath are also preserved. A variety of instruments may aid in dissection of the scarred tendons from inner surfaces of the major pulleys.[289–291] Whenever possible, the FDS and FDP tendons are separated from one another. In some cases with severe adhesions, the FDS tendon has to be resected locally. Dissection is continued until normal tissues are revealed and no scar around the tendon is visible. Adequacy of the release is then checked by active digital flexion if the patient is wide-awake, or by a gentle proximal traction on the proximal part of the tendon. A separate proximal incision in the palm can be created to pull the tendon. The quality of the tendon and integrity of the pulleys are checked. If tendon continuity is maintained only by scar or greater than one-third of the tendon width is lost, the tendon is unlikely to function properly and the case should proceed to staged tendon reconstruction. If the critical pulleys are destroyed, it is appropriate to proceed to pulley reconstruction (Box 9.11).

Over the years, many attempts have been made to develop strategies to block or limit adhesion formation.[292–302] Thus far, few of these attempts have reliably reduced adhesions clinically and are used routinely. Some surgeons favor use of steroids.[286] One multicenter clinical trial indicated benefits of using a hyaluronan gel in reducing adhesions after tenolysis.[303]

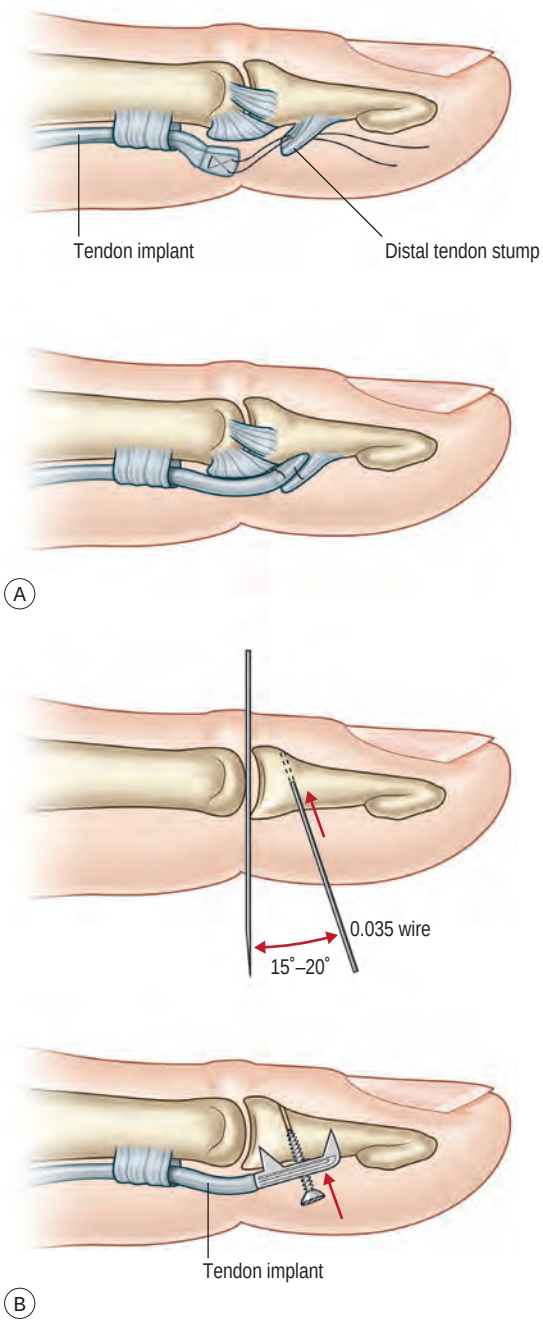

Fig. 9.54 Distal junction of the tendon implant in stage 1. **(A)** The distal junction wire method. A figure-of-eight suture of a monofilament wire (no. 32) is placed in the implant and sutured to the FDP stump. Additional sutures are supplemented on each side of the implant. **(B)** Screw-plate fixation method. A self-taping Woodruff screw (2-mm) is used, which is inserted into a drill hole in the phalanx using a K-wire (0.035-inch).

Postoperative treatment

Oral analgesics usually alleviate pain during the postoperative period. Transcutaneous placement of local anesthetic catheters may be considered for patients with low pain thresholds or those undergoing extensive operations. Repeated digital nerve block can also be used.[304] Active motion of the fingers can begin on the first day after surgery. Some surgeons advocate waiting for several days or until soft-tissue inflammation and pain subside to start motion.

Postoperative tendon movement is critical to the success of tenolysis and remains the most effective method to prevent recurrence of adhesions.[305–309] The amplitude, frequency, and forces of motion should be decided based on intraoperative findings. The surgeons should directly discuss with the therapists to consolidate a therapy program. A tendon appearing nearly normal in a minimally scarred bed with a strong pulley system is appropriate for a more vigorous motion protocol. When a tendon is of poor quality – with a dense scar, a lysed segment, or a decrease in tendon caliber – or if pulleys have been reconstructed, gentle active motion or delayed initiation of the finger motion are indicated.[234] In this instance, a "place and hold" maneuver after passive digital motion into full flexion is useful to reduce tension and the likelihood of tendon disruption. Passive motion of the fingers is helpful in preventing finger joint contractures and in decreasing the resistance to active finger movement. The motion program usually is continued for 4–6 weeks.

Future directions

Though most hand surgeons are performing a stronger primary flexor tendon repair than previously, postoperative motion regimes have not been updated and active flexion exercises have yet to be used in some regions or units. The most efficient rehabilitation protocols for the hand with various injury conditions remain to be determined. Some surgeons or therapists advocate early hand and wrist mobilization with short splints from fingertip to the wrist. Though this appears to have merits and is reasonable, we are awaiting for validation with the scope of its application being defined. Currently, traditional tendon-to-bone junction repairs have been questioned and alternatives are sought, but it remains to be determined mechanically and clinically what methods can reliably replace traditional pullout repairs. Wide-awake flexor tendon repair has become a favorite practice of some surgeons (including the author); we anticipate greater popularity. Reducing adhesion formation in severely jeopardized tendons, a long tendon defect, or loss of multiple tendons (which are often seen in complex or extensive hand or forearm injuries) continue to present major clinical challenges and are unsolved problems. We expect that advancements in basic science – in biological modulation of tendon healing and adhesion formation, development of engineered tendon grafts or tendon allografts – will help provide solutions to these very difficult conditions associated with tendon injuries.

BOX 9.11 Tenolysis

1. Local anesthesia is advised, to allow active finger flexion when needed during surgery.
2. Adequate surgical exposure is required to expose all adhesions.
3. Preserve the critically located annular pulleys (A2 and A4 as a minimal).
4. Check mobility of the released tendon to confirm adequacy of surgery.
5. Postoperative motion is paramount to the success of this procedure.
6. Rigor of motion regimes is decided according to intraoperative findings of the released tendons. Motion exercise should always be applied and continued for 4–6 weeks.

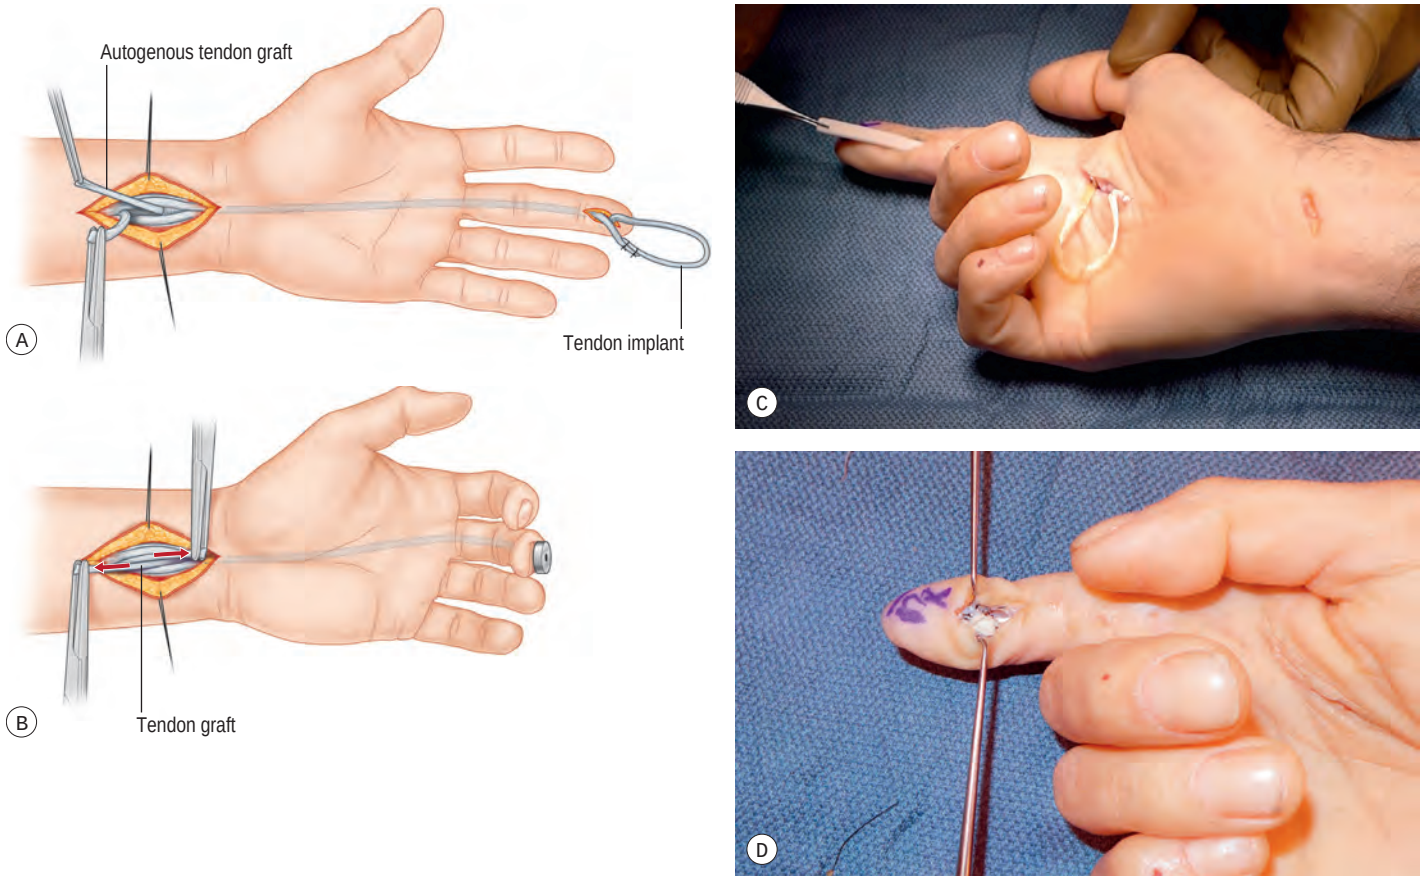

Fig. 9.55 In stage 2, the tendon implant is replaced by a tendon graft. **(A)** The implant is exposed through a small incision at the distal part of the finger. After being disconnected from the flexor digitorum profundus tendon stump, the implant is sutured to the tendon graft. The implant is pulled proximally through the newly formed sheath to lead the grafted tendon. **(B)** The graft has been tunneled in the hand. The distal tendon junction is completed in a way similar to tendon grafting either through a pullout suture or a robust direct suture repair. The proximal junction of the graft is made at either the distal forearm or the palm as shown. **(C)** An intraoperative view of pulling the implant out of the finger. Note the proximal end of the implant was sutured to the grafted tendon. Therefore, after the implant was pulled out, the grafted tendon was inside the sheath. **(D)** The distal end of the graft was securely sutured directly to the distal stump of the FDP tendon, which is my preferred method in recent years.

19. Tang JB. Indications, methods, postoperative motion and outcome evaluation of primary flexor tendon repairs in Zone 2. *J Hand Surg (Eur)*. 2007;32:118–129. *This article provides a comprehensive and updated review of the current indications for primary tendon repairs in zone 2. The author's techniques of multistrand repairs and rehabilitation are detailed. Most importantly, the author defines the needs, mechanical basis, and areas of releasing the critical parts of the major digital annular pulleys to facilitate tendon repairs. The author highlights the importance of releasing the critical pulley parts and strong surgical repairs in achieving predictable primary flexor tendon repairs in this most difficult area. Subdivision of zone 2 and novel criteria for outcome evaluation are also presented in this article.*

25. Giesen T, Sirotakova M, Copsey AJ, Elliot D. Flexor pollicis longus primary repair: further experience with the Tang technique and controlled active mobilisation. *J Hand Surg (Eur)*. 2009;34:758–761. *This clinical study reported the most up-to-date clinical outcomes of repairs of lacerated flexor pollicis longus (FPL) tendons from a renowned center dealing with flexor tendon injuries. These authors have made a series of reports of their results in treating FPL injuries over the past two decades; this most recent report documents their outcomes in 50 FPL injuries. With a six-strand core tendon repair alone (without peripheral repairs), they achieved good or excellent functional recovery in 80% of thumbs, with zero tendon rupture with an active motion regime. These are the best clinical results of FPL tendon repairs reported thus far. It is worth noting that the authors did not elaborate peripheral sutures in these FPL tendon repairs, and the oblique pulley in the thumb was vented to accommodate tendon repairs.*

42. Boyes JH, Stark HH. Flexor-tendon grafts in the fingers and thumb. A study of factors influencing results in 1000 cases. *J Bone Joint Surg Am*. 1971;53:1332–1342. *This classic article reported perhaps the largest case series of free tendon grafting in the fingers and thumbs. The authors analyzed the factors influencing the prognosis for free tendon grafting and showed that the tendon grafting procedure used can produce clinically acceptable function. However, hand conditions are extremely important. Prognostic factors include conditions of the soft tissues and joints. Extensively scarred tendon bed and joint damage led to the worst prognosis after tendon graft surgeries.*

Extensor tendon injuries

Kai Megerle and Karl-Josef Prommersberger

Access video content for this chapter online at expertconsult.com

SYNOPSIS

- A thorough understanding of the complex anatomy is crucial for successful treatment of extensor tendon injuries.
- Injuries are classified into nine anatomic zones. Treatment strategies vary considerably according to the location of the lesion, ranging from splinting to tendon grafting.
- Minimal variations in tendon length may result in considerable alteration in range of motion.
- As in flexor tendon injuries, postoperative care is an essential part of the treatment concept.
- Closed ruptures of the extensor tendon at the level of the distal interphalangeal (DIP) and proximal interphalangeal (PIP) joints are typically treated conservatively.
- Lacerations at the level of the metacarpophalangeal (MP) joint (zone V) are not infrequently caused by human bites and are prone to infection unless thoroughly debrided.
- Ruptures of the sagittal bands may result in subluxation of the extensor tendon at the level of the MP joint.
- The swan-neck deformity is characterized by DIP joint flexion and PIP joint hyperextension. It can be caused by an untreated mallet injury or palmar plate laxity.
- The boutonnière deformity is characterized by hyperextension of the DIP joint and PIP joint flexion. It can be caused by rupture of the central slip of the extensor tendon or palmar subluxation of the lateral bands.
- Complex injuries to the dorsum of the hand can involve skin, tendon, and bone. Adequate debridement is of paramount importance. Before reconstructing tendons, fractures must be stabilized and soft-tissue coverage must be provided.

Introduction

Injuries to the extensor tendons are frequently underestimated. Several reasons might contribute to this phenomenon, including easy access to the tendons due to the thin soft-tissue envelope, their extrasynovial nature, and limited retraction. However, in contrast to common belief, injuries to the extensor tendon apparatus are often more difficult to treat than those of flexor tendons. First of all, a thorough understanding of the complex interactions between the long extensor tendons and the intrinsic muscles of the hand is necessary to achieve good postoperative results. Second, the extensor apparatus consists of superficial, thin structures that are very close to the underlying bones, which makes them prone to develop severe adhesions. Moreover, their excursion amplitude is limited, so that even subtle lengthening or shortening will result in severe restrictions of range of motion. Postoperative regimes vary considerably in respect to the exact location of the lesion and have to be selected carefully.

However, not only the tendon itself but also the surrounding soft tissues have to be taken into consideration when establishing a treatment concept. Extensor tendons are easily exposed on the dorsum of the fingers and hand even after minor trauma due to the thin tissue envelope. Additional procedures are frequently necessary. Shortcomings in adequate soft-tissue coverage will inevitably result in poor overall results, even if the tendons themselves were addressed properly.

Basic science/disease process

The anatomy of the extensor mechanism is complex and some functional details are still subject to discussion. However, in order to be able to provide the best possible treatment in a given pathologic situation, fundamental knowledge about the functional anatomy of this complex system is paramount.

Anatomy of the extensor tendons

The extensor mechanism consists of extrinsic muscles, which are located on the forearm (extensor digitorum, extensor

Historical perspective

The history of tendon surgery reaches back to about AD 200. Galen (130–201) mistook the tendons for nerves and suggested in his *Ars Parva* that no sutures should be placed within the tendons in order not to cause pain and convulsion. The error was not corrected until the 10th century, when Avicenna of Boukhara (980–1037), in Persia, advocated surgical suturing of tendons. However, this new concept did not reach the west until much later – Galen's dogma was not refuted until the 18th century. The basic structure of the extensor tendon mechanism was illustrated by Albinus in 1734. The next step forward was the concept of tendon transplantation, which was introduced in the late 19th century. In the beginning of the 20th century extensive clinical and experimental research was conducted, especially in Germany. Lexer published the results of 10 flexor tendon grafts in 1912. During the first half of the 20th century, Bunnell developed basic principles of flexor tendon surgery which were published in his masterly book *Surgery of the Hand* in 1944.[1] Fowler and Landsmeer advanced the concept of the balanced forces and dynamics between the flexor and extensor apparatus in the 1940s. During the 1960s operating techniques were introduced that are still in use today.

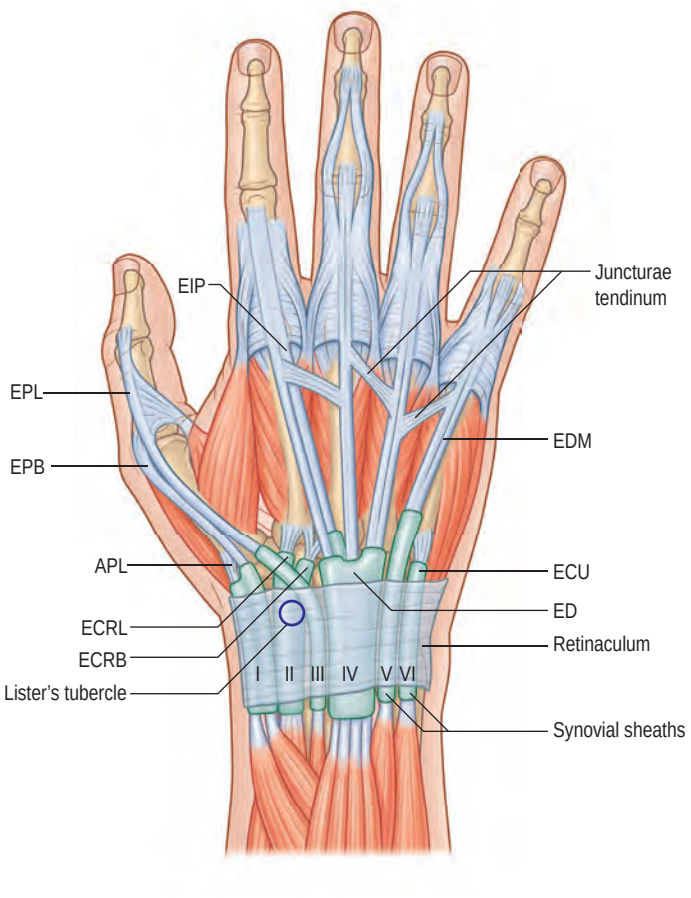

Fig. 10.1 Extensor compartments: I, APL and EPB; II, ECRL and ECRB; III, EPL; IV, ED and EI; V, EDM; VI, ECU. APL, Abductor pollicis longus; ECU, extensor carpi ulnaris; ECRB, extensor carpi radialis brevis; ECRL, extensor carpi radialis longus; ED, extensor digitorum; EDM, extensor digiti minimi; EI, extensor indicis; EPB, extensor pollicis brevis; EPL, extensor pollicis longus.

indicis, extensor digiti minimi (EDM)), intrinsic muscles, which are located at the level of the metacarpals (interosseous and lumbrical muscles), and fibrous structures.

Extrinsic muscles

All extrinsic tendons pass through the six compartments of the extensor retinaculum on the back of the wrist (Fig. 10.1). The first compartment is attached to the outer rim of the radius and contains the tendons of the abductor pollicis longus (APL) and extensor pollicis brevis (EPB) muscles. In 34% of patients the compartment is further divided by an additional septum, which has implications for the etiology and treatment of de Quervain's disease.[2] The extensor carpi radialis longus (ECRL) and extensor carpi radialis brevis (ECRB) tendons run through the second compartment, which is bordered by Lister's tubercle on the ulnar side. The third compartment crosses the wrist in a diagonal fashion above the second compartment, while Lister's tubercle acts as a pivot point for the extensor pollicis longus (EPL) tendon. While passing through the compartment, the tendon is quite vulnerable to ruptures, e.g., in fractures of the distal radius. The fourth compartment contains both the extensor digitorum (ED) and extensor indicis (EI) tendons. The EDM and extensor carpi ulnaris (ECU) tendons run through the fifth and sixth extensor compartments, respectively. The ECU not only functions as an extensor for the wrist, but is also part of the triangular fibrocartilage complex (TFCC) and thus a major stabilizer for the distal radioulnar joint.

The two extensor proprii tendons of the index and the little finger are located on the ulnar sides of the corresponding communis tendons and allow for individual movements of the peripheral fingers. On the dorsum of the hand, the ED tendons are interconnected by the juncturae tendinum which facilitate combined extension of the fingers. Lacerations of the extensor tendons which are located proximal to the juncturae may be masked by the function of these bands. The patterns of the intertendinous connections are highly variable and have been classified into three types: filamentous, fibrous, and tendinous bands.[3] At the level of the proximal phalanges, the extensor tendons split up into three parts: the central band and two lateral bands (Fig. 10.2). These merge with the intrinsic extensor system to form the complex extensor apparatus of the digits.

The extrinsic extensor tendons themselves have three insertion sites on the phalanges. Proximally, the tendon is fixed at the level of the metacarpal heads to the palmar plate by the sagittal bands. This attachment centers the tendon of the MP joint and prevents hyperextension. The most important insertion is located at the base of the middle phalanx. Distally, the terminal tendon is attached to the distal phalanx. In addition to these three sites, there is a variable degree of attachment of the tendon to the proximal phalanx.

Intrinsic muscles

The intrinsic muscular system of the hand consists of seven interosseous and four lumbrical muscles. The three palmar interosseous muscles arise from the medial sides of the second, fourth, and fifth metacarpal bones and join the extensor

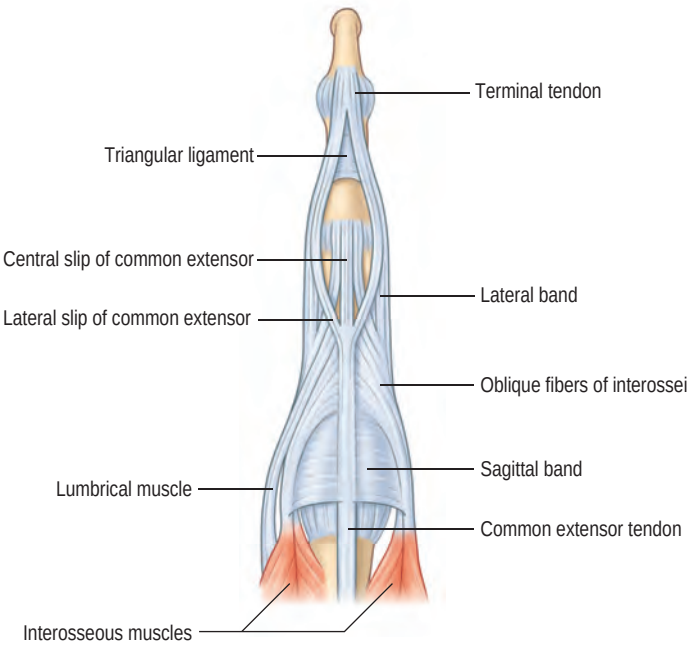

Fig. 10.2 Extensor apparatus.

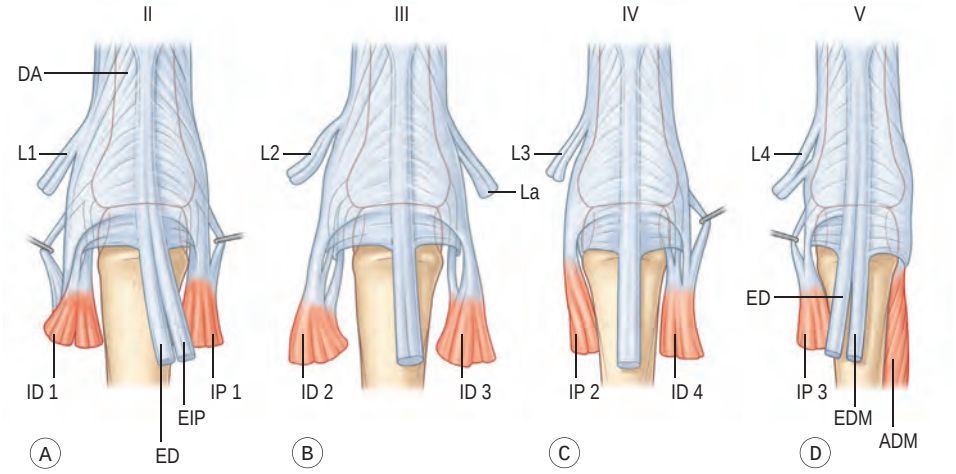

Fig. 10.3 The distribution of intrinsic muscles in the fingers. Roman numbers indicate finger numbers. ADM, Abductor digiti minimi; DA, dorsal aponeurosis; ED, extensor digitorum; EDM, extensor digiti minimi; EI, extensor indicis; ID, dorsal interosseous muscles; IP, palmar interosseous muscles, numbered from radial to ulnar; L, lumbrical muscles, numbered from radial to ulnar; La, accessory lumbrical muscle (variation).

apparatus of the digits at the level of the proximal phalanx after crossing palmar to the axis of the MP joint. The four dorsal interosseous muscles originate with two heads each from the adjacent sides of the five metacarpal bones. The first two interosseous muscles approach the index and middle finger from the radial side; the third and fourth approach the middle and ring finger from the ulnar side. They have insertions at the proximal phalanges and the interosseous hood of the extensor apparatus before joining the lateral bands.

The lumbrical muscles are considered some of the most variable muscles of the human body, while the degree of variation increases from the radial to ulnar muscles. In general, they arise from the radial sides of the flexor digitorum profundus tendons at the level of the metacarpals and join the extensor apparatus from the radial side.

With this arrangement, all four digits have three intrinsic muscles contributing to the extensor apparatus, with the missing ulnar interosseous muscle for the little finger being equivalent to the abductor digiti minimi muscle (Fig. 10.3). The thumb also has three short muscles that join the extensor apparatus: the flexor pollicis brevis (FPB) and abductor pollicis brevis (APB) muscles on the radial side and the adductor pollicis (ADP) muscle on the ulnar side.

Functional anatomy

Linked chains

The movement of the fingers is a highly complex mechanism. It is dependent upon a delicate equilibrium between the extrinsic extensor and flexor muscles and the intrinsic muscles. Biomechanically, the finger can be compared to a multiarticular chain comprised of the three phalangeal bones (Fig. 10.4).

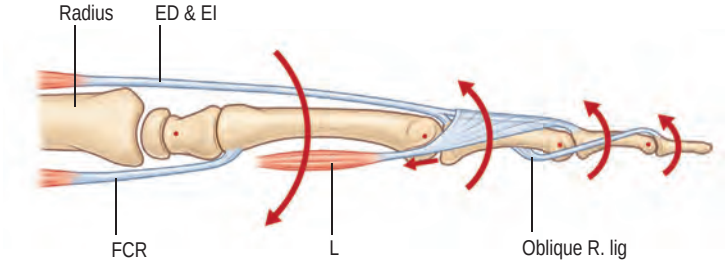

Fig. 10.4 Linked chains. ED & EI, Extensor digitorum and extensor indicis; FCR, flexor carpi radialis; L, lumbrical muscle; Obliq. R. lig., oblique retinacular ligament (Landsmeer's ligament).

Landsmeer was able to show that at least three muscles are necessary to control two joints in such a multiarticular chain.[4] For the proximal phalanx, these are the extrinsic extensor and flexor muscles and the diagonal intrinsic system (lumbrical and interosseous muscles). In the middle phalanx there is no diagonal muscle system; instead the third component is made up of the oblique retinacular ligament (Landsmeer's ligament) which has its origin at the flexor pulley and inserts distally into the extensor apparatus. Both of these diagonal systems run palmar to the joint axis proximally and dorsal to the joint axis distally. They play a crucial role in the coordination of extension and flexion movements of the fingers by linking the extrinsic flexor and extensor muscles.

Functions of the intrinsic muscles

It is generally believed that the intrinsic muscles of the hand act as flexors at the MP joints and extensors at the interphalangeal joints. However, this is not always true for the interosseous muscles. They approach the extensor apparatus at a much smaller angle (less steep) than the lumbrical muscles. Due to this little anatomical difference, the function of the interosseous muscles is highly dependent on the position of the interosseous hood and therefore as well of the position of the MP joint. When the MP joints are in extension, the interosseous muscles cover the articular space and the oblique fibers of the interossei are put into tension, which translates into extension of the interphalangeal joints. However, when the MP joints are in flexion, the interosseous muscles slide distally on the proximal phalanx. During contraction of the muscles, the interosseous hood is pulled towards the hand and the flexion movement of the MP joint is enforced. In this position, the interossei lose the extensor function on the distal joints.

The lumbricals join the extrinsic tendon at a much greater angle than the interossei and are therefore not depending in their function on MP joint position. They act as extensors at the proximal and DIP joint in both extension and flexion of the MP joint.

Extrinsic muscle function

It has been shown biomechanically that both the extrinsic flexor and extensor muscles have a component that acts as an extensor on the proximal phalanx. Under physiologic conditions this force is counteracted by the intrinsic muscles. Paralysis of these muscles (as in ulnar nerve palsy) therefore results in hyperextension of the MP joints. Without intrinsic muscle function the long extensors exhaust their potential at the level of the proximal phalanx. Anatomical studies have demonstrated that isolated contraction of the extrinsic extensors results in hyperextended, clawlike position of the MP joints, but not complete finger extension.[3] For complete extension of the interphalangeal joints intrinsic muscle function is therefore mandatory.

Mechanisms of joint extension

The MP joint is extended by the extrinsic extensor tendon. However, there have been debates about how tendon force is transmitted to the joint. The variable direct attachment of the tendon to the proximal phalanx has been shown to have no significant contribution to MP joint extension.[5] It has been postulated that instead the fibrous connections of the extensor tendon to the flexor sheath are the primary transmitters for extension of the joint.

Extension of the PIP joint is mediated by the central slip of the extensor tendon. However, as stated above, intrinsic muscle function is necessary in order to enable the extrinsic extensor tendon to act on the PIP joint. At the level of the PIP joint, the extensor tendon is centered by the transverse retinacular ligaments. Harris and Rutledge have stressed the importance of the correct position and balance between the central slip and the lateral bands in order to maintain normal PIP extension.[5]

Until the late 1940s, extension of the DIP joint was thought only to be mediated by the terminal part of the extensor mechanism. In 1949 Landsmeer defined the function of the oblique retinacular ligament, which had been unclear since its identification in the 1800s.[6] He described the extension of the DIP joint as a combination of the terminal lateral bands and a tenodesis effect mediated by these ligaments. Later these findings were questioned.[5] However, dissection of the ligament results in lack of extension of the DIP joint.

Diagnosis/patient presentation

The diagnosis of extensor tendon injuries is often evident. However, partial lesions can be missed if the remaining tendon is strong enough to create some extension force. As a general rule, open lesions should therefore be surgically explored to identify the extent of the injury and prevent secondary ruptures. The function of the ED tendon should be assessed by extension of the MP joint of the affected digit against resistance.

Clinical tips

Always obtain a focused history, including the exact mechanism of injury. Expect concomitant osseous involvement in crush injuries. Long-term outcomes should be kept in mind and communicated with the patient when formulating a treatment plan.

Clinical tips

Intrinsic muscle function may obscure complete lacerations of the ED tendons by extension of the PIP and DIP joints. Always check extension of the MP joints to rule out ED injuries.

Fig. 10.5 Test of the extensor pollicis longus tendon.

The EPB tendon inserts into the extensor tendon apparatus of the thumb at varying levels and may be able to extend the IP joint of the thumb. If there is a questionable rupture of the EPL tendon, it should therefore not be tested by extension of the IP joint. Instead, the patient should be asked to lift the thumb off the table, which will be impossible without an intact EPL tendon (Fig. 10.5).

Kleinert and Verdan proposed a system to classify lesions of the extensor tendon apparatus into eight zones according to the level of the lesion.[7] Doyle has added a ninth zone by dividing the forearm into the distal (zone 8) and proximal forearm (zone 9).[8] This classification is presented in Fig. 10.6.

Patient selection

The repair of simple lacerations of the extensor tendon can be safely performed in the emergency room. However, as the lesions are generally underestimated and require sufficient exposure of the tendon, a thorough knowledge of the surgical anatomy and treatment regimes is mandatory. Lesions proximal to zone VI should be treated in the operating room. The use of loupe magnification should be considered. The patient should be aware that, despite the often short duration of

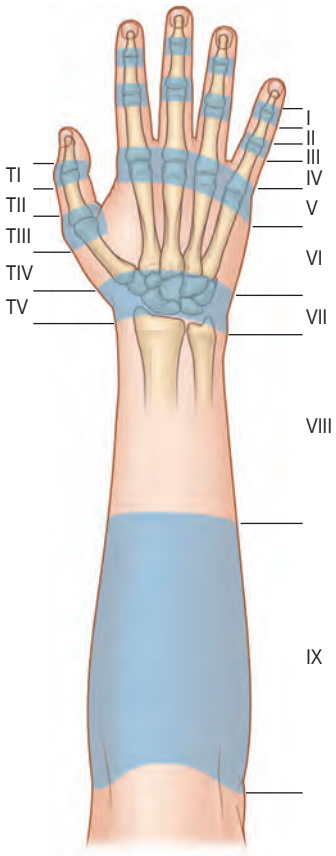

Fig. 10.6 The zones of extensor tendon injuries.

operations, postoperative treatment protocols can be complicated and may last for several months.

Wide-awake surgery is a concept that is becoming increasingly accepted. In this approach, procedures are performed with no sedation and no tourniquet with the use of tumescent lidocaine and epinephrine. This technique has been proven to be safe and cost-effective.[9–12] Most importantly, however, with the patient able to move the fingers during the operation, the surgeon can verify the success of tenolysis or tendon repair procedures immediately.[13] Not only tendon repairs and tenolysis, but also tendon transfers can be most effectively performed in this approach.[14]

Treatment/surgical technique

Suturing techniques

The size of the extensor tendon varies considerably during its course from the distal forearm to its terminal insertion at the distal phalanx. While the tendon is round and thick proximally, it becomes thin and flat more distally. Suturing techniques therefore have to be adapted specifically to the location of the lesion. Whatever technique is chosen, it should provide the best stability with the least shortening possible.

In zones II to IV, extensor tendons are thin and flat and, thus, less amenable to suture techniques involving multiple core sutures. For lacerations in theses areas, epitendinous suture techniques have demonstrated favorable results.[15] In zones VI and proximally, the extensor tendon resembles a flexor tendon and as such can be repaired with a core suture and an epitendinous running suture. Commonly used suture strengths include 3-0 and 4-0 for core sutures and 5-0 for epitendinous sutures. For neither flexor nor extensor tendons is there any scientific evidence for an advantage of using resorbable or nonresorbable suture materials. Fig. 10.7 gives an overview of common types of core suture. In order to achieve maximum core suture strength, locking stitches should be preferred over grasping stitches in order to prevent suture pull-out and reduce gapping.[16] However, grasping suture techniques have a higher tensile strength and less gap formation in extensor tendon repair than mattress or figure-of-eight stitches.[17] For flexor tendons, it has been shown that at least four core strands should be applied in order to enable early active motion[18] and the same is probably true for extensor tendon repair.

In the more distal zones of injury, locking or grasping core stitches become increasingly difficult due to flattening of the tendon. Newport *et al.* report that grasping stitches in zone IV injuries are strong enough to enable postoperative early active motion.[19] More recently, Chung *et al.* have demonstrated that a single cross-stitch may even be superior to multiple cross-stitches in a modified Becker repair of the extensor tendon in zone IV.[20] Simple running stitches should be avoided due to the low pull-out strength in favor of more complex locking suture techniques.

Clinical tips

Always check the stability of the sutured tendon intraoperatively by gentle movements of the finger. If possible, use locking core stitches in preference to other techniques. Soft-tissue coverage can be very thin in fingers, so patients may be able to make out dyed suture material through the skin.

Zone I

The mallet finger

The mallet finger is characterized by persistent flexion of the distal phalanx due to a lesion of the extensor apparatus at the level of the DIP joint. It represents a classic closed injury that

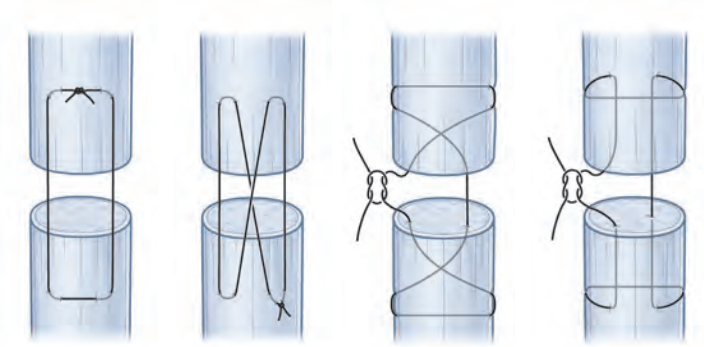

Fig. 10.7 Different types of core sutures.

is usually treated conservatively, although open injuries may occur as well.

The flat terminal extensor tendon inserts at the base of the distal phalanx where it blends with the joint capsule. Since its excursion is only about 4 mm, even small gaps may result in a considerable lack of extension. It should be kept in mind that the full extension of the distal phalanx is also dependent on an intact oblique retinacular ligament.

Mallet fingers can be classified by the degree of osseous involvement. Isolated tendinous ruptures are differentiated from injuries that involve bony avulsions. The latter have been classified into avulsions of small triangular fragments, large fragments that result in palmar subluxation of the phalanx, and epiphyseal detachments in children.

Most surgeons prefer conservative treatment with splints over operative therapy for uncomplicated injuries, although the scientific evidence is limited.[21,22]

Niechajev reviewed 135 patients who had been treated for various types of mallet finger with a minimal follow-up of 12 months.[23] The author concludes that operative treatment should only be performed in cases with subluxation of the distal phalanx or avulsed fragments that are more than one-third of the joint surface and with a diastasis of more than 3 mm. Stern and Kastrup reviewed 123 mallet injuries retrospectively.[24] Thirty-nine patients were treated surgically, resulting in a complication rate of 53%, including infection, nail deformities, joint incongruities, fixation failure, and bony prominence. The authors conclude that splinting is the preferred treatment option in nearly all mallet fingers. Handoll and Vaghela included four trials in a systematic review.[25–29] They concluded that there is insufficient evidence from randomized trials to establish the effectiveness of custom-made or off-the-shelf finger splints, the advantage of surgical treatment over splinting, or even the advantage of splinting over no treatment at all.

The best available evidence therefore supports conservative treatment by splinting for the majority of cases. Conservative treatment usually implies immobilization of the DIP joint in extension while sparing the PIP joint. By extension or slight hyperextension of the joint the two ruptured ends of the tendon are approximated (Figs. 10.8 & 10.9). The fibrous tissue of the resulting scar is thought to be strong enough to restore extension of the joint. The type of splint is not nearly as important as patient compliance. Prefabricated stack splints have been shown to be equally effective as simple aluminum splints or custom sandwich splints (Figs. 10.10 & 10.11). Most authors recommend full-time splinting for at least 6–8 weeks followed by a period of 2–6 weeks of splinting at night to enable further shrinking of the immature scar. All patients should be thoroughly instructed to avoid ineffective use of the splints. The splints should only be removed when flexion of the DIP joint by the strong pull of the FDP tendon is counteracted, e.g., through resting the finger flat on a table. By thorough splinting, a residual lack of extension of 10° or less can be expected.[30]

Surgical treatment for closed injuries should only be considered in fragment sizes greater than one-third of the joint surface. Transfixation of the DIP joint with a Kirschner wire has been suggested for sole treatment of the mallet injury in addition to other surgical interventions.[31,32] To avoid scarring of the finger pulp, Tubiana has suggested an oblique angle when crossing the DIP joint.[33]

Fig. 10.8 Acute mallet injury, reduced by stack splint: posteroanterior view.

Fig. 10.9 Acute mallet injury, reduced by stack splint: lateral view.

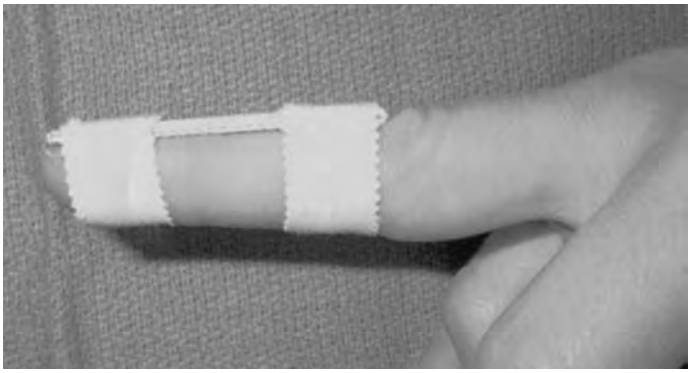

Fig. 10.10 Aluminum splint.

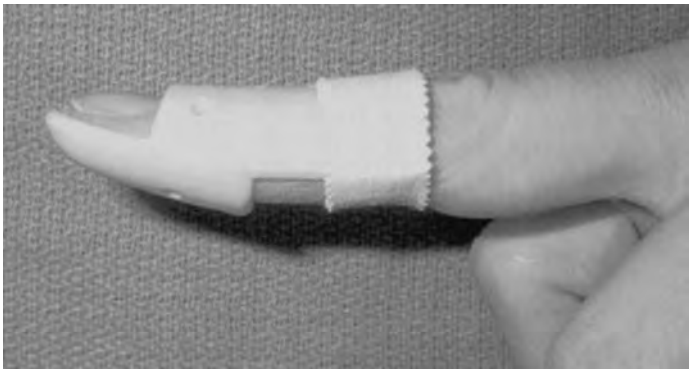

Fig. 10.11 Stack splint.

When surgical intervention is indicated, the size of the avulsed fragment should be carefully evaluated for direct fixation. This can be very difficult to achieve and may result in further fragmentation of the avulsed bone. In case of a rather small fragment, indirect reduction by extension block pin fixation should be preferred ("doorstop osteosynthesis"). In this technique the distal phalanx is maximally flexed and a 1.0-mm Kirschner wire is advanced into the middle phalanx dorsal to the avulsed fragment at a 45° angle, creating the extension block against which the fragment is reduced. The joint is then extended, reducing the fragment. This position is secured by a second Kirschner wire inserted longitudinally across the DIP joint for transfixation. The wires are cut and a splint is applied for at least 6 weeks (Figs. 10.12–10.15).

If the avulsed fragment seems large enough, it may either be pinned directly percutaneously or reduced in an open fashion through a zigzag incision of the distal and middle phalanges. In case of open reduction, screw fixation seems preferable. Alternatively, a pull-out suture may be applied, as described by Doyle.[8]

Fig. 10.13 Mallet injury: lateral view. Despite the stack splint, the fragment is not properly reduced.

Open injuries

Most authors agree to operative treatment for open injuries. In some cases, suturing of the skin alone and supporting the joint in extension or slight hyperextension is enough to

Fig. 10.12 Mallet injury: posteroanterior view.

Fig. 10.14 Postoperative doorstop: posteroanterior view.

Fig. 10.15 Postoperative doorstop: lateral view 6 weeks after doorstop osteosynthesis.

approximate the ends of the ruptured tendon and allow direct healing. When sutures are needed to approximate the tendon ends, a suture that incorporates both skin and tendon may be superior to individual suturing of the tendon, because further tendon dissection may decrease the blood supply and compromise healing.

Chronic injuries

If tendinous ruptures over the DIP joint are not or insufficiently treated, gapping of the tendon ends will result in the incorporation of fibrous tissue and lack of extension. A swan-neck deformity may occur. The approach to these conditions is described below (under secondary procedures).

Zone II

Injuries to the extensor tendon over the middle phalanx usually result from sharp, direct lacerations or crush injuries. Acute lacerations should be explored to determine the extent of the tendon injury. If less than 50% of the tendon substance are injured, the tendon is considered stable and no further treatment is necessary. If more than half of the tendon is involved, additional suturing is necessary. When evaluating these injuries, phalangeal extension should always be tested against resistance. Doyle recommended a running stitch combined with a Silfverskiöld cross-stitch[8] (Fig. 10.16). Care should be taken to avoid considerable shortening of the tendon which will result in lack of flexion of the DIP joint.

Zone III

Injuries to the extensor tendon at the level of the PIP joint (zone III) occur as both closed and open injuries, ranging from minor strains to complete ruptures or lacerations. Injuries at this level can give rise to the characteristic boutonnière deformity when the proximal phalanx herniates through the central slip defect. However, the deformity will not develop immediately after the injury. Disruption of the tendon first leads to an inability to extend the PIP joint actively while passive extension is possible. Only after the lateral bands migrate palmarly and retraction of the central slip occurs will hyperextension of the DIP joint develop.

Closed injuries

A closed avulsion injury of the central slip may not be immediately evident and extension may be retained by means of the lateral bands. If in doubt, extension of the PIP joint should therefore always be tested against resistance.

The central slip may be restored without surgical intervention by extension splinting. As flexion of the DIP joint stretches the extensor mechanism and facilitates dorsal relocation of the lateral bands, the DIP joint should not be included in immobilization. Instead patients should be encouraged to move the DIP joint actively and passively while wearing the PIP splint (Fig. 10.17). Several authors have proposed pinning the PIP joint in extension by a Kirschner wire.[34–36] Most authors suggest keeping the joint in extension for 5–6 weeks.[35–37]

Surgical treatment has been suggested for avulsion injuries with large bony fragments or unstable transarticular fractures.[33] If the fragment is too small to be pinned directly, it may be excised and the tendon reinserted into the middle fragment with a bone anchor.

Open lacerations

Open injuries should always be thoroughly explored. Care should be taken specifically to include the lateral bands and the triangular ligament in the inspection.

Clinical tips

Because of the excursion of the tendon at the time of injury, the full extent of tendon involvement may not be visible at first sight. It is therefore mandatory to carefully inspect the tendon proximally and distally to the skin lesion.

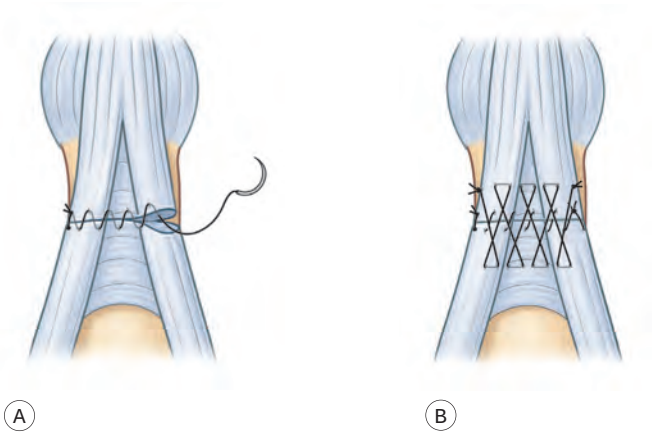

Fig. 10.16 (A,B) Silfverskiöld cross-stitch for sutures in zone II injuries.

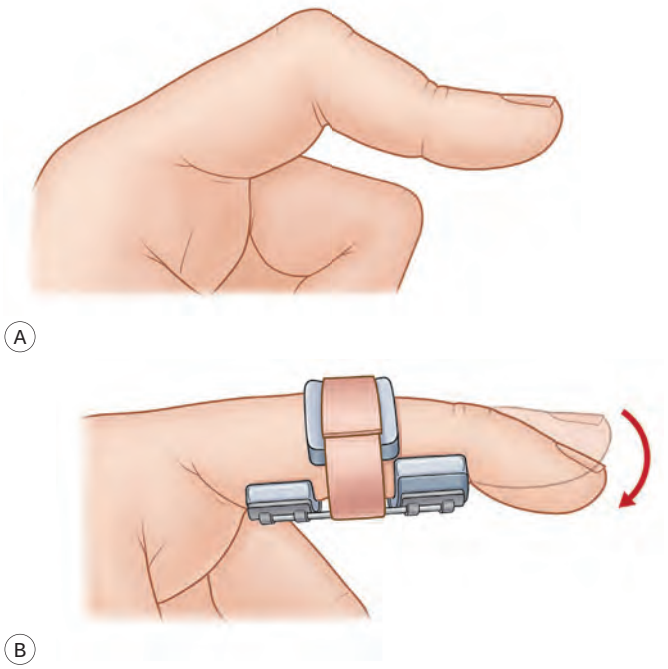

Fig. 10.17 (A,B) Splinting for closed extensor tendon ruptures in zone III.

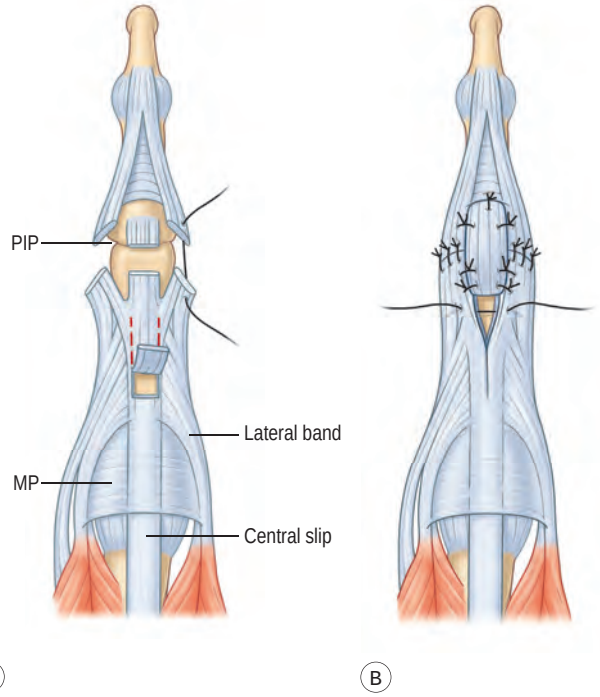

Fig. 10.18 (A,B) Snow's technique of reconstructing the central slip. MP, Metacarpophalangeal; PIP, proximal interphalangeal.

The mechanism of injury is of special importance in open zone III injuries with regard to the extent of injury to both the tendinous structures and the surrounding soft tissues. In clean and sharp lacerations, the wound can be easily enlarged and the injured tendon should be sutured directly or reinserted into the middle phalanx. A Silfverskiöld cross-stitch may be used where appropriate to enforce the suture. In contrast, contaminated defect wounds, e.g., after saw injuries, are a lot more difficult to deal with. If there is considerable loss of tendon, an immediate reconstruction should be attempted. Snow described a retrograde tendinous flap created from the proximal tendon that is flipped over to bridge the defect over the joint (Fig. 10.18).[38] Aiache *et al.* proposed a longitudinal split of the two lateral bands that are joined in the midline to reconstruct the tendinous insertion and to cover the joint (Fig. 10.19).[39] Any loss of covering skin should be replaced immediately as well; options include local random pattern flaps, reversed cross-finger flaps, or flaps from the dorsal metacarpal artery system.

Postoperatively, a Kirschner wire may be used to reinforce splinting of the PIP joint, which should be kept for 4–6 weeks. Tenolyses or joint releases are frequently necessary, but should be delayed until 3–6 months after the injury.

Zone IV

As the extensor becomes very broad over the proximal phalanx, partial lacerations are more commonly observed than complete injuries of the tendons. Therefore extension should be examined against resistance. Surgical inspection is necessary to assess the exact extent of the injury. Newport *et al.* have demonstrated that modified Kessler sutures do not result in significant shortening of the tendon and allow 30° of flexion in the PIP joint without gapping.[19]

Extensor tendon injuries in zone IV are often associated with fractures of the proximal phalanx.[40] Due to the close relationship between tendon and bone, adhesions frequently occur and tenolysis is often necessary. Some form of a postoperative early active motion regimen is therefore advisable to reduce loss of range of motion. Maintenance of the wrist in an extended position will "unload" the tendon and allow early range of motion of the finger.

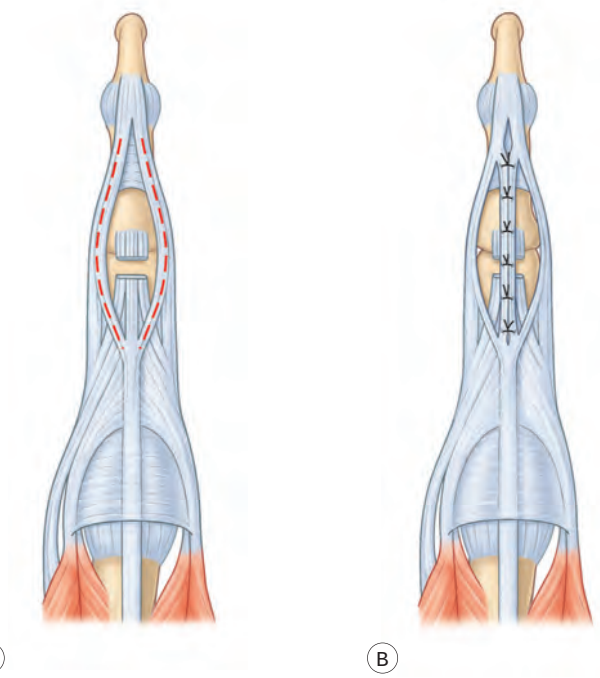

Fig. 10.19 (A,B) Reconstruction of the central slip involving splitting of the lateral bands (Aiache's technique).

Zone V

At the level of the MP joints, the extensor tendon consists of the central extensor tendon and the sagittal bands. Due to the broad width of the extensor apparatus complete lacerations are uncommon. On the other hand, partial lacerations can be easily missed because the remaining tendon may be sufficient to maintain extension function. Surgical exploration is therefore warranted. It should be taken into account that the injury to the tendon may be located more proximally than the skin laceration if the tendon was injured in flexion and the exploration is performed with the digit in extension. If possible, a core suture with an epitendinous running stitch should be performed. In the rare cases of complete lacerations, the tendon will not significantly retract proximally, as it is restrained by the sagittal bands and the juncturae.

Human bite injuries

A common mechanism of injuries to the extensor tendon in zone V is a human bite injury caused by a punch to the opponent's face (fight bites; Fig. 10.20). Bite wounds are heavily contaminated and prone to serious infection. As skin damage is often minimal, these injuries are frequently underestimated by the patient and treatment is delayed until infection has developed. Primary inspection is mandatory in fresh injuries, as are X-ray studies to detect avulsed bony fragments or teeth. During exploration, the tendon should be split longitudinally and the MCP joint irrigated with antibiotic solution.[41] Partial lacerations of the tendon often do not require suturing; a number of authors suggest delayed primary treatment after the occurrence of infection has been ruled out.[42]

Sagittal band injuries

The central tendon is centered over the MP joint by the lateral bands which attach to the palmar plate of the joint. Open or closed injuries to the sagittal bands may result in subluxation of the tendon to the unaffected side during flexion. Partial lacerations will not result in subluxation unless two-thirds of the sagittal band is affected.[43] Stable lacerations can be treated by buddy-taping of the affected finger to an adjacent finger for 3 weeks. In case of an unstable tendon, the laceration should be sutured.

Closed ruptures of the sagittal bands are much more common than open injuries and usually occur in the course of a primary disease of the joints such as rheumatoid arthritis. Ishizuki describes two layers of the sagittal bands, a superficial and a deep layer.[44] He postulated that degenerative ruptures affect only the superficial layer, while traumatic ruptures affect both layers. Traumatic and spontaneous ruptures of the sagittal bands may be treated by splinting within 10–14 days.[45,46] In older injuries, direct suturing of the bands should be attempted. Reconstruction of the sagittal bands in chronic subluxation is discussed in the section on secondary surgery, below.

Fig. 10.20 Fight bite in the ring-finger metacarpal. The extensor tendon is split longitudinally.

Zone VI

Extensor tendon lesions at the level of the metacarpal bones have a better prognosis than in more distal zones.[40] This is due to several reasons. First, the tendons are very broad and can usually be sutured by a 3-0 core stitch and an epitendinous running suture. Moreover, they are extrasynovial and are not associated with any joints. At the same time, tendon excursion is greater than in more distal locations and imbalances between extensor and flexor systems are less likely to occur. Soft-tissue coverage is better than in distal zones, but still quite thin compared to flexor tendons.

At this level, the function of the extrinsic extensor tendon is to extend the MP joint. Therefore MP joint extension should be tested against resistance. However, the extrinsic tendons are linked by the juncturae tendinum and patients may still be able to extend the joints by means of the adjacent tendons.

Postoperatively, early mobilization with a dynamic splinting regime is indicated to reduce tendon adhesions. Loss of flexion has been reported to be more common than loss of extension.[40]

Zone VII

Injuries to the extensor tendons at the level of the extensor retinaculum are due to either open lacerations that often affect multiple tendons or closed ruptures, most often after distal radius fractures.

In order to repair open lacerations at this level, at least a part of the retinaculum has to be opened. There has been an ongoing debate whether or not to reconstruct the retinaculum over the affected tendon. Some surgeons advocate excising the retinaculum in order to avoid postoperative adhesions. Others suggest reconstructing at least parts of the retinaculum to prevent subluxation or bowstringing of the tendons. Although adhesions between the tendons and the retinaculum seem more likely, Newport *et al.* found no differences between the outcomes of zone VII lesions in comparison to lesions in adjacent zones.[40] The tendon repair itself should be performed with a stable core suture and an epitendinous running stitch. Special attention should also be paid to concomitant injuries of sensory branches of the radial and ulnar nerves. Primary coaptation of the nerve ends should be performed in order to prevent the development of painful and difficult-to-manage neuromas.

As the tendons are arranged very close to each other, injuries of multiple tendons through one laceration occur

frequently. Identification of the tendons can be quite difficult, because they tend to retract into the forearm. A thorough knowledge of the surgical anatomy is therefore mandatory. Botte *et al.* described a useful technique of labeling the retrieved tendons by placing sterile labels on hemostats that are clamped to sutures placed in the proximal ends of the tendon.[47]

Ruptures of the EPL tendon are most often associated with fractures of the distal radius or rheumatoid arthritis. Two main causes for EPL ruptures after distal radius fractures have been hypothesized.[48] On the one hand, the tendon may be injured while drilling the holes for palmar plate fixation or by choosing screws that are too long and protrude into the extensor compartments. On the other hand, dislocated dorsal fragments of the fracture may harm the tendon. Because of the degenerative nature of the process, an end-to-end repair of the tendon is usually not possible without unacceptable shortening of the tendon. Instead, reconstruction of the tendon can be performed by EI to EPL tendon transfers or interposing tendon grafts. Both techniques are discussed in the section on secondary surgery, below.

Zones VIII/IX

Lesions of the extensor tendons at levels VIII and IX include injuries of the musculotendinous junctions and muscle bellies. As in zone VII injuries, the recovery and identification of retracted tendons can be quite challenging. Combined injuries to muscles and/or nerves are possible. Knowledge of the sequence of motor innervation helps to distinguish a motor nerve injury from a tendon injury. The motor branches of the wrist and fingers have been divided into two groups, a proximal superficial group and a distal deep group.[42] The proximal superficial group consists of the ECRL, ECRB, ED, EDM, and ECU muscles. The entry of nerve fibers into the muscles is near the lateral epicondyle. When exposing the posterior interosseous nerve, the interval between the wrist ECRB and ECRL tendon (proximal to the supinator muscle) and the ED, EDM, and ECU (distal to the supinator) should be chosen to avoid injury to motor branches. The distal deep group consists of the APL, EPB, EPL, and EI. They originate in the distal half of the forearm, close to the skeletal plane.

Adequate repair of muscles and tendons can be very difficult in this area. Sutures of muscle fibers alone have virtually no tensile strength. Therefore an effort should be made to suture tendons or fascial layers instead of muscle fibers alone. Nevertheless, these sutures are usually not strong enough for dynamic postoperative treatment protocols and immobilization for 3–4 weeks should be initiated postoperatively.

Postoperative care

As with flexor tendon injuries, the importance of an adequate postoperative treatment cannot be overestimated. Extensor tendon healing itself does not differ very much from flexor tendon healing. However, it has to be considered that the treatment protocol needs to address the powerful antagonist force of the opposing flexor tendons. Initially, static postoperative treatment regimes were considered sufficient for all injuries, as in theory tendon adhesion is limited due to the mostly extrasynovial nature of extensor tendons. In reality, however, while prolonged immobilization allows healing of the tendon without disturbances, it still promotes loss of motion due to the formation of adhesions. The problem can be addressed by early active or passive motion which in turn increases the risk of gap formation and ruptures of the sutured tendons. As for flexor tendon injuries, in recent years, dynamic postoperative treatment protocols have been developed that reduce postoperative adhesion formation without jeopardizing the stability of the sutured tendon.

Nevertheless, strict immobilization is the treatment of choice for some indications. Mallet injuries should be treated by full-time static splinting for 8 weeks. The same is true for closed ruptures of the central slip (zone III injuries). Immobilization should also be considered for injuries proximal to the extensor retinaculum (zones VIII and IX) because it may not be possible to achieve adequate tensile strength by suturing fascial layers around the muscle.

Postoperative immobilization of open injuries in zones III–V will inevitably result in severe adhesions, because the tendon is very broad and in close relationship to the adjacent bone in this area. To overcome this problem, Evans described a postoperative treatment protocol that reduces adhesions by limited early active motion ("short arc motion").[49] The regime is based on biomechanical studies that examined the extensor tendon excursions necessary to prevent adhesion formation. Duran *et al.*[50] found that 3–5 mm of passive tendon glide is sufficient to achieve this goal. Evans[51] compared intraoperative measurements of tendon excursions in zone IV and V with previous measurements of Brand and Hollister,[52] and estimated that 60° of PIP joint flexion translates into 5 mm of tendon glide at Lister's tubercle.

For the protocol, three finger splints are required. The affected digit is immobilized between training sessions in an extension split in 0° extension of the DIP and PIP joints. At every waking hour, the splint is removed and a controlled active motion protocol is followed. First a splint is put on to block flexion of the PIP joint at 30° and flexion of the DIP at 20–25°. After 20 repetitions of active and passive motion within the defined limits, a third splint is put on that stabilizes the PIP joint in 0° extension while sparing the DIP joint. The patient then actively extends and flexes the DIP joint 20 times. During the second and third week of the protocol, flexion of the PIP joint is increased to 40° and 50°. In a retrospective study, Evans reported on significant improvement of clinical results with the dynamic protocol when compared to a group of patients who were immobilized postoperatively.[50]

Dynamic mobilization for injuries in zones V–VII can be achieved by passive extension with a rubber band system combined with active flexion of the affected digit (Fig. 10.21). This protocol has also been termed the "reversed Washington" or "reversed Kleinert" regimen. The patient is encouraged to perform active flexion and passive extension exercises 10 times every hour for 3 weeks, starting on the second postoperative day. The range of motion for flexion of the MP joint is restricted at 30° in the beginning and gradually increased to 60° until the end of the third week. Active motion is initiated after 3 weeks and the splint is removed after 6 weeks. The load of the tendon is gradually increased over 6 weeks. In a prospective, randomized study, better total active motion was achieved in zone V and VI lesions after 4, 6, and 8 weeks after a dynamic splinting protocol when compared to static splinting.[53]

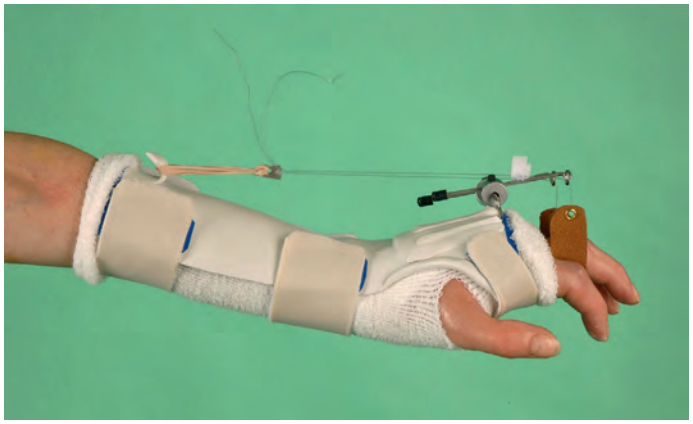

Fig. 10.21 Dynamic extension splint.

Early dynamic motion is also superior to immobilization after transfer of the EI tendon for EPL reconstruction.[54] After performing a Pulvertaft weave, the tendon is more stable and splinting can be discontinued after 3 weeks. However, active extension of the thumb has no advantage over dynamic splinting after transfer of the EI tendon.[55]

A different concept for lacerations in zones IV to VII is the immediate controlled active motion (ICAM) splinting protocol.[56] This protocol, also referred to as relative motion splinting, encourages active motion of the affected digit which is kept in 15° to 20° less relative motion than the adjacent joints by a simple splint for 6 weeks. The rationale for this concept is that placing the finger in a slightly more extended position than the neighboring digits results in a reduction of force, regardless of the position of the MP joint.[57] Recently, ICAM has also been applied for postoperative care after correction of boutonnière deformities, sagittal band ruptures and side-to-side tendon-transfers in caput ulnae syndrome.[58]

Outcomes, prognosis, and complications

Outcomes

Outcomes vary considerably with the location of the lesion, the extent of concomitant injuries to the bone or surrounding soft tissues, timing of the repair, and adequate postoperative care. Clinical results are most often assessed by total active motion.[59] Hung *et al.* established 270° of total active motion in a digit as a normal value.[60] Some authors have adapted evaluation systems for flexor tendon injuries.[7,61] Alternatively, results can be compared by total lag of extension or flexion, as proposed by Miller in 1942.[62]

Lesions distal to the MP joints lead to less favorable results than more proximal lesions. Newport *et al.* report the results of a retrospective analysis of 101 patients, most of whom were treated with static splinting.[40] Good or excellent results with an average total active motion of 230° were achieved in 64% of patients without an associated injury. However, lesions in zones I through IV resulted in good or excellent results in only 50% of patients. Evans found a total active motion of 147° 6 weeks after repair of lacerations in zone III and an early active motion regimen.[49]

Hung *et al.* reported on 38 patients with an average of 229° of total active motion after postoperative dynamic splinting.[60] Patients with lesions in zones II–IV showed the worst results, with an average of 188° total active motion. For lesions at the level of the MP joint, several studies reported superior results after postoperative dynamic splinting protocols when compared with immobilization, ranging from 237° to 254° of total active motion.[60,63,64]

Complications

The most common complication after extensor tendon injuries is the formation of adhesions between the tendon and surrounding tissues. Under these circumstances, a tenodesis restraint may occur, limiting PIP joint flexion when the MP joint is also flexed. Adhesion formation should be addressed first by hand therapy and splinting of the affected joints in order to improve tendon gliding. If there is not adequate improvement in range of motion after 4–6 months, extensor tendon tenolysis can be considered. A stable skin envelope is a prerequisite before performing any additional procedures. Tenolysis can be elegantly performed utilizing the wide-awake technique with no sedation and no tourniquet with the use of tumescent lidocaine and epinephrine (see patient selection, above).

Tenolysis alone may not be sufficient to achieve an improvement in range of motion. An additional capsulotomy, collateral ligament release, or even flexor tendon tenolysis may be necessary.[65] Creighton and Steichen reported the results of extensor tenolysis after phalangeal and metacarpal fracture repair.[66] Total active range of motion was improved by 31% on average, but only 21% when an additional capsulotomy was necessary.

Secondary procedures

Clinical tips

Secondary correction of established finger deformities is exceedingly difficult. Patients should be aware that restoration of "normal" finger movement is rare.

The hanging fingertip

Even a minimal increase in tendon length will result in an extensor lag after a mallet injury. In many patients, therefore, some residual deformity will occur. However, this deformity is rarely of any relevance in terms of long-term prognosis.[67] With the extension lag exceeding 40–50°, however, a considerable number of patients will desire correction. In this case, additional immobilization should be considered for up to 6 months after the injury, especially if there is any doubt about the adequacy of the primary treatment.

If conservative treatment fails, surgical treatment should be discussed with the patient. Due to the delicate equilibrium between the extensor and the flexor tendon system, results are not always satisfactory after secondary surgery. None of the procedures available will invariably provide reliable results. Correction of the deformity may be incomplete, there may be some loss of flexion in the DIP joint, and pain reduction cannot

Fig. 10.22 Hanging fingertip.

Fig. 10.23 Resection of skin and tendon.

be reliably predicted. Any accompanying arthritis of the joint should be ruled out; in case of cartilaginous deterioration, DIP joint fusion should be considered.

If surgical correction is indicated, a simple combined excision of callus and skin may be the procedure of choice. This dermatotenodesis has also been referred to as the Brooks–Garner procedure. In this procedure, an elliptical wedge of skin and underlying soft tissues, including the scarred extensor tendon, is excised from the dorsum of the involved DIP joint (Figs. 10.22–24). The wound edges are closed by en bloc sutures, resulting in a slight hyperextension of the joint. The DIP joint is then transfixed with a Kirschner wire to keep the joint in the desired position for 6 weeks.

Alternatively, a Fowler release (central slip tenotomy) or even a reconstruction of the spiral oblique retinacular ligament may be performed. Both procedures are primarily used to correct swan-neck deformities and require a supple PIP joint. They are therefore discussed in the following section.

The swan-neck deformity

The swan-neck deformity is a classic finger deformity that can be caused by many reasons, including congenital PIP palmar plate laxity and intrinsic tightness. Often it is associated with some form of arthritis; however, it can also result from a mallet injury. A thorough history-taking and physical examination will distinguish the mallet etiology from other causes. In this case, the disrupted extensor tendon results in a concentration of extensor force at the PIP joint (Fig. 10.25). If the palmar plate of the joint is lax, the swan-neck deformity will occur immediately. However, even if it is not lax to begin with, it will stretch over time due to increased extensor pull. If hyperextension of the PIP joint exceeds a critical point, snapping of the joint will occur. This may be often more disconcerting to the patient than the postural deformity.

A tenotomy of the central slip has been used to address the swan-neck deformity in patients with a chronic mallet deformity in which the terminal extensor tendon cannot be repaired.[68] This procedure has also been referred to as the Fowler release. By transection of the central slip, rebalancing of the extensor mechanism should occur in order to increase the extension force on the DIP joint. Grundberg and Reagan reported on a series of 20 patients with an average reduction of PIP joint extension of 10° to less than 2°.[69] A biomechanic study demonstrated the ability to correct an extensor lag of

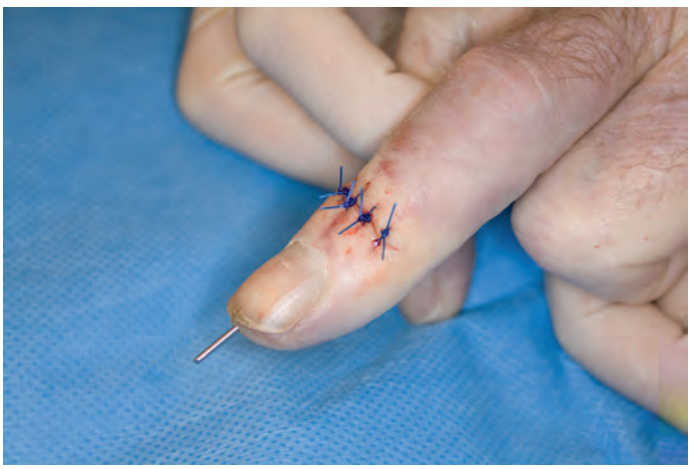

Fig. 10.24 Transfixation of the distal interphalangeal joint.

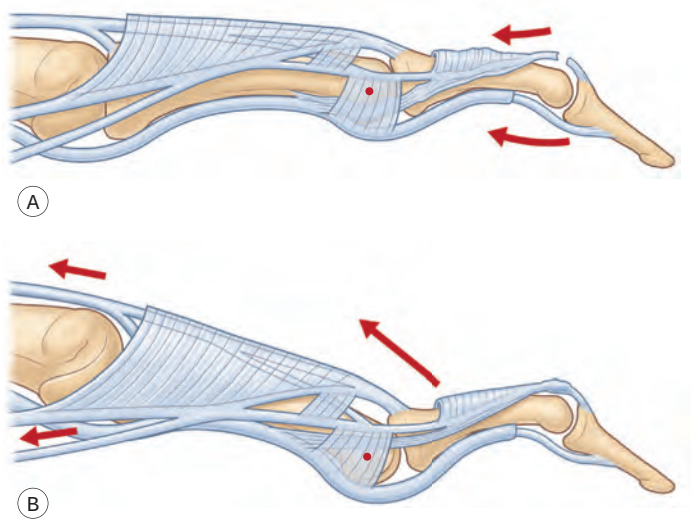

Fig. 10.25 (A,B) Pathophysiology of the swan-neck deformity. The deformity persists when the tendon heals with lengthening.

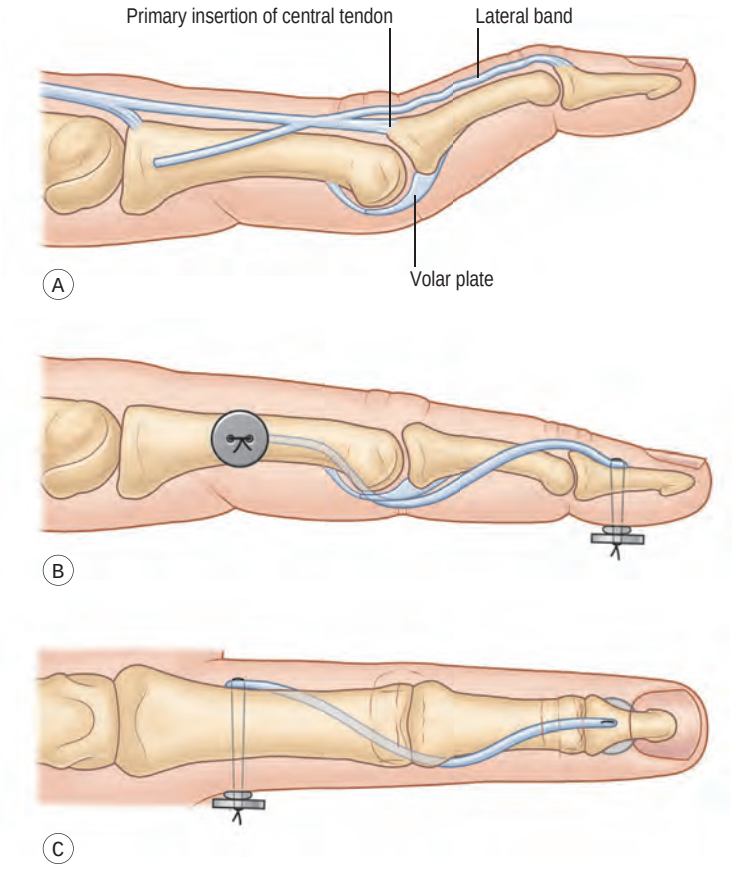

Fig. 10.26 (A–C) Spiral oblique retinacular ligament. A palmaris longus tendon graft is passed between the flexor tendon and the palmar plate and fixed to the distal phalanx by a pull-out suture.

up to 46°.[70] The authors noted that extensor lags greater than 36° may not achieve full correction of the deformity. Increasing the extent of the release will potentially increase the risk of a secondary extensor lag of the PIP joint, but there was no clear relationship between the occurrence of a lag and the amount of release in a recent biomechanical study.[71] It should be noted that there is some confusion in the literature about the operation that is referred to as a "Fowler release". Fowler also described a procedure to address the boutonnière deformity by rebalancing the extensor tendon (see below). However, in this operation the extensor tendon is divided distal to the insertion of the central slip and thus even increasing extension forces at the level of the PIP joint.

Alternatively, the extensor tendon may be reconstructed by a tendon graft (spiral oblique retinacular ligament or SORL reconstruction: Fig. 10.26). Thompson *et al.* described a procedure using a palmaris tendon to restrain PIP extension and to extend the DIP.[72] In this technically demanding operation, the tendon graft is fixed to the distal phalanx by a pull-out suture. It is then passed between the flexor tendon and the palmar plate of the PIP joint into an osseous tunnel in the proximal phalanx (see Fig. 10.26). Although Girot *et al.* reported a 95% success rate to correct PIP hyperextension, experience with this procedure seems to be limited.[73]

Swan-neck deformities which are not primarily related to injuries of the distal extensor tendon should be approached differently. Frequently, these deformities are caused by hyperlax palmar plates at the level of the PIP joint. In these cases, correction of the laxity can be indicated, e.g., by a tenodesis of the flexor digitorum superficialis tendon.

The boutonnière deformity

Acute injury to the central band of the extensor tendon will result in an acute boutonnière deformity as both lateral bands shift palmarly due to the accompanied disruption of the triangular ligament. In the acute phase, the deformity should be easily reducible and may be treated as described above. However, if left untreated, a chronic contracture results from shortening of the oblique retinacular ligament (Fig. 10.27). This condition has long been recognized as one of the most challenging problems in hand surgery.[74]

Preoperative considerations

Any surgical correction of the deformity should only be performed if the PIP joint can be extended passively. This can sometimes be achieved conservatively by a physical therapy program in combination with static and dynamic splinting. In severe cases, an additional operative tenoarthrolysis may be necessary. This procedure can sometimes be combined with revision of the extensor tendon from a dorsal approach. However, in severe cases a first-stage palmar approach to release the joint contracture is combined with a staged secondary procedure from dorsally. If combined with a splinting regimen, the tenoarthrolysis may be sufficient to achieve functional improvement, so that further operations can be avoided.

Burton and Melchior have listed several more aspects that should be considered before attempting a surgical correction of the deformity.[75] Patients should be aware that postoperative splinting is an essential part of the treatment strategy and may

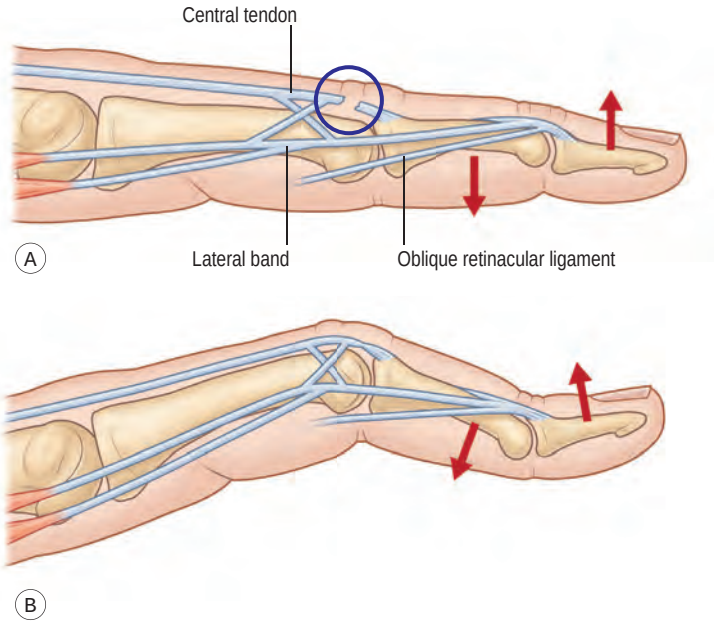

Fig. 10.27 (A,B) Pathophysiology of the boutonnière deformity. Subluxation of the lateral bands results in redistribution of forces and an extensor lag in the proximal interphalangeal joint. Retraction of the oblique retinacular ligament prohibits reduction in chronic deformities.

be necessary for months after surgery. Any attempt to reconstruct the soft tissues around the PIP joint should be avoided if the joint shows any signs of arthritis. In this case, joint fusion or arthroplasty should be considered. The boutonnière deformity does not necessarily compromise the extent of flexion in the PIP joint or grip strength. An increase in extension of the joint should not be traded for a stiff finger or loss of grip strength.

There are two main categories of procedure to address the boutonnière deformity: tenotomy or reconstruction of the extensor tendon by tendon relocation or tendon grafting.

Tenotomy

Tenotomy of the extensor tendon on the middle phalanx is referred as the Dolphin or Fowler procedure.[76,77] It may be the procedure of choice when patients mainly complain about hyperextension of the DIP joint. The incision should be performed just distally to the insertion of the central slip. In Dolphin's description, the tendon is divided more proximally in order to preserve the distal insertions of the oblique retinacular ligament (Fig. 10.28). The lateral bands should be able to slide proximally in order to increase the tone on the PIP joint to allow improved extension and reduce tension on the DIP joint. Postoperatively, the PIP joint should be splinted in extension, allowing free range of motion of the DIP joint. It has been recommended to apply splinting for 6–8 weeks.[75]

Secondary reconstruction of the extensor tendon

If the main patient complaint is the lack of extensor function, secondary reconstruction of the extensor should be considered. This goal can be achieved by either tendon relocation or tendon grafting. Intraoperative transfixation of the PIP joint with a Kirschner wire has been subject to controversial discussion for any type of reconstruction. In severe flexion contractures of the joint, it may be beneficial.

The central slip can be reconstructed as described by Snow (see Fig. 10.18). The end of the reconstructed tendon is either sutured to the remaining insertion on the middle phalanx or reinserted directly into the phalanx.

A large number of techniques have been described to reconstruct the central slip using the lateral bands. By relocation of the lateral bands the tension of the terminal tendon on the DIP joint is reduced while increasing the extension force on the PIP joint. Littler and Eaton described the resection of both lateral bands in order to relocate them dorsally and suture them on to the insertion of the central slip, thus

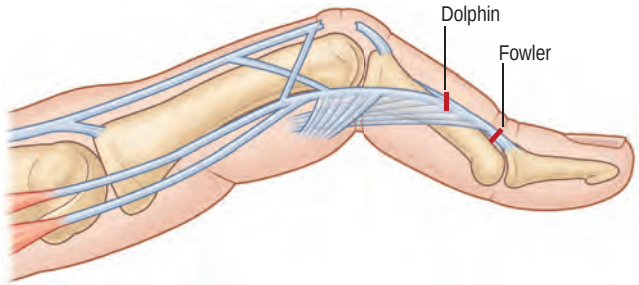

Fig. 10.28 Treatment of the boutonnière deformity by tenotomy as described by Dolphin and Fowler. Dolphin's tenotomy preserves the insertions of the oblique retinacular ligament.

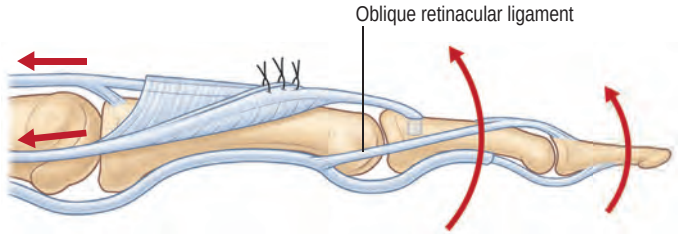

Fig. 10.29 Littler operation. The lateral bands are resected and relocated to the central tendon.

combining a tenotomy and tendon relocation (Fig. 10.29).[78] In Matev's technique, the lateral bands are incised at different levels (Fig. 10.30). The distal end of the longer slip is sutured to the proximal end of the other slip, resulting in an increase in length of the terminal tendon in order to reduce tension on the DIP joint. The free slip is then relocated medially to restore the central slip.[79]

In extensive defects of the central slip, the lateral bands may be insufficient for reconstruction. In these cases, free tendon grafts may be indicated. Littler described a figure-of-eight weave through the base of the middle phalanx and the lateral bands.[80] Several other variations of fixation of the graft have been proposed.[32,77,81]

Delayed sagittal band reconstruction (Video 10.1 ▶)

The function of the sagittal bands is to align the tendon centrally on the MP joint. If the sagittal band is ruptured, the tendon may subluxate to the unaffected side. The lesion most often involves a longitudinal or oblique tear on the radial side of the tendon which leads to an ulnar dislocation at the level of the MP joint.[82] Tendon dislocation rarely occurs in patients not suffering from rheumatoid arthritis. If conservative treatment fails, surgical reconstruction of the sagittal band is indicated. In addition to the reconstruction, a release of the contracted contralateral sagittal band may be necessary in long-standing cases.[43] Several techniques have been described for reconstruction, if direct repair is not possible because of missing soft tissue or severe scarring[82–85] (Fig. 10.31).

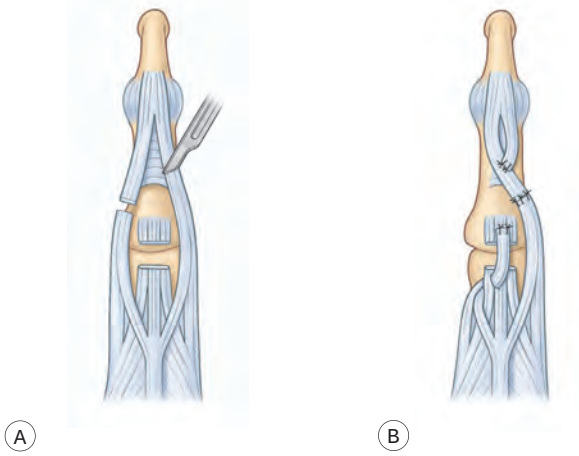

Fig. 10.30 (A,B) Matev's technique for reconstruction of the central slip. Both lateral bands are cut at different heights and relocated to reconstruct the central slip.

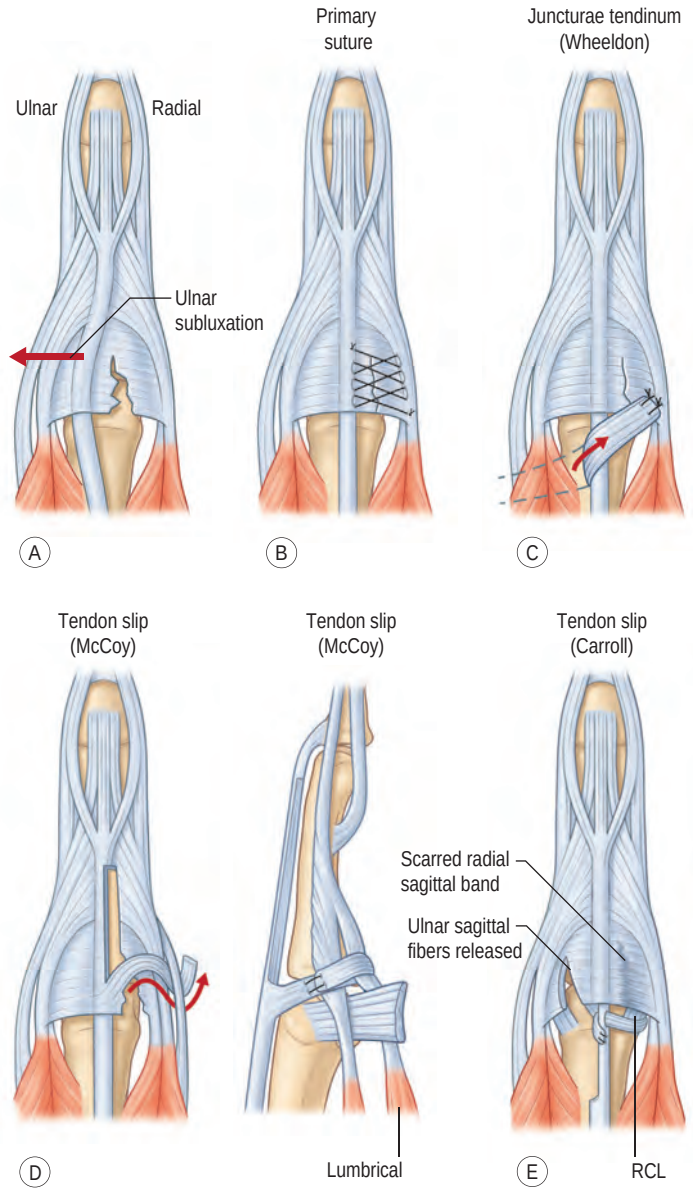

Fig. 10.31 Different techniques for reconstruction of the sagittal band. **(A)** Disruption of the radial sagittal band results in ulnar subluxation of the extensor tendon. **(B)** Primary suturing. **(C)** Wheeldon's technique: the ulnar junctura tendinum is relocated to the deep intercarpal ligament. **(D)** McCoy's technique: the tendon is split distally and wrapped around the lumbricalis muscle. **(E)** Carroll's technique: an ulnarly distal-based slip of the extensor digitorum tendon is wrapped around the radial collateral ligament (RCL).

Wheeldon described an anchoring of the ulnar-sided junctura tendinum to the radial side of the extensor hood.[85] Elson passed a retrograde tendon slip beneath the deep transverse metacarpal ligament and sutured it to the joint capsule.[86] McCoy and Winsky described another reconstructive procedure that used a proximally based tendon slip.[84] In their "lumbrical loop operation" the tendon was wrapped around the lumbrical muscle and then sutured to itself. Kilgore *et al.*[87] and Carroll *et al.*[83] both described techniques that utilized distally or ulnarly based tendon slips that were passed around the radial collateral ligament and then sutured to themselves. In Watson's technique, a distally based central tendon slip is looped through the deep transverse metacarpal ligament.[82]

Clinical tips

Regardless of the preferred technique for sagittal band reconstruction, make sure the tendon is stabilized while maintaining full finger flexion. A dynamic postoperative protocol is advisable.

Carroll *et al.* reported the results of three patients who were operated on with their technique in five fingers.[81] No recurrent subluxation was noted. Watson *et al.* found no recurrent subluxation in 21 sagittal band reconstructions in 16 patients after a mean of 16 months.[82]

The missing tendon: tendon transfers versus tendon grafting (Video 10.2)

In cases of degenerative rupture of an extensor tendon, direct suturing is not usually possible because of an existing gap or extensive degeneration of the tendon ends. In the absence of rheumatoid arthritis, the EPL tendon is most often affected. To reconstruct extensor function two options exist. First, the tendon can be reconstructed with the use of a tendon graft, e.g., derived from the palmaris longus tendon (Fig. 10.32A–D). Second, reconstruction is possible by transfer of another tendon. In case of an EPL rupture, the EI tendon is most frequently used (Fig. 10.33A–D).

Good results have been reported for both techniques.[88–91] In general, both show similar results.[92] However, each technique has specific advantages and disadvantages. For reconstructions with tendon grafts two weaving sutures are performed, which increases the risk of insufficiencies and ruptures. Harvesting of a tendon graft is necessary, but donor site morbidity should be minimal with the use of a palmaris longus graft. In contrast to tendon transfers no cortical rearrangement and adaption are needed. However, clinical results after tendon grafting are worse in long-standing ruptures because of atrophy and contracture of the affected muscles.[93]

Cortical adaptation is necessary after tendon transfers, but this is usually not a problem even in older patients. The operative technique is usually easier and faster. Because only one weaving suture is performed, the risk of tendon ruptures may be lower than in tendon transfers. After transfer of the EI tendon isolated extension of the index finger is maintained in most patients.[94] However, it has to be considered that the strength of isolated index finger extension is weakened.[95,96] This is not a problem for daily life activities, but may be a problem in specific patients, such as musicians.

Soft-tissue management and staged reconstruction in combined injuries

Clinical tips

Soft tissue coverage of the fingers must allow for full flexion of the finger joints. After debridement of skin on the dorsum of the fingers, local flaps are often necessary to avoid exposure of the extensor tendon postoperatively.

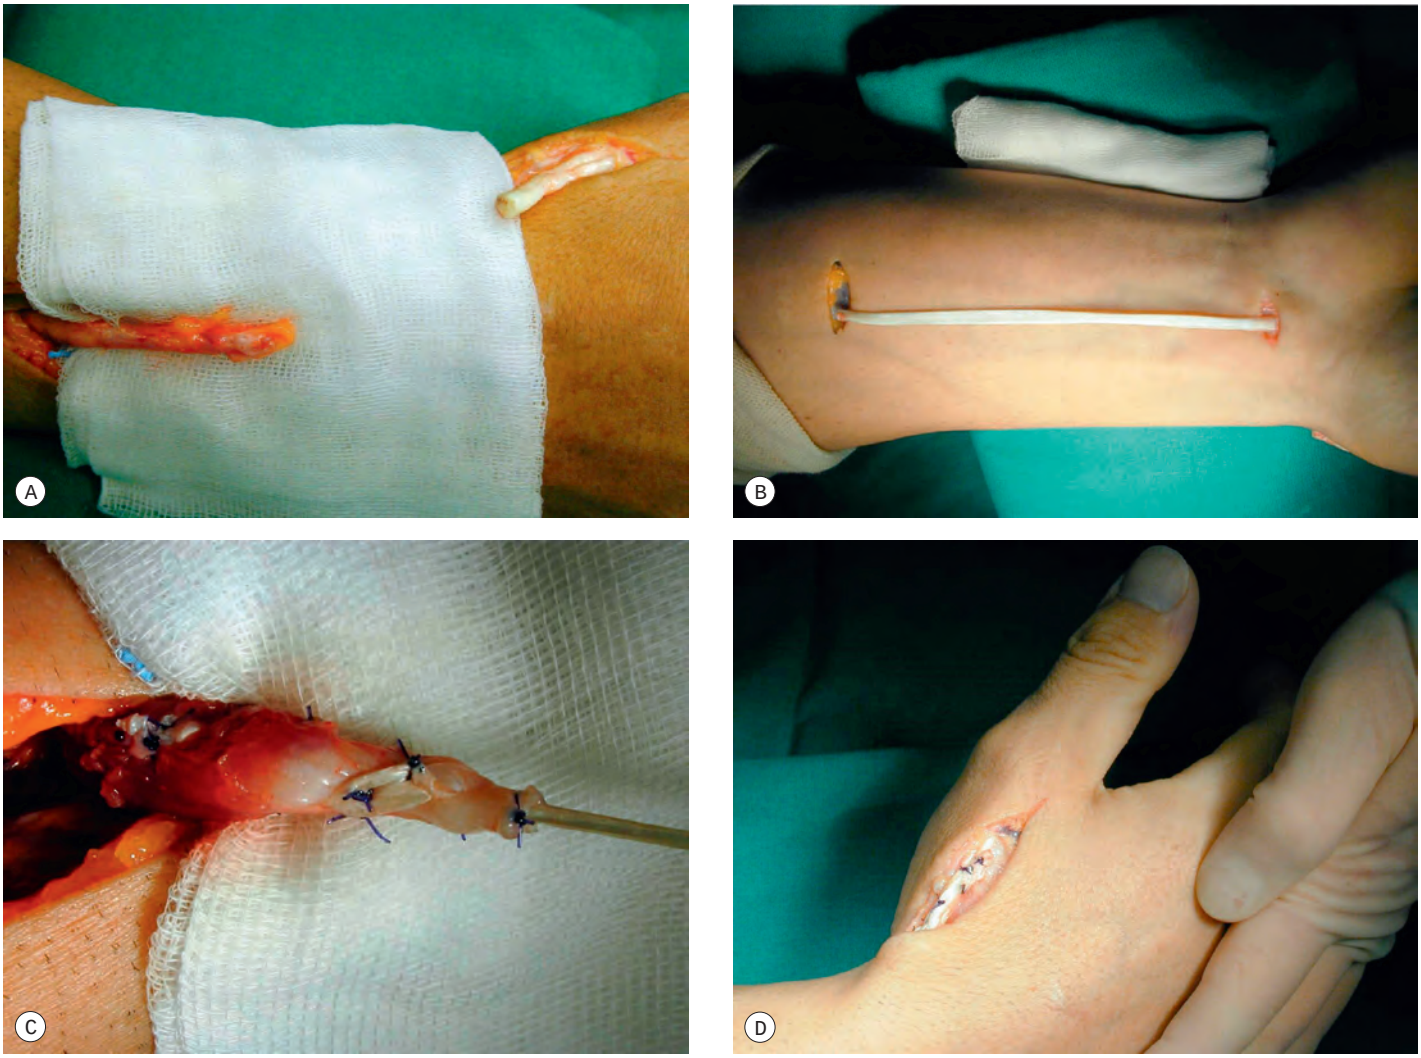

Fig. 10.32 Reconstruction of a ruptured extensor pollicis longus (EPL) tendon with the use of a palmaris longus tendon graft. **(A)** Degenerative rupture of the extensor pollicis longus tendon. Direct suture is not possible. **(B)** Harvest of the ipsilateral palmaris longus tendon as a graft. **(C)** Weaving suture of the graft to the proximal stump of the tendon. **(D)** Weaving suture of the graft to the distal stump. Notice full extension of the thumb in wrist flexion.

Lesions of the extensor tendons are often complicated by lesions of the bones and joints and by loss of skin. The treatment of these combined defects poses a difficult problem for the treating surgeon. Extensive scarring can be expected and must be taken into consideration when formulating a treatment plan. As in other mutilating injuries, basic reconstructive principles apply. Before attempting reconstruction of the tendons, several requirements must be fulfilled. First of all, radical debridement of all devitalized tissue is mandatory. Before closure, the wound should not contain any contamination or tissue of compromised blood supply in order to prevent infection. Primary radical debridement has been shown to be superior to several serial debridement steps, because of the formation of edema and infected granulation tissue, which is only poorly penetrated by antibiotic treatment.[97–100]

Clinical tips

Extensive undermining of the skin should be avoided at the back of the hand. Soft tissue coverage is thin and breaks down easily, leading to complex defects.

Second, osseous structures must be stabilized before turning to soft tissues. This can be achieved by internal or external fixation as appropriate. Third, a stable soft-tissue coverage for tendons and bony structures must be provided. In case of combined lesions of the dorsum of the hand, often pedicled or free tissue transfer is necessary. While the dorsal side of the hand is frequently used as a donor side to harvest soft-tissue flaps for coverage of palmar defects, the opposite is not true. Instead, flaps are usually harvested from adjacent proximal or distal regions on the hand and forearm. The pedicled radial forearm flap is a classic pedicled workhorse flap for coverage of the dorsum of the hand. However, due to sacrifice of the radial artery and the conspicuous donor site, variations of the original technique such as perforator-based flaps or fascial flaps should be considered.[101] Another classic pedicled flap is the posterior interosseous artery flap (Figs. 10.34–10.38). With the advancement of microsurgical techniques, free tissue transfers are now more frequently performed.[102]

The timing of combined reconstructive procedures has been subject to discussions. Traditionally, these injuries have been addressed by multistage procedures.[103] However, since Godina's classic work on the value of early debridement and

Fig. 10.37 Recovery of extensor function.

free tissue transfer for lower-extremity defects, today probably most surgeons apply the same principles in upper-extremity reconstruction with the aim of achieving soft-tissue coverage within 72 hours.[104] Several authors have reported excellent results after one-stage procedures for defects involving the dorsum of the hand with the use of emergency free flaps.[105–107] Reconstruction of missing tendons is usually performed at the time of soft-tissue coverage by primary grafting or tendon transfers. Because the creation of a secondary tendon sheath is not necessary, staged reconstruction of extensor tendons utilizing silicone rods is rare.[108–110] Adams reported on six patients who were treated by two-staged reconstructions of complex defects of the extensor tendon at the level of the PIP joint.[110] Active extension of the PIP joint could be achieved in all patients with an average extensor lag of 15°. In contrast, Quaba *et al.* presented good clinical results in nine patients

Fig. 10.38 Flexor function 12 weeks after reconstruction.

with complex defects in zones VI and VII who received soft-tissue coverage only without reconstruction of tendon defects.[111]

Conclusion

Extensor tendon injuries are frequently underestimated. However, even slight disturbances in the delicate balance between the flexor and the extensor tendon systems will result in significant loss of finger function. Therefore, a clear understanding of the pertinent anatomy is essential to achieve good treatment results. Acute injuries require early diagnosis and treatment, which should always take the surrounding soft-tissue structures into consideration. Chronic injuries and subsequent finger deformities such as swan-neck and boutonnière deformities are very difficult to correct and require a thorough analysis of the underlying tendon imbalance. As is true for other tendon injuries, good results cannot be achieved without the choice of the right postoperative treatment protocol.

Future directions

The functional anatomy of the extensor mechanism is complex and certain aspects less clear than some publications might suggest. Therefore, biomechanical research will hopefully improve the treatment of injuries to the extensor apparatus and especially their sequelae. However, most research today is probably directed towards other aspects, namely suture techniques and postoperative treatment protocols. These two are connected, as stronger suture techniques allow earlier and more extensive motion exercises. These developments are reflected in the latest revision of this chapter and will hopefully continue to improve clinical results for our patients.

Replantation and revascularization

William W. Dzwierzynski

Access video content for this chapter online at expertconsult.com

SYNOPSIS

- Replantation should be considered for all amputated parts; the only absolute contraindication to replantation is a patient too sick to tolerate surgery.
- A "string sign" or "ribbon sign" in the amputated part suggests the digital vessels are not suitable for replantation.
- Skeletal shortening should be considered. Bone shortening also facilitates a primary nerve and vessel repair.
- Rigid bone fixation is desired for early mobilization. Interosseous wires offer an excellent option for rigid fixation.
- Revascularization of amputations proximal to the wrist should be performed before 12 hours of cold ischemia (6 hours of warm ischemia). If ischemia time is over 4 hours, consideration should be given to temporary arterial shunting prior to bone fixation.
- Pharmacological management of replantation and revascularization remains controversial. Our current protocol includes heparin irrigation at a dilution of 100 units/mL during surgery and a heparin bolus of 50–100 units/kg before release of microvascular clamps.
- The psychological implications of amputation and replantation must be considered. The hand plays a significant role in a patient's identity and psyche.

Introduction

Restoring life has always been a dream. From the mythological resurrection of the phoenix to the rising of Lazarus from the dead, returning life to the dead remains a miracle. Replantation restores life to the lifeless extremity: a miracle of modern surgery.

Access the Historical Perspective section online at http://www.expertconsult.com

Basic science/disease process

Pathophysiology of ischemia and reperfusion

Tissue tolerance to ischemia varies significantly. In normal ambient temperature, irreversible changes can occur in muscle with only 2 hours of ischemia; skin properly cooled and stored in a nutrient media can be viable for over a month.[4] Ischemia causes tissue hypoxia and the conversion from aerobic to anaerobic metabolism. Adenosine triphosphate (ATP) is produced by glycolysis which leads to the buildup of lactic acid in the tissue and the resultant reduction of intercellular pH.[5] As the supply of ATP is diminished, intracellular Na^+ and Ca^{2+} concentrations are increased. Chemical mediators and enzymes are triggered by ischemia, resulting in the production of phospholipase A_2 and lysozymes. If continued beyond the critical point, these processes lead to eventual cell necrosis.

Revascularization is essential before these processes become irreversible, but revascularization can lead to its own problems. Reperfusion injury can cause problems as severe as the initial ischemic insult. When ischemic tissue is suddenly reperfused, reactive oxygen species (ROS) are produced. These include superoxide (O^-_2), hydrogen peroxide (H_2O_2), and hydroxyl radical (OH^-).[6] The ROS react with the cell membranes, especially in the endothelial cells. They cause direct cell damage and produce inflammatory mediators, complement activation, and leukocyte adhesion. This cascade increases vascular permeability and can cause cell death despite revascularization. Reperfusion-generated mediators may have systemic effects when vessels are unclamped and the inflammatory mediators are released to the circulation. This can lead to a decreased level of consciousness, jaundice, cardiac arrhythmia, metabolic acidosis, myoglobinuria, and multisystem organ failure.[7] Methods to prevent or reduce ischemia–reperfusion injury include hypothermia, interarterial flushing, ischemic preconditioning, antithrombotic agents,

Historical perspective

Malt performed the first replantation on May 23, 1962 at the Massachusetts General Hospital on a 12-year-old boy who had his arm amputated in a train accident.[1] The first digital replantation was performed in Japan on January 7, 1965 by Komatsu and Tamai.[2] Subsequent to these historical events, replantation surgery took off with a flourish. China was the epicenter of early replantation surgery. The American Replantation Mission to China report in 1974 highlighted the replantation efforts in China to an astonished American surgical audience.[3] The boundaries of replantation surgery continue to expand, now reaching into the realm of extremity transplantation.[2]

free-radical scavengers, and leukocyte inhibitors.[4,5] While many of these techniques show promise experimentally or in elective free flap surgery, pretreatment is not an option in traumatic replantation and revascularization. In major limb replantation, once arterial flow is established, the vein should be allowed to bleed to eliminate ROS, prior to establishing flow to the systemic circulation.

Diagnosis/patient presentation

Transportation

The most critical factors in replantation and revascularization surgery are management of the patient and the amputated part. Proper handling of the amputation is essential to revascularization and replantation success. The part is wrapped in moist saline gauze and placed in a waterproof plastic bag. The plastic bag is placed in a container of ice (Fig. 11.1). The part should not come into direct contact with the ice. Freezing the severed extremity can cause direct irreversible damage to the microvascular system. Timely, efficient transportation of the patient and the amputated part to the replantation center is critical for survival and function. Muscle undergoes irreversible damage with ischemia times greater than 6–9 hours. Digits can tolerate longer periods of ischemia. Successful replantation can be achieved even after prolonged ischemia. VanderWilde *et al.* reported a successful hand replantation after 54 hours of cold ischemia.[8] Wei *et al.* reported a series of three successful digital replants with 84, 86, and 94 hours of cold ischemia.[9] All patients had satisfactory functional results and no vascular compromise. Lin *et al.* reviewed their experience with 31 replantations (two thumb, 21 finger, and two hand amputations), all with over 24 hours of either cold or warm ischemia. The overall success rate was 64%. Only one of the hands was successfully replanted; 15 of the 23 digits were salvaged.[10]

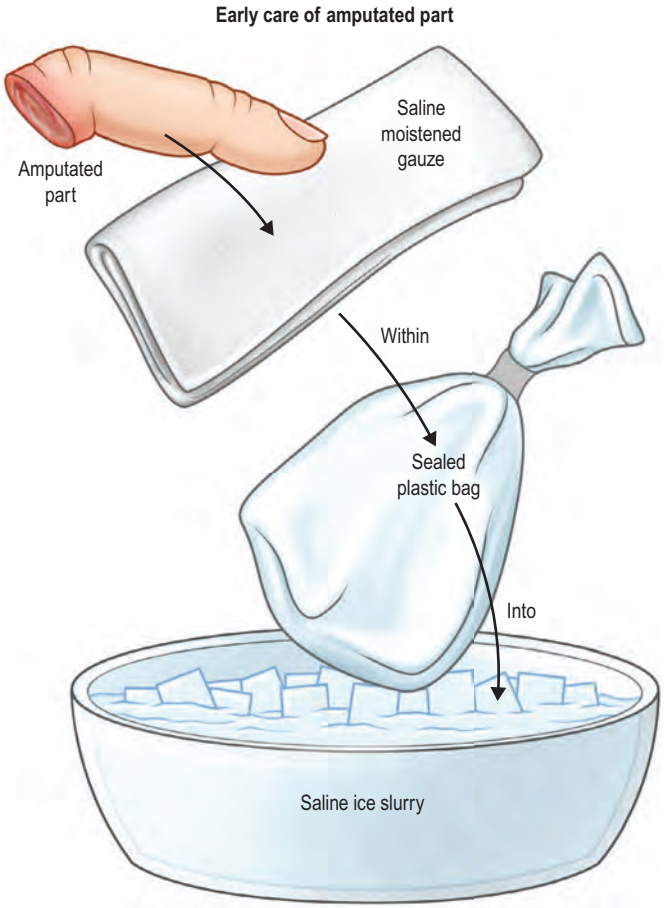

Fig. 11.1 The amputated part should be wrapped in moist gauze placed in a plastic bag which is chilled in an ice–water mixture. Direct contact of the part with the ice must be avoided.

Table 11.1 Replantation center criteria

1. An efficient ground and air transportation system to transfer the patient from the injury site or referring hospital to the replant center
2. Experienced microsurgical teams, able to work in shifts
3. A well-prepared emergency room staff to stabilize and quickly evaluate the patient with physical examination, X-rays, and laboratory tests
4. Experienced anesthetists, operating room, and microsurgical staff available 24 hours/day, 7 days/week
5. Proper microscopes, instruments, and sutures
6. A carefully trained nursing staff for postoperative care and monitoring
7. Physical and occupational therapists trained in post replantation rehabilitation
8. Psychologists and social workers to help the patient cope with his or her injuries and continue an active and useful life

Replantation center

A replantation center, usually a trauma center, with a dedicated team is optimal for success of replantations. The replantation center should include an emergency room and paramedic system familiar with the transportation of the injured patient and the amputated part (Table 11.1). This often includes a medical air transportation system to facilitate rapid transportation from the accident scene. At the replantation center, the operating room should be large enough to allow two independent surgical teams to operate, one on the patient and the second on the amputated part (Fig. 11.2). Chung *et al.* reviewed the database from the Agency for Healthcare Policy and Research, evaluating 304 cases of finger replantation. Over 906 hospitals were represented in the database but only 15% performed a finger replantation in the year reviewed; 60% of these hospitals performed only one replant. Only 2% of the hospitals in the database performed 10 or more cases. He postulated that replantations should be best performed at high-volume centers.[11] Chen and Narayan reviewed the economic trends of upper extremity replantations over a 10-year period and found an increasing tendency for these surgeries to be performed at large teaching institutions.[12] A survey of members of the American Society of Surgery of the Hand found that only 56% of its members perform replantation surgery, despite 94% of the responders describing their microsurgical training as good or excellent.[13]

Fig. 11.2 Replantation operation room set-up. The pressure pump is situated at the patient's head. The fluid cooler/warmer (far right) is used for icing the amputated part.

Patient selection

Indications and contraindications

Needless to say, the critical patient selection criterion for replantation is a patient with an amputation. The amputated part must be both available and in satisfactory condition for the replantation (Table 11.2). Digits recovered from the stomach of an attacking animal or extracted from industrial grinders generally do not meet this criterion. Outside these obvious examples, replantation should at least be considered for all amputated parts. Generally accepted indications for replantations in the upper extremities are thumb amputations, multidigit amputations and any amputation in a child.[14] Often adult patients with single-digit amputations, especially the index finger, are generally not considered candidates for replantation.[15] Replantation of a single digit is generally indicated in children. This is partly due to improved healing in children but also because of the future potential of the child. Lower-extremity and upper arm replantations also are indicated in a child.

Thumb amputations also deserve special emphasis. While thumb reconstruction can be achieved with methods such as pollicization or toe transfer, these reconstructions have a significant donor site cost. Thumb replantation should be considered even if shortening or arthrodesis is necessary. The thumb primarily functions as a post for opposition. Decreased motion in a thumb is generally well accepted, and even a stiff thumb contributes to the overall function of the hand.

Patients who have lost multiple digits also deserve an extra consideration in replantation. Where a single digit loss may be well tolerated, patients who have lost multiple digits have a significantly greater disability. Salvaging one or two fingers in a mutilated hand may preserve essential function of the hand. In multiple-digit amputations consideration should also be made for "spare-parts surgery". If an amputation is through the metacarpophalangeal (MCP) joint of the long finger and more proximal on the index finger, replantation of the index finger to the long finger ray, preserving the joint, may increase the patient's overall function. Replantation above the elbow is advocated for preservation of elbow function but generally distal function in the hand is poor.[16] Fingertip replantations, once considered not indicated, are now seen as an excellent level of replantation. Replantation of a digit distal to the flexor digitorum superficialis (FDS) insertion generally has excellent function because only one flexor tendon requires repair, and should be strongly considered.

The only absolute contraindication to replantation is preserving life over limb. A patient with life-threatening injuries or multiple medical problems who cannot withstand prolonged surgery should not undergo replantation. An uncooperative patient is also a contraindication for replantation.[14] In a patient with acute major life-threatening injuries, an amputated hand or digit may be kept in cold storage and the patient reassessed in 24 hours. If the patient is stable enough to undergo surgery, delayed replantation may be considered.

There are several relative contraindications to digital replantation[17] (Table 11.3). These contraindications are related both to the microvascular success rate and ultimate hand function compared to an amputation revision. All patients must be evaluated individually to determine if they are a candidate for digital replantation. While age is not an absolute contraindication for replantation, older patients carry a greater risk of arteriosclerosis of the vessel, joint stiffness, and generally decreased function secondary to less recovery of sensation. Okada *et al.* reviewed eight replantations in patients over

Table 11.2 **Indications for replantation**

Strong indications
• Multiple digital amputations • Thumb amputations • Whole hand • Transmetacarpal and partial hand amputations • Any amputated part in a child • Single digit amputation distal to flexor digitorum superficialis insertion
Relative indications
• Sharp injuries at elbow or proximal forearm • Humeral-level amputations

Table 11.3 **Relative contraindications to replantation**

- Concomitant life-threatening injury
- Systemic illness (e.g., small-vessel disease)
- Poor anesthesia risk
- Mentally unstable patients
- Single finger proximal to flexor digitorum superficialis insertion in adults
- Multiple segmental injuries in the amputated part
- Severe crushing or avulsion of the tissues
- Extreme contamination
- Prior surgery or trauma to the amputated part
- Prolonged warm ischemia time
- Ribbon sign, red line sign
- Most index finger amputations

65 years old. Function of these digits was generally classified as poor, although all patients were satisfied with their results. Expectations in the elderly patient may be less than those of a younger patient.[18]

Treatment/surgical technique (Video 11.1 ▶)

Operative sequence

Replantation surgery is an exacting and strenuous operation. It should proceed in an organized and deliberate fashion. When replantation is considered feasible, the amputated part is brought to the operating room and explored to identify the neurovascular structures. This may even be performed while the patient is still in the emergency room being evaluated and stabilized.

If two surgical teams are available, both the amputated part and the patient can undergo simultaneous surgery. The amputated part is brought to the operating room first. Using loupe magnification, all structures are examined. The blood vessels and nerves are usually examined at high magnification with the operating microscope before committing to perform a replantation. Under the operating microscope, the part is examined for suitability of replantation. Tissue loss is evaluated, along with the level of amputation. Multiple levels of injury may be found which were not apparent during the emergency room examination. The neurovascular structures should be evaluated for evidence of avulsion injuries. A string sign or ribbon sign means the digit is not suitable for replantation. These signs are indicated by a red streaking of blood along the path of the artery, usually implying an avulsion injury. The artery and nerves should be identified and tagged with a 7-0 polypropylene suture or microclips. If the digital vessels cannot be readily identified through the wound, the digital vessels can be exposed through a midaxial incision (Fig. 11.3). Dorsal veins are identified and tagged in a similar fashion. The location of the veins is more variable, and they may not be readily visible. Two or three veins should be identified. Preliminary bone fixation and methods of tendon repair are considered at this time. The digital tendon suture may be placed while the amputated digit is on the back table. The distal aspect of the bony fixation can also be secured, whether this is with K-wires, interosseous wires, or a mini fixation plate.

Once the patient is under anesthesia, the proximal level of the injury is explored. Replantation surgery is usually performed under general anesthesia. Regional anesthesia may be considered for a cooperative patient. Regional anesthesia offers the added benefit of decreased postoperative pain and possible vasodilatation. A Foley catheter is inserted and proper body warming is assured by utilizing a warming blanket and warming the operating room. All pressure points should be well padded to avoid pressure injuries; this includes the occiput to avoid scalp alopecia.

The sequence of the repair in digital replantation varies among surgeons, with some advocating arterial repair after bony fixation and flexor tendon repair while others advocate repair of the dorsal structures, including the extensor tendon, dorsal veins, and skin prior to repairing any volar structures.[17] The author favors repairing the volar structures first, and then proceeding to the dorsal structures. Repair of the extensor tendons is performed prior to releasing the tourniquet. Dorsal veins are repaired either before or after tourniquet release, depending on their visualization.

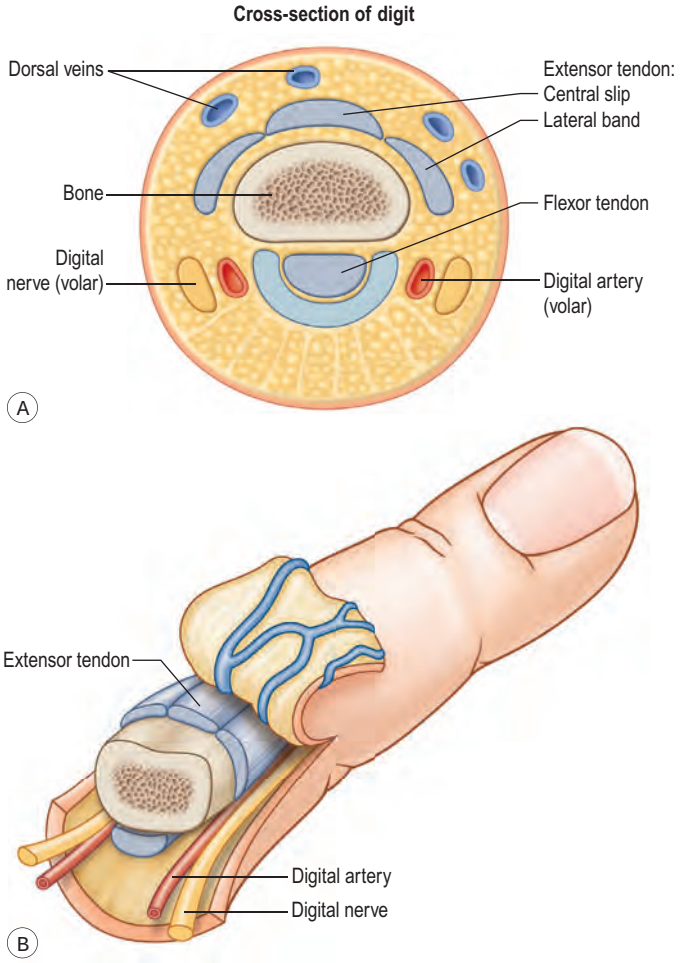

Fig. 11.3 (A,B) A midlateral exposure of the amputated part offers greater access to the neurovascular structures.

Bone fixation

The time spent in achieving rigid digital fixation is well worth the additional effort required (Fig. 11.4). Adequate fixation of the replanted digit is essential not only for short-term healing but also for long-term function. Rigid fixation of the bony fracture can reduce pain, allow early mobilization of the hand, and improve long-term function. The final outcome of the replantation lies in the ultimate function of the hand. Function is linked to motion, and motion is optimized by early mobilization. Rigid bone fixation is desired for early mobilization. Skeletal shortening should be considered in all replantations; this can allow more secure bone fixation and lessen the need for vessel and nerve grafting[14] (Fig. 11.5). In a thumb, shortening of the digit should be performed judiciously.[19]

A variety of methods are available for bone fixation. The simplest method is K-wire fixation. K-wires are universally available and can be easily and rapidly inserted. The simplest fixation is a longitudinally placed K-wire. While easily performed, longitudinal K-wires have many disadvantages.

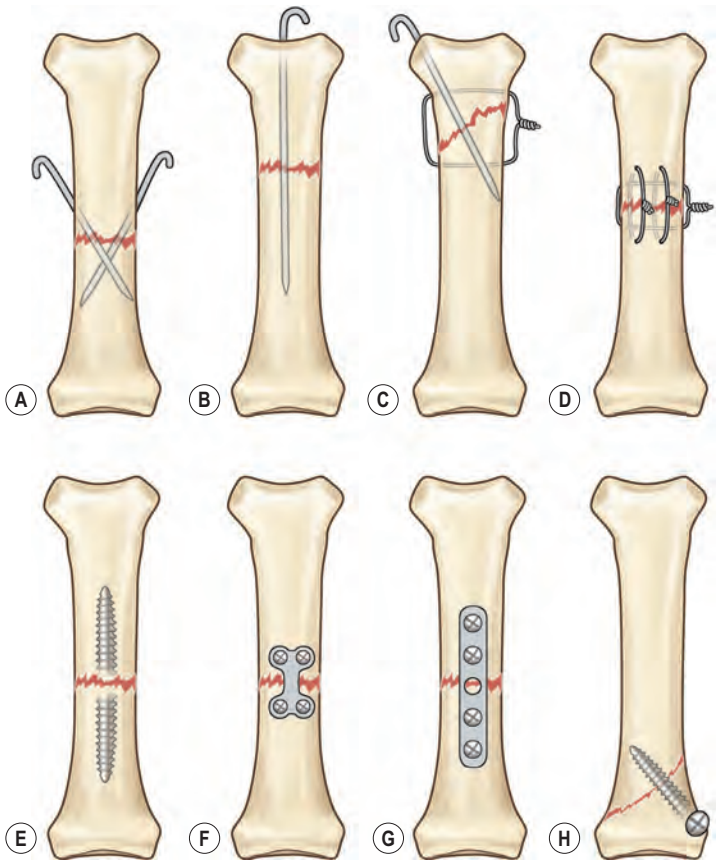

Fig. 11.4 Techniques of bony fixation include: **(A)** crossed K-wires; **(B)** single longitudinal K-wire; **(C)** I-O wire and K-wire; **(D)** 90-90 I-O wires; **(E)** intermedullary fixation; **(F)** compression plate; **(G)** H-plate; and **(H)** lag screw.

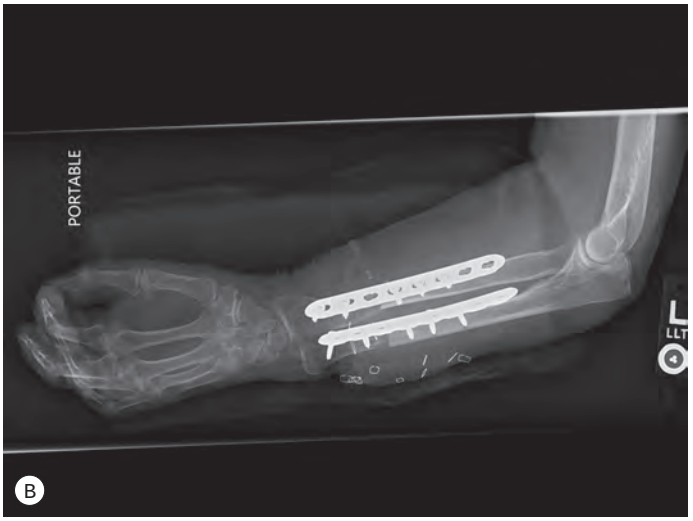

Fig. 11.5 **(A)** 46-year-old with distal forearm amputation. **(B)** Bone shortening and dynamic compression plating allowed primary repair of the neurovascular structures. **(C)** Hand after replantation and fasciotomies.

K-wires do not offer rigid fixation, longitudinal K-wires do not control against rotation and, almost by necessity, must go through the joint. Longitudinal K-wires are best utilized in distal replants and revascularizations where other fixation methods may not be technically feasible.

Cross K-wires offer more advantages than longitudinal K-wire fixation, most notably the control of rotation. Cross K-wires can be difficult for the novice to perform in simple fracture fixation and devascularization injuries, but complete amputation simplifies the process of cross K-wire placement. While the amputated digit is on the back table, the K-wires can be inserted in a retrograde fashion. The neurovascular structures need to be meticulously protected and the amputated part securely held to avoid spinning the part uncontrollably.

Kirschner wires offer control of rotational deformity but greater care must be taken with early digital motion. Cross K-wires give an acceptable result although rigid fixation is not achieved. Late digital stiffness and fracture malunion may occur. Kirschner wires should be reserved for cases where rapid fixation is necessary and in children.[19]

Interosseous (I-O) wires offer an excellent option for rigid fixation in amputations. I-O wires can be technically demanding to perform, but offer the advantage of rigid fixation and the ability to correct for any rotational deformity prior to final tightening of the wires. Three sets of wires, two longitudinal and one radial ulnar, give as much rigidity as a fixation plate. The exposure granted by the amputation allows easier access to the bone for I-O wire placement. The ends of the wires should be turned in to the fracture site to add additional strength to the configuration and to avoid impingement on the tendons.[20] Ninety-ninety-wire bone fixation has a low nonunion rate and provides secure compression of the fractures.[17,19,21,22] Bioabsorbable poly-DL lactic acid rods have been introduced for rapid intermedullary fixation of phalangeal replantations . A series of 9 replanted digits show initial strength to tolerated early motion protocols and good to excellent results in all cases.[23]

Clinical tips

Interosseous wire fixation is a quick and secure method of bony fixation for digital replantations. While the amputated part is on the back table, two tunnels – one radial to ulnar and one dorsal to volar – are made with a 21-gauge hollow needle or K-wire. The 21-gauge needle allows a 26-gauge wire to pass through the tunnel easily.

Plate fixation offers secure fixation for fractures. Standard miniplates, while offering secure fixation and compression, have the disadvantage of requiring significant periosteal stripping and more extensive soft-tissue exposure. Small "H" plates offer similar fixation strength with less exposure and periosteal stripping. One disadvantage of plates is the lack of adjustability. If distinct registration points are not present on the bone, improper fixation can lead to rotational deformities. The increased dissection and periosteal stripping may lead to increased scarring and tendon adhesions. Generally plate fixation is more time-consuming than other methods of fixation. A low-profile H-plate may allow less dissection; however, this application is technically demanding and angulation and malunions can occur.[19]

Tendon repair

Secure tendon repair is necessary for early-motion protocols. Inexperienced surgeons may desire to fix the tendons quickly in order to move on to the revascularization of the fingers. In properly cooled digital amputations, ischemia time can be safely prolonged without any deleterious effects on success rates and overall function. The extra 20–30 minutes required to obtain a good tendon repair is time well spent. We prefer to use a modified Kessler repair along with an epitendinous suture. The Kessler repair is easy and quick to perform. The use of a looped 4-0 braided polyethylene fiber suture allows a strong four-strand repair without significant bulk. The epitendinous suture supplies increased strength, facilitates tendon gliding, and allows proper tendon tensioning of the core suture. The pulleys should always be preserved. The distal core suture may be first performed and then the tendon is glided under the pulley for the final repair.

The distal core tendon suture is usually performed on the back table. The proximal tendon is identified and secured with a 25-gauge needle to the underlying tissue to prevent retraction. Utilizing a 6-0 polypropylene suture, the epitendinous repair is started on the dorsal aspect of the tendon, with a locked, running suture. After completion of the dorsal epitendinous repair, the core suture repair is woven through the proximal portion of the tendon. The knot is tied in the substance of the tendon. Finally the volar epitendinous repair is performed with a running locking stitch, utilizing the remaining portion of the 6-0 polypropylene suture. This four-strand repair is strong enough to initiate early active motion protocols.

Clinical tips

In tendon repair, performing the back wall of the epitendinous suture first allows better approximation of the core suture. The tendon is held securely with a 25-gauge needle to the soft tissue, and then a running locking 6-0 polypropylene suture is used for the back wall. The core suture is placed without any tendon "bunching". The running polypropylene suture is then continued on the volar aspect of the tendon.

Controversy exists among surgeons as to whether both the FDS and FDP tendons should be repaired in zone 2 replantations.[24] Waikakul *et al.*, in their series of 1018 replantations, found patients who had a sharp guillotine zone 2 amputation had good to acceptable results in terms of range of motion with repair of both tendons. In crush, degloving, or avulsion injuries, repairing only the FDP tendon or both tendons gave poor results. Repairing the FDP stump to the proximal superficialis tendon gave the best result, which was statistically significant.[25] Ross *et al.* prospected and evaluated tendon function after replantation using a modified Kessler repair with 4-0 polyester suture. The average total active motion was 129°. Patients with zone 1 and 5 injuries had a significantly better active range of motion. Replantation after avulsion injury resulted in lower range of motion compared to sharp injuries. When they evaluated patients who had one tendon

repaired versus those with a repair of both tendons, the average motion for fingers with both tendons repaired was 136° compared to 111° for fingers with only the FDP tendon repaired. This was statistically significant. Of all factors in the surgeon's control, the most important was initiating early therapy. Early therapy increased both active and passive range of motion and did not significantly increase the incidence of tendon rupture.[24]

Artery repair

A patent arterial repair is essential to successful replantation. The red line sign, or ribbon sign, is an indication of torsion or stretch of the vessel and suggests a relative contraindication to replantation.[26] Arteries should be debrided to beyond the zone of injury. The lumen of the artery should be explored to make certain there are no intimal flaps which can cause thrombosis. The arteries should be examined and cut back, as necessary, prior to inflation of the tourniquet. The vessel is flushed with a dilute heparin solution at a concentration of 100 units/mL. The heparinized saline solution can be placed in a pressure bag to assure a constant, accurate irrigation pressure (Fig. 11.6). Manual irrigation with a standard 3-cc syringe may produce excessive irrigation pressure. Yan *et al.* found that irrigation pressures under 80 mmHg are as effective as higher pressures at removing clots and did not damage the vessel endothelium.[27] After irrigation, the vascular clamp is released to visualize the arterial flow. If the artery does not have a strong pulsatile flow, the vessel is cut back and irrigated until pulsatile flow is obtained. It is preferable to repair both digital arteries, if possible. Zumiotti *et al.* found that when two arteries and more than one vein were anastomosed, the success rate was highest.[28] In the index finger, long finger, and thumb, the ulnar digital artery is usually larger and should be preferentially repaired. In the small finger, the radial digital artery is usually of larger diameter. Adequate exposure to the blood vessels is essential. Skin hooks attached to rubber bands may facilitate artery exposure. If this is not adequate, additional incisions should be made to aid exposure. In the proximal and middle phalanx, zigzag incisions are preferable, while in distal replantations a midaxial incision is preferred.[14]

If after proper debridement the gap precludes primary repair, a vein graft should be used. Theoretically an increased potential of thrombosis exists when vein grafts are used since there are two microvascular anastomoses. However, clinical studies do not support an increased incidence of thrombosis. When vein grafts are utilized, venous discrepancies may be managed by a variety of techniques, including fish mouth incisions, sleeve anastomosis, or end-to-side coupling or step-down vein grafts.[29] Vein grafts can be harvested from the palmar side of the thenar eminence of the hand, the distal volar forearm, or the dorsal foot (Fig. 11.7). For arterial reconstruction in the finger, the author prefers the dorsal foot veins because they are thicker-walled and better match the digital artery. For more proximal amputations the greater or lesser saphenous veins can be harvested. When there is a large discrepancy between the distal and proximal vessels, an

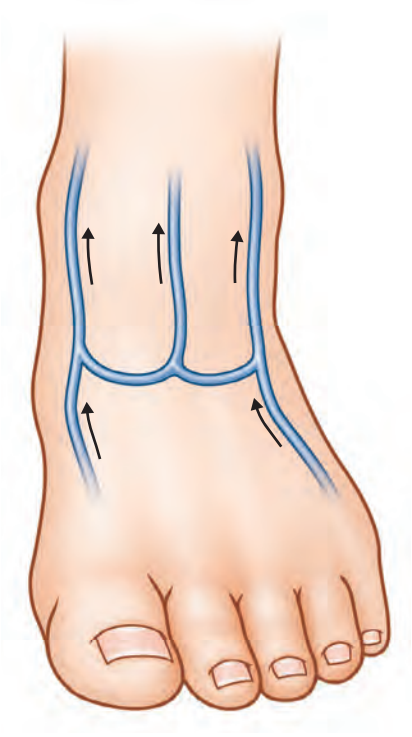

Fig. 11.7 The dorsum of the foot provides a source of potential vein grafts. The branching pattern allows revascularization of several vessels.

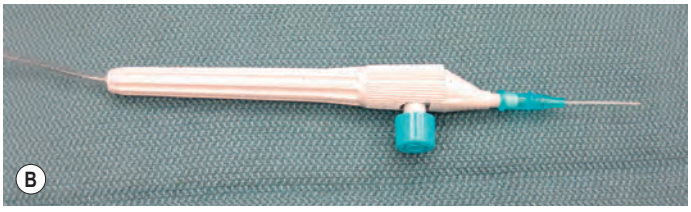

Fig. 11.6 **(A)** Pressure bag irrigation with pharmacy-prepared heparin irrigation solution. **(B)** Irrigation hand control.

arterial graft should be considered. Sources of grafts include the superficial or deep inferior epigastric arteries, the descending branch of the lateral femoral circumflex artery and the subscapular artery system. Shuck and Masden reviewed the use of arterial grafts; no long term outcome studies have been published but intermediate outcome studies show patencies up to 100%.[30]

Lee *et al.* prospectively followed 75 finger replantations with Doppler examinations for 60 days postoperatively. In 37% of successful replantations Doppler signals, which were initially present, were not heard on postoperative day 15. This rate was five times greater for crush injuries than for guillotine amputation. Their replantation center now routinely administers anticoagulants for 2 weeks in all replantations, regardless of the degree of tissue damage. They postulate that by continuing anticoagulation, reduced morbidity such as cold intolerance and sensory abnormalities may be achieved.[31]

Vein repair

Repair of the veins is one of the most crucial steps in replantation. The number of veins repaired correlates well with success in digital replantation.[32,33] In a devascularized extremity or digit, a small skin bridge of only a few millimeters can allow adequate venous outflow. Dorsal veins can be found by identifying bruising or small hematomas just under the skin (Fig. 11.8). The veins are usually repaired after repair of one or both of the digital arteries. If ischemia time is prolonged, the vein can be repaired after the first digital artery and then the hand supinated to repair a second digital artery. Vein grafts to bridge segments of venous loss are used as required. Additional length on dorsal veins may be achieved by dividing the interconnecting branches between the veins. At least one vein should be repaired prior to release of the arterial clamp. If a vein could not be identified on the initial exploration of the amputated part, release of the arterial clamp will allow visualization of the dorsal veins as they fill with blood; but the resulting bleeding may obscure the clean microvascular field.

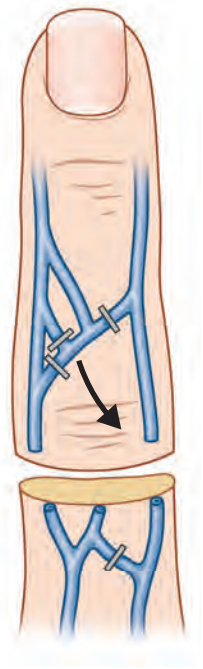

Fig. 11.8 Ligation of branches of the dorsal subcutaneous veins can provide additional length for primary venous repair.

A functional venous anastomoses is important to overall success rate in replantation; however, the more distal the amputation, the less this factor comes into play. Distal amputations can be successfully replanted even without a venous anastomosis as long as some method of venous egress is assured.[34–37] In a series of 120 replantations distal to the FDS insertion, a 91.7% success rate was achieved when two veins were repaired. This success rate dropped to 84.4% when only one vein was repaired, but with no vein anastomosis, a 40% success rate was still achieved.[38] The Chang Gung hospital group from Taiwan reviewed 30 fingertip amputations performed without a venous anastomosis. 90% of the digits survived, however the average transfusion rate was 4.0 units of blood; and the average length of time needed to maintain external bleeding was 6.8 days.[39] Various methods of venous outflow other than direct vein coaptation have been described. These include use of leeches (Hirudo medicinal), arterial venous anastomoses, nail plate removal, heparin rubs, subcutaneous heparin instillation, nail ablation, and dermal implantation.[34,35,39–41]

Nerve repair

Sensibility is even more important than range of motion.[14] Primary repair of the nerve can be performed in most clean guillotine-type injuries. Bone shortening facilitates a primary nerve repair.[42] Patient factors influencing nerve recovery are age, level of injury, and mechanism of injury. Surgeon-controllable factors include digital blood flow and postoperative sensory re-education. Repair of more than one artery improves nerve recovery.[43] If there is any question of the quality of the nerve it should be debrided to identify a good fascicular pattern. Nerve grafts or conduits can be used for small nerve defects. Conduits are constructed utilizing a variety of materials, including segments of vein, collagen, silicone, Gore-Tex, polyester, and polyglycolide.[44] Conduits are best limited to defects of less than 2 cm in length.[45] Some conduits are extremely rigid and may impede motion if placed over a joint or are at risk for erosion of overlying skin. Conduits are best used for sensory nerve defects; for motor nerves standard nerve autografts are preferred. Nerve grafts can be harvested from a variety of donor sites. In the upper extremity these include the posterior interosseous or median antebrachial cutaneous nerves. The sural nerve is the standard donor graft in the lower extremity. The fascicles of the sural nerve match the digital nerve topology well. After successful nerve repair, replanted fingers typically achieve protective sensation with a two-point discrimination under 15 mm, and the majority will achieve static two-point discrimination less than 12 mm.[46]

Skin closure

Skin closure should be performed with special precautions not to constrict arterial inflow or venous outflow. If there is any concern a skin graft should be utilized. A small graft over the midlateral incision covering the vascular pedicle is far safer than a tight closure. If there is a deficit of skin and an

arterial defect requiring a vein graft, consideration should be given to using a venous flow-through flap (vascularized by the digital artery).[47] The flap is harvested from the distal ipsilateral volar wrist or forearm. A vein of sufficient size is identified and a skin flap slightly larger than the skin defect is designed, centered over the vein. The flap should not extend more than 1.5 cm from the vein. The vein is reversed and used to bridge the arterial defect and the skin island covers the skin defect.

Special circumstances

Thumb replantation

Thumb replantation and revascularization deserve special consideration (Fig. 11.9). The ulnar digital artery of the thumb is usually of larger caliber and is preferentially repaired. The ulnar digital artery of the thumb, however, is difficult to access under the microscope. Even with the use of a lead hand, exposure is a challenge. It is the rare revascularization where a direct arterial repair is possible. The use of an interpositional vein graft from the radial artery to the snuff box simplifies revascularization in thumb replantation[17,19] (Fig. 11.10). An 8–10-cm vein graft is harvested, usually from the dorsal foot or saphenous vein. The graft is reversed and irrigated. The distal anastomosis of the vein graft is performed on the back table before bone and tendon fixation. Performing the anastomosis on the back table allows easy positioning of the amputated thumb. The distal aspect of bone fixation should be performed prior to the distal revascularization. Care should be taken when doing the proximal bone fixation, as the vein graft can easily become wrapped up in the power equipment. In the thumb pulp sizable palmar veins can usually be identified superficial to the arteries and these should be identified.[48]

Rosson *et al.* compared the functional outcome of thumb replantation versus great toe transplantation. In 384 thumb amputations over a 20-year period, an 85% success rate was obtained in thumb replantations. Complications occurred in 29% of cases. The average replant patient underwent four additional operations. Patients achieved 30% diminished protective sensation and light touch as compared to the normal contralateral thumb. In great toe to thumb transplantations the surgical success rate was 93%, but 43% of patients had complications. The motion in the interphalangeal joint was better in toe transplants than in the replanted thumb; sensation was comparable in both groups.[49]

Multiple digits

Multiple digit replantations are a significant surgical challenge and should be performed in a replantation center with significant experience in this type of surgery (Fig. 11.11). The time commitment is considerable: 3–4 hours should be allowed for each amputated finger. There may be a time-saving benefit from performing all the bony and tendon work first, then bringing in the microscope to do the microvascular repairs. Although total surgical time may be reduced, the warm ischemia time for each digit is increased. As many digits as possible are replanted. The finger with the best chance of function is repaired first. An exception to this rule is the index finger. If the index finger is stiff or has decreased sensation, the patient often avoids use of this finger.[19] Replantation of the distal amputation of the ring and little finger is strongly advocated because of their need for full length in order to get optimal hand closure and good grip function, especially when torque needs to be applied.[14]

A functional hand can be achieved with an opposable thumb, a satisfactory first webspace, a stable wrist, and at least two fingers. Heterotrophic replantation can maximize hand function. If the thumb and index finger are amputated and the distal thumb is not replantable, replantation of the index finger to the thumb position, a microvascular pollicization, should be performed.[50] Forty to 50% of hand function is accounted for by the thumb. Restoration of at least two fingers is most important in achieving hook grasp, power grasp, and precision handling.[51] The value of the ulnar digits to hand function, especially power grip, is underappreciated. Priority should be given to restoration of the ulnar digits after salvage of the thumb.

A functional MCP joint is a significant priority for determining digital reconstruction. Digits with injuries through the MCP joint should be considered for heterotrophic transfer to another ray with a functional MCP joint. "Spare-parts surgery" should be considered in any multidigit amputation. If a digit is non-replantable, skin can be harvested for use as a skin graft. Tendon, nerves, and vessels can also be used for grafts.

Proximal amputations

Amputations at the level of the palm and proximal forearm offer unique challenges and opportunities. The functional deficit of amputations at this level is devastating and replantation and revascularization offer the opportunity for meaningful function of the hand. At this level, the vessels are larger and the procedure is technically easier. Because of the presence of muscle in the amputated part, timing of revascularization is critical. Revascularization of wrist and more proximal amputations should be performed before 12 hours of cold ischemia or 6 hours of warm ischemia.[3] Rapid revascularization is necessary to preserve muscle viability and prevent myoglobinuria. For injuries at the level of the distal forearm and hand, preservation of the intrinsic muscles is important to hand function but unlikely to result in myoglobinuria if critical ischemia time is exceeded. The risk of reperfusion injury is low due to their small mass; if function of the muscle is to be preserved, revascularization should be expediently performed (Fig. 11.12). If the injury is at the level of the palmar arch or distal, an arterial graft or reversed "Y" vein graft, usually from the dorsal foot, can be harvested to revascularize multiple common digital arteries (Fig. 11.13).

Injuries in the distal forearm and wrist have excellent functional results after replantation and every effort should be made to salvage these injuries.[52] Bone fixation should be performed first, shortening of the bones at this level provides quicker fixation and decreased need for vein and nerve grafts, and yields almost no functional loss. If ischemia time is over 4 hours, consideration should be given to temporary arterial shunting prior to bone fixation. A carotid shunt or an intervascular catheter is used (Fig. 11.14). Only one artery and one vein is required to revascularize the extremity successfully. After opening the arterial clamp, bleeding from multiple distal veins will require ligation or clamping with microvascular clamps. The risk of exsanguination with arterial and

The patient developed protective sensation and useful opposition function of the thumb.

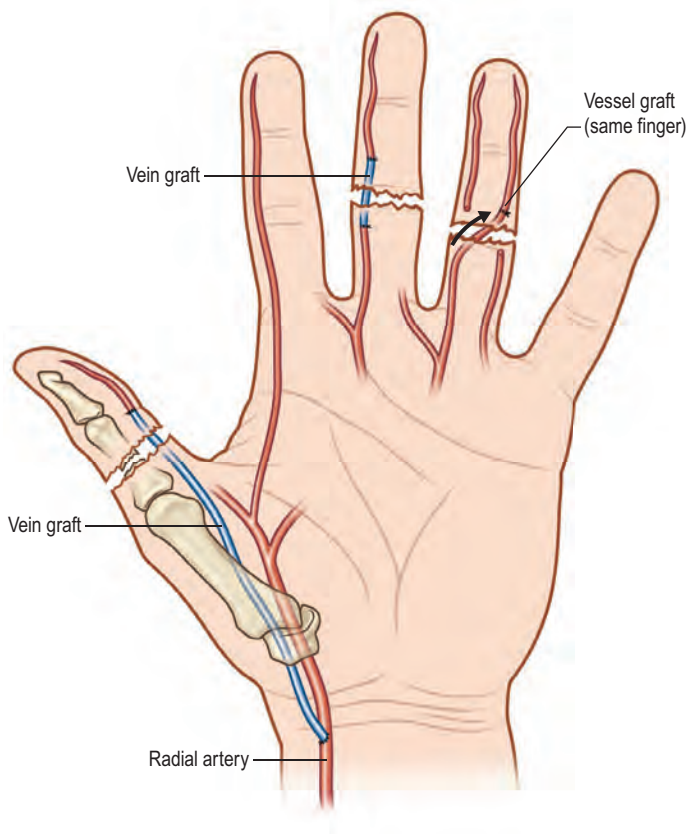

Fig. 11.10 If a primary anastomosis cannot be performed, the gap can be bridged with a reversed vein graft or transposition from an adjacent proper digital artery.

venous shunts is significant. Considerable bleeding can occur and the patient should have matched blood available. If shunting is utilized, the vein should be allowed to drain prior to connecting it to the proximal circulation.[53]

In patients with a multiple-level mangled extremity, the goal of treatment is to restore prehension and sensibility. A sensate partial hand is quite often better than a prosthesis[16] (Fig. 11.15). However patients with crush or avulsion injuries may be poor candidates for replantation. Adequate debridement is the critical first step in reconstruction.[54] Vein grafts should be liberally used to avoid injured segments of artery and vein.[29] With major limb replantation, fasciotomies are usually required. Godina emphasized that, upon completion of aggressive debridement, the wound should resemble a tumor resection.[55] Nonviable tissue with bacterial contamination is associated with loss of salvaged limb. The sequence of repairs for forearm replantation is bony fixation followed by arterial and venous repair. The vena comitantes should be repaired primarily; if this is not successful, then dorsal or antecubital veins are utilized. Nerves should be repaired after the arteries with the possible exception of the ulnar nerve, which lies deep to the ulnar artery.[54]

Amputations at the proximal forearm present a difficult clinical decision process. Functional results are generally worse at this level than in more distal amputations. Because of the loss of muscle tissue, poor motor nerve recovery, loss of intrinsic function and postoperative scarring, results after replantation at this level are disappointing.

Amputations proximal to the elbow should be considered, if only to salvage a functional elbow joint. Recovery of distal function is poor. The greater muscle mass in a proximal limb

amputation is more susceptible to ischemia time. Metabolic breakdown products from the muscles entering the systemic circulation after revascularization can result in reperfusion syndrome. Death may occur in patients with above-elbow replants who develop reperfusion syndrome.[56] A functional elbow and below-elbow prosthesis may offer the patient the best result, but many patients are reluctant to undergo a revision amputation after a successful replantation despite having poor function.

Distal amputations

Replantation distal to the distal interphalangeal (DIP) joint was once considered as folly. Patients with amputation revisions at this level generally did very well functionally. Recent experience with distal replantations now shows both excellent success and functional and aesthetic results with replantations (Fig. 11.16). These distal anastomoses can challenge the surgeon's microvascular skills (Fig. 11.17). In distal crush injuries it is often difficult to get the proper size match of the distal artery. Transfer of a digital artery from an adjacent digit may be utilized, especially in children where the size match is critical.[57] A step-down arterial graft should be utilized if a vein graft is required and the reversed vein segment has too great of a size mismatch. A method of temporary intravascular stenting using 4-0 to 6-0 (0.199–0.07 mm) nylon monofilament stents for very-small-vessel anastomoses has been advocated for distal fingertip amputations; 11-0 or 12-0 sutures are placed in the vessel around the stent, which is removed prior to the last two sutures being placed. Vessels as small as 0.15 mm have been anastomosed using this technique. Microvascular survival of 85% has been reported.[58]

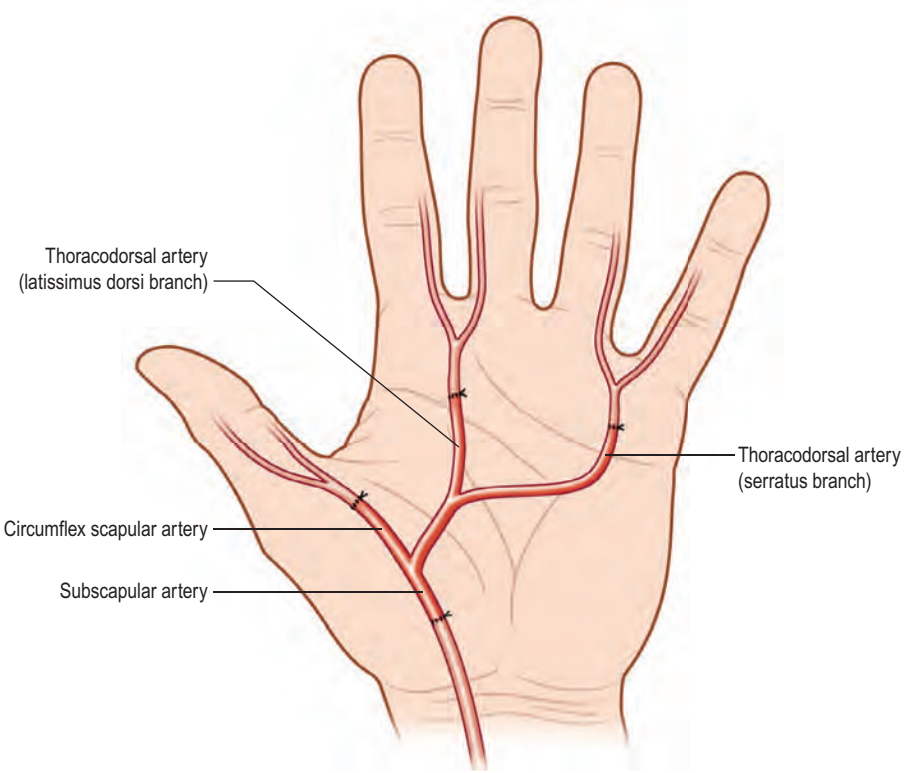

Fig. 11.13 Branches of the subscapular artery are utilized for revascularization of multiple distal vessels.

While arteries in very distal replants can be difficult to repair, veins may be a nightmare. The surgeon should be familiar with the venous anatomy of the digits and the thumb. Repairing volar veins may be preferable in these distal injuries, since they are easier to dissect than the dorsal veins, which lie in a dense fibrous tissue.[59] Occasionally suitable veins for repair are not available; a successful outcome can still be obtained in these cases if there is an effective means of ensuring temporary venous outflow while the collateral circulation develops. The primary method of temporary venous outflow is medicinal leeches. Leeches effectively remove congested blood and detach when engorged. Additionally, they inject hirudin, a potent anticoagulant which results in bleeding long after the leech detaches.

The leech is applied to the congested part and allowed to attach. If the arterial blood supply is poor, the leech may detach prematurely and attempt to wander to another site, this usually implies that the initial diagnosis of venous congestion was wrong. The patient's dressing should be fabricated to allow the leech to attach only to the congested part. Leeches

feed usually for 10–40 minutes, after which they detach or should be removed. Absorbent dressing is utilized to avoid further constriction from the continued oozing, which may last for up to 6 hours. A new leech is applied if the finger appears congested again, usually no sooner than 4 hours.

Leech therapy is slowly weaned at approximately 5 days. At this point venous circulation should be re-established. *Aeromonas* species bacteria in the leech gut are essential for digestion of blood.[34] *Aeromonas hydrophila* is not normally a pathogen, but precautions should be utilized. Prophylactic antibiotics to cover *Aeromonas* should be considered. These are mainly third-generation cephalosporins or aminoglycosides. Leeches may not always be available and other methods of venous outflow can be utilized. Removing the distal nail plate and mechanical rubbing of the sterile matrix followed by application of a dressing with a 1000 unit/mL heparin solution may achieve active oozing in the congested finger. This technique is repeated hourly until congestion is improved.[35,59] Another option is the injection of heparin subcutaneously. In this technique, a fish mouth incision is made in the distal digit to allow venous outflow. A solution of 1000 units of heparin in 0.1 mL saline is injected subcutaneously into the tip of the congested replanted finger. Heparin subcutaneous injections are reported to be more cost-effective than medical leeches and simpler to administer, and heparin action can last for over 6 hours.[36]

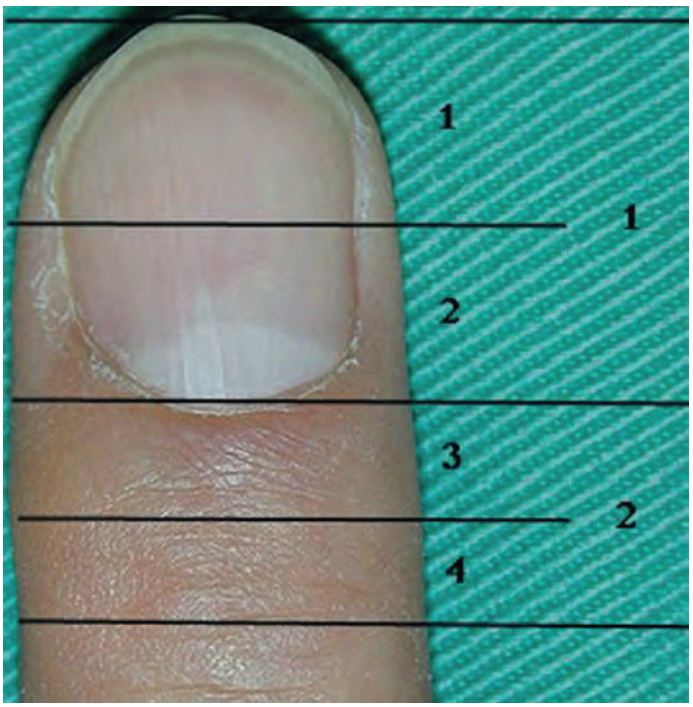

Fig. 11.17 Ishikawa and Tamai classification for distal replantation.

Another technique which should be considered is subcutaneously pocketing of the distal replantation. This technique was initially described using a subdermal pocket on the chest wall[36] to prevent the awkward immobilization of a chest flap; the subdermal pocket has been described on the palm.[60] An arterial repair is performed if possible. If there are no veins to repair or the finger appears congested, the pulp of the amputated finger is de-epithelialized and a subdermal pocket is made in the palm or thenar crease. The finger is secured in a flexed position attached to the palm for 7 days. After 7 days the patient is brought to the operating room and the finger is detached. Retrospective reviews have found this method to be reliably successful in saving the nailbed, and preserving length even in adult patients without an artery or vein repair.[61,62] With distal phalanx amputation, replantation can achieve a success rate of over 90% when venous anastomosis is performed. Even without venous anastomosis, success rates over 75% can be achieved.[38,41,43,44] Given these success rates, distal fingertip replantation is justifiable and these fingers should be aggressively treated.[63] The aesthetic and psychological benefit of distal fingertip replantation should not be ignored.

Ring avulsion injuries

Ring avulsions are some of the most difficult injuries to treat. The classification scheme popularized by Urbaniak *et al.*[64] and modified by Kay *et al.*[65] is commonly used (Table 11.4). Injuries of class 2 and above require microvascular repair; class 3 ring avulsions are the most challenging, due to their degloving, avulsion, and amputation (Fig. 11.18). Under the operating microscope a midlateral incision is made on the ulnar aspect of the amputated digit. Nonviable tissue should be debrided. Damaged arteries should be bypassed. Inadequate debridement leads to poor outcome. Vein grafts are almost universally required due to the significant extent of the vascular damage. Because of difficulty in arterial size matching, a second step-down vein graft can be harvested; alternatively, an arterial pedicle from the adjacent digit may be used.[66]

A minimum of two veins should be repaired. Vein grafts should be utilized if needed. If the amputation occurs at the DIP joint, primary arthrodesis of the joint should be

Table 11.4 Ring avulsion injuries classification		
I	Circulation adequate	
II	Circulation inadequate, no skeletal injury	
	a	Arterial circulation inadequate only
	v	Venous circulation inadequate only
	av	Arterial and venous circulation inadequate
III	Circulation inadequate, skeletal injury

	v	Venous circulation inadequate only
	av	Arterial and venous circulation inadequate
IV	Complete amputation	

considered. Following replantation at this level, motion at the DIP joint is poor and fusion may permit bony shortening, which may aid in nerve repair and skin closure. The skin should not be pulled taut in order to close the skin defect or to attempt to get a primary skin closure. Skin grafts should be utilized to avoid a tight closure. A venous flap should be considered for coverage of the skin defect. A retrospective review of venous flaps used for ring avulsion injuries showed 100% survival of all flaps and fingers. The venous flaps produced a supple skin envelope and made subsequent surgeries such as tenolysis or capsulotomy easier to perform. Venous flaps should be vascularized only by the arterial inflow, as

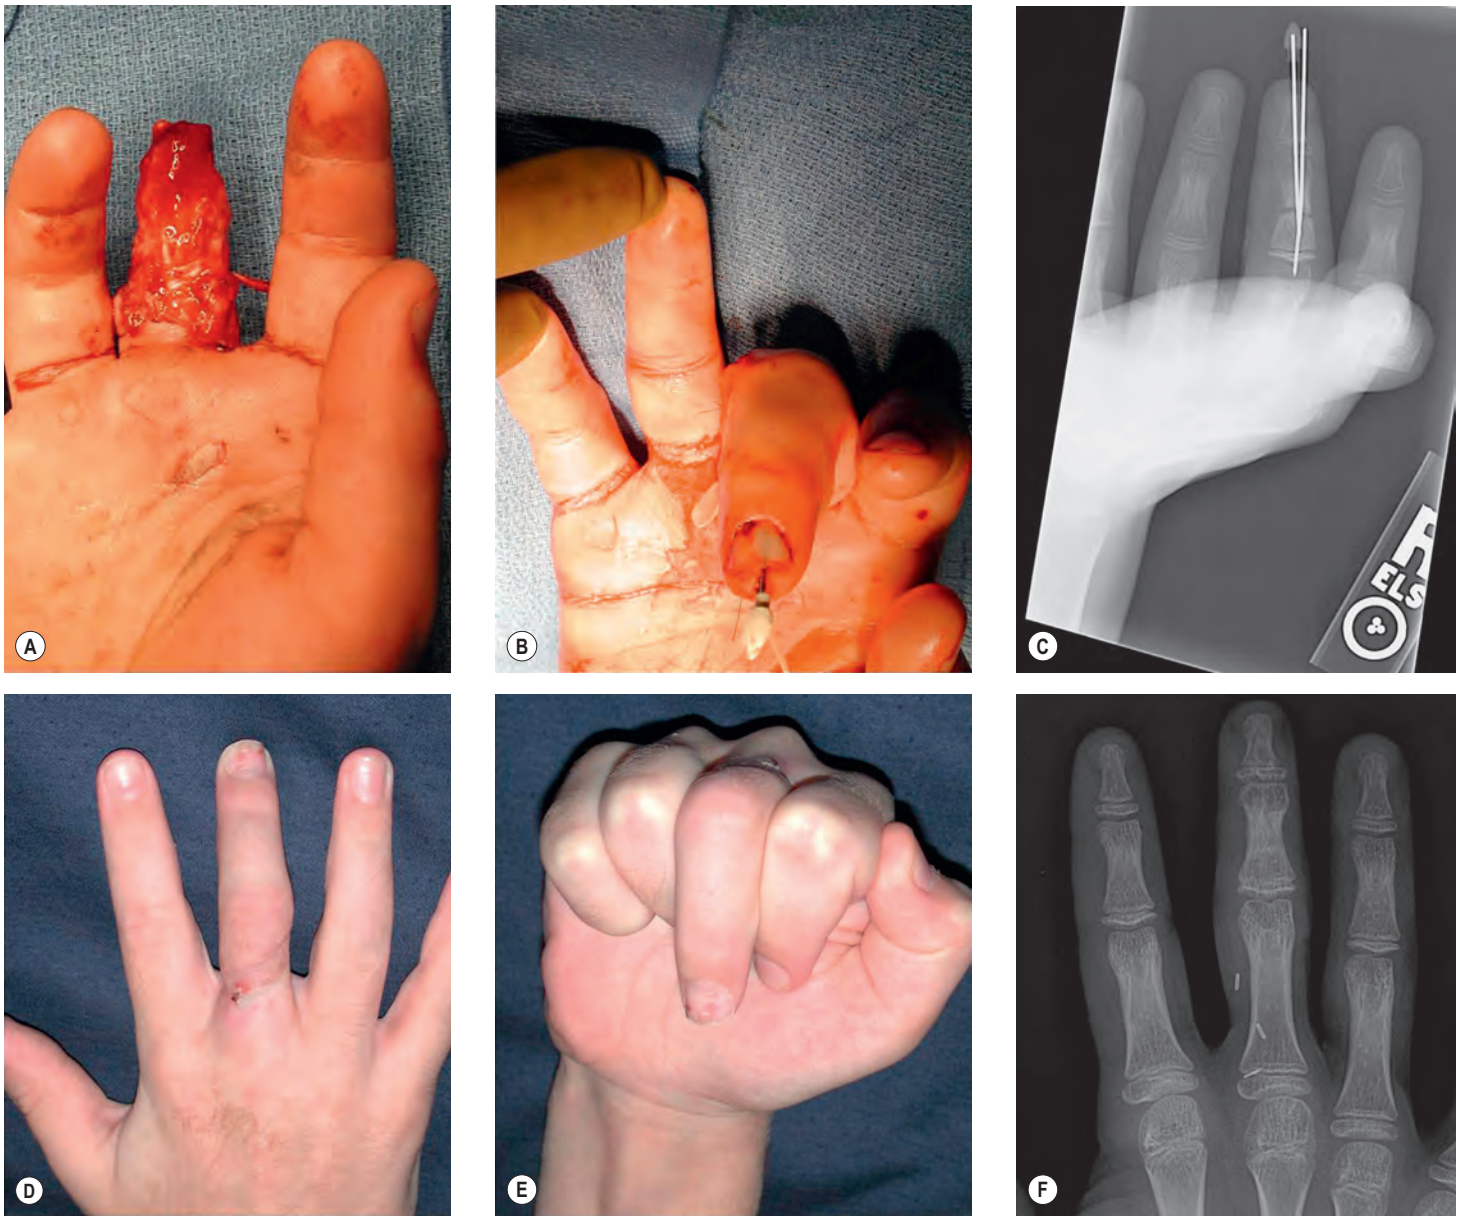

Fig. 11.18 **(A)** Child with a type IV ring avulsion injury. **(B)** Immediately postoperative after replantation. **(C)** Crossed K-wire fixation. **(D)** Fourteen months after injury, extension of finger. **(E)** Flexion of fingers. **(F)** Radiographs demonstrate bone union but premature closure of growth plate. *(Courtesy of James R. Sanger, MD.)*

flaps vascularized with venous outflow have had poor survival rates.[47] (Fig. 11.19).

Survival rates for ring avulsion injuries requiring revascularization range from 60% to 81%. Adani *et al.* achieved an 88% success rate in 33 patients, with an average total arc of motion (TAM) of 185°. They concluded the most important factor for success was resection of the avulsed digital artery and vein.[67] The factor most significantly associated with revascularization failure is repair of fewer than two veins. Cigarette smoking and level of bone injury have not been found to affect survival. The most commonly occurring complications are flexion contracture, cold intolerance, and malunion. A majority of patients can expect two-point discrimination greater than 8 mm. In patients with ring avulsion injuries, finger reconstruction generally gives a better result than amputation, although in patients with ring avulsion amputation proximal to the insertion of the flexor superficialis tendon, amputation or ray amputation should be considered, since these patients are likely to have poor hand function.[68] Sears and Chung performed a systematic review of avulsion injuries and found the results are much better than historically cited and challenged the practice of performing amputations for these injuries.[69]

Clinical tips

In type III and IV ring avulsion injuries, fusion of the distal interphalangeal (DIP) joint can allow easier bony fixation and sufficient shortening to allow primary approximation of the dorsal veins, skin, and nerves. Range of motion of the DIP joint is generally poor even after attempts to preserve the joint.

Ectopic transplantation secondary at replantation

Godina *et al.* performed the first ectopic replantation in 1983 when they transferred an amputated hand to the axilla after a contaminated multilevel farm injury.[70] Sixty-five days later the hand was successfully replanted to the forearm. This technique has subsequently been utilized for a variety of amputated parts, including fingers, thumbs, ears, penises, and scalps.[71–74] The recipient sites best used are the thoracodorsal, the deep inferior epigastric, the superficial inferior epigastric, the radial and the dorsalis pedal vessels. These vascular pedicles are familiar to most microsurgeons. The choice of recipient vessel for ectopic replant depends on the

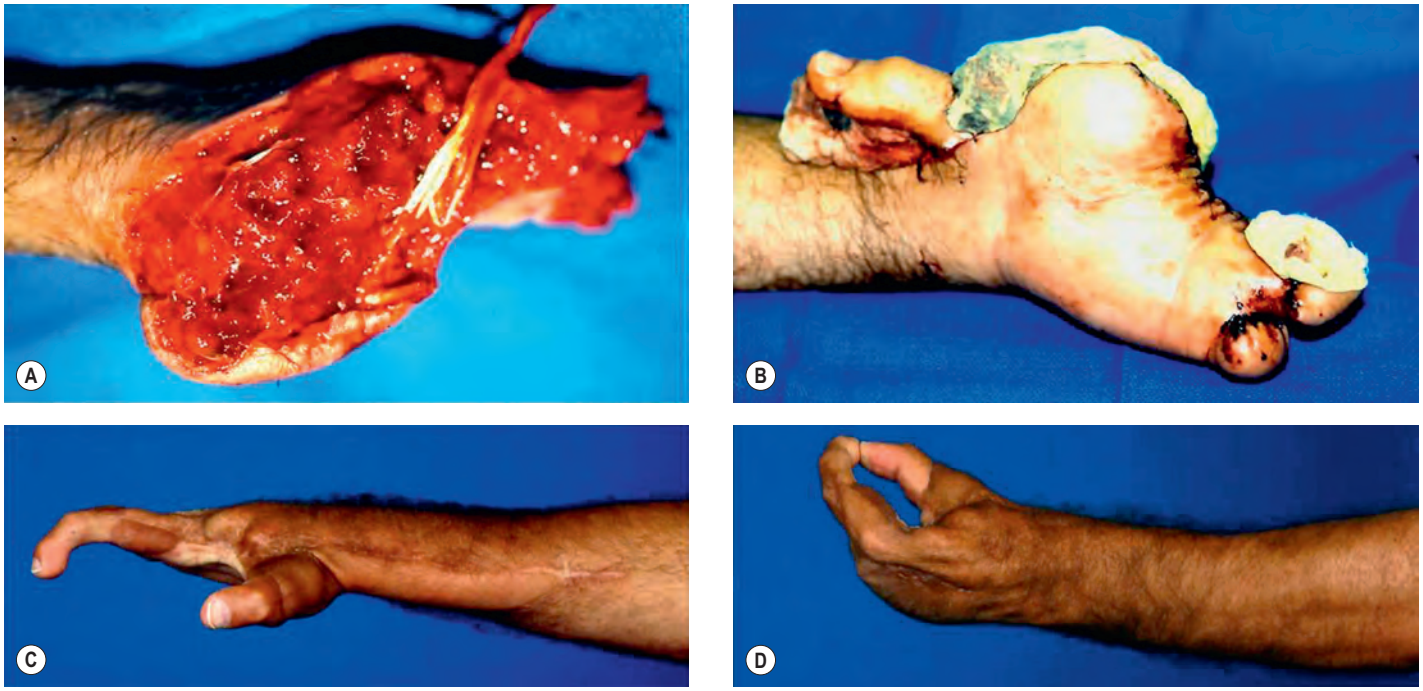

Fig. 11.20 **(A)** Avulsion injury of the radial aspect of the forearm and wrist. **(B)** Thumb ectopically transplanted to the wrist via the radial artery. **(C)** Thumb replantation after staged reconstruction with second toe second metatarsophalangeal joint and dorsalis pedis free flap. **(D)** Opposition of the thumb and toe transfer. *(Courtesy of N. John Yousif, MD.)*

length of the expected pedicle as well as donor site morbidity (Fig. 11.20). Adequate surgical debridement is essential prior to replantation of the digit. Often a staged local or free flap is needed for soft-tissue coverage prior to second-stage transplantation. The ectopic site must be outside the zone of injury.

Complications were significant in all series of ectopic replantations.[72] These occurred mostly after the second stage of transplantation. Nazerani and Motamedi[74] reported a series of 24 staged distal finger ectopic replantations, initially transplanting the digit to the ipsilateral groin, anastomosing an artery and a vein. After 8–12 weeks, the finger was transferred to the hand as a pedicle groin flap. A success rate of 75% was achieved by this method with few complications. This technique may be of clinical use in thumb amputation where there is need for flap coverage along with salvage of bony length and the cosmetic appearance of the thumb.

Pediatric replantation

In children, less stringent criteria for replantation and revascularization are generally employed. Replantation should be considered for all amputated parts, including amputations of the lower extremity. Success rate in replantation is lower in children than in adults, but this may be due to the fact that surgeons are more aggressive in salvaging and attempting to replant parts in children. Disparities have been found to exist in the management of children with amputations in the US. Whites and children with private health insurance are more likely to receive replantation than Blacks, Hispanics and children without insurance.[75] Clean guillotine amputations generally have the greatest success; however, crush and avulsion injuries from bicycle and mechanical sports equipment with spokes or chains are the most common form of injury in children. The operative procedure in children is similar to that in adults, and the sequence of the procedure is identical. Surgery may be more challenging because of the size of the vessels and a greater tendency for spasm in the pediatric age group.[57] Replantation of multiple digits should begin with the thumb, then with the most ulnar amputated digits. An opposable thumb and two ulnar digits provide essential power grip. In finger replantation, K-wire fixation is preferred over plate fixation to avoid growth disturbances.[76] The replanted part can be expected to grow to 90% compared to normal unless there is significant damage directly to the growth plate.[77]

Recovery of nerve and muscle function is generally better in pediatric patients. After a mutilating hand injury, children tend to rebound more quickly from both functional and psychological aspects. Parents add a level of complexity to the care of the child, often because of guilt issues. Family psychological counseling may be beneficial. A long-term follow-up of 14 children with digital replantation shows an 88% success rate. Satisfactory sensory recovery was obtained in all fingers. The growth rate of the digit was 86% compared to the contralateral, non-injured extremity. Twelve of the 14 cases were judged to have excellent results.[78]

Postoperative care

Anticoagulation

Pharmacological management of replantation and revascularization remains a controversial topic. Platelet aggregation is the most prevalent underlying cause of arterial thrombosis. Venous thrombosis is generally caused by fibrin clotting. The

risk of thrombosis is highest in the first two postoperative days, with 80% of thromboses being seen in this time period. Various schemes of pharmacological management have been utilized. No consensus exists on the use of anticoagulation therapy after microsurgery. The most commonly utilized agents are heparin, low-molecular-weight dextran, and aspirin, but little evidence is available on the efficacy of any of these regimens. A survey of microsurgeons showed that 90% used anticoagulation in free flap and microvascular surgery.[79]

Heparin has been used for over 50 years. Heparin binds to antithrombin III, enhancing its antiprotease activity. Various factors, including thrombin and factor Xa, are rendered inactive.[80] Heparin also has a vasodilatory effect. Heparin can be administered systemically by intravenous methods, by subcutaneous injection, or by direct irrigation. When given intravenously or subcutaneously, heparin needs to be monitored by measuring activated partial thromboplastin time levels. Side-effects of heparin include hematoma formation and heparin-induced thrombocytopenia. Low-molecular-weight heparin (LMWH) is a derivative of standard unfractionated heparin with the same activity against factor X but weaker antithrombotic factor II activity. LMWH is as effective as heparin in its antithrombogenic effects but has fewer adverse reactions. The advantage of LMWH is that there is no need for monitoring and it can be used on an outpatient basis. Chen *et al.* examined topical effects of LMWH compared to unfractionated heparin in a crush injury model and found the thrombosis rates were significantly reduced with both treatments.[81] A Cochrane review of LMWH found no difference in microvascular success rate compared to unfractionated heparin but few postoperative bleeds and hypocoagulability.[82] Dextran 40 is a group of polysaccharides synthesized by *Leuconostoc mesenteroides* streptococcus. The exact mechanism by which Dextran 40 works is unclear. The antithrombotic effect of dextran is thought to be due to binding to erythrocytes, platelets, and the vascular endothelium. It is mostly thought to interfere with the formation of fibrin clot and to prevent the aggregation of red thrombi. This effect is thought to be significantly greater than any effect on platelets. Dextran has a low risk of postoperative bleeding and hematoma formation. It has some rare, but serious, consequences, including that of pulmonary edema due to fluid overload.[83]

The use of Dextran 40 has been shown to be beneficial in animal studies. There has been no trial to date that demonstrates any significant beneficial effect in humans with the use of dextran. There is no generally accepted regimen for the administration of dextran. Jallali in his review on the use of dextran advocates initiation of Dextran 40 at a rate of 0.4 cc/kg per hour for 2 days, then reducing the rate to 0.2 cc/kg per hour on day 3 and 4, and weaning on day 5.[83] Ridha *et al.*[84] surveyed the practice of 161 microsurgeons and found 45% routinely used dextran postoperatively with 17% combining it with aspirin or heparin. Forty percent of surgeons using dextran used it for less than 72 hours; 52% used it for 5 days. Eight percent used it for greater than 5 days. There was no difference of survival in the patients who used dextran versus those who did not use dextran. A single institutional study from Memorial Sloan Kettering compiled data from 505 free flap surgeries. One group treated by surgeons who routinely used only aspirin was compared to a group treated by a surgeon who routinely used low-molecular-weight dextran. There was no significant difference between the two groups in regard to microvascular thrombosis, flap loss, hematoma, or bleeding.[85] Disa *et al.*[86] prospectively analyzed 100 consecutive patients undergoing microvascular free flap surgery. All patients were randomized into one of three anticoagulation groups, which included low-molecular-weight dextran (20 cc/h for 48 hours), low-molecular-weight dextran (20 cc/h for 120 hours), or aspirin (325 mg for 120 hours). There were no total flap losses, three flaps were re-explored, and systemic complications were greatest at 51% in patients with 120 hours of dextran, 29% in patients who had 48 hours of dextran, and only 7% in patients receiving aspirin. Based on this prospective study, the surgeons at this institution eliminated the use of dextran for microvascular surgery at their institution.[86]

Aspirin (acetylsalicylic acid) inhibits platelet enzyme cyclooxygenase and impedes arachidonic acid breakdown through thromboxane and prostacyclin. Preoperative aspirin has been shown to decrease microvascular thrombosis formation; however, the administration is very time-dependent. Rat studies suggest aspirin needs to be given 10 hours before surgery.[80]

Many animal studies have suggested that anticoagulation may be useful, especially in the crush or avascular injury, yet prospective studies in humans are limited. Khouri and the International Microvascular Research Group prospectively studied the use of anticoagulation in microvascular surgery. This was a 6-month study of 23 free flap surgeons analyzing data for 493 free flaps. While the study was prospective in nature, it was not randomized, and all of the surgeons performed their standard anticoagulation therapy, including the use of heparin, aspirin, and Dextran 40. This study was on elective free flap surgeries and not replantation. They found the overall rate of thrombosis was 9.9% with a 60% salvage rate after re-exploration of thrombosed vessels. There was no increased risk of thrombosis in young or old patients, smokers, or diabetics. The use of intraoperative anticoagulation therapy did not reduce the risk of thrombosis. They concluded that only subcutaneous heparin given postoperatively may have decreased the rate for thrombosis, but the use of heparin irrigation intraluminally had no beneficial effect on preventing thrombosis.[87]

Conrad and Adams reviewed the use of anticoagulation in microsurgery. They conceded that most of the better studies have been performed in animals and very few studies with a high level of evidence have been performed in humans. Irrespective of these limitations, they recommended in replantation surgery using a loading dose of aspirin, 1.4 mg/kg (100 mg aspirin in a 70-kg adult) followed by aspirin 1.4 mg/kg/day for 2 days. They advocate the use of heparin irrigation at a dilution of 100 units/mL during surgery and a heparin bolus of 50–100 units/kg before release of a microvascular clamp.[88]

Continuous brachial plexus blockade may be beneficial in preventing microvascular thrombosis and for early continuous pain relief. Sixteen patients were evaluated after replantation or revascularization surgery. One group received continuous brachial plexus blockade; the second received conventional management. The group undergoing conventional treatment had two microvascular thromboses, which were explored and salvaged. Pain control was adequate in both groups, although

Table 11.5 Circulation

	Normal circulation	Venous occlusion	Arterial occlusion
Color	Pink	Blue/purple hue, cyanotic	Pale, mottled
Capillary refill time	1–2 seconds	Increased, <1 second	Decreased, >2 seconds
Temperature	Warm	Warm–cool	Cold
Turgor	Full	Distended, swollen	Hollow
Dermal bleeding	Bright red blood	Dark red or bluish Bleeds briskly	Minimal bleeding only serum

those in the conventional anesthesia group required more intravenous pain medication.[89]

For revascularizations and sharp guillotine-type injuries, the author uses heparin irrigation intraoperatively (100 units/mL) and aspirin. Aspirin 325 mg is given in the recovery room and daily for 1 month. In patients with crush or avulsion injuries, LMWH at a deep-vein thrombosis prophylaxis dose is utilized. The first dose is given in the operating room, and it is continued for 2 weeks postoperatively. The patient and family are instructed on home injection prior to discharge. The LMWH regimen is based on animal studies on the efficacy of heparins in crush injuries.[90] The advantage of the LMWH regime is that patients can be discharged home while still on therapy.

Postoperative monitoring

Careful postoperative monitoring is essential in replantation surgery. Eighty percent of vascular occlusions occur within the first 48 hours after surgery. The salvage rate in a failing replantation explored early ranges from 66% to 80%.[91] A dedicated replantation team is essential for monitoring the patient. The best monitor is a conscientious nursing staff. When the patient arrives on the floor, the physician should examine the replant with the nurse, judging its color, capillary refill, and turgor. The finger is examined every hour by the nursing staff. If there is any change from the baseline level, the physician should be notified (Table 11.5). Proper handoff between nursing shifts is essential: at the bedside the clinical parameters are assessed with both nursing teams at each shift change. Venous occlusion is more insidious and harder to assess than acute arterial thrombosis. Venous occlusion will eventually lead to arterial thrombosis. If there is any doubt regarding the clinical assessment of the digit, the pulp of the finger can be pricked with a 25-gauge needle. If the blood is blue, has brisk bleeding, delayed bleeding or serous fluid exudate; exploration of the digit should be performed.

Technology cannot replace a dedicated, experienced nurse, but can aid in the postoperative assessment of viability. The most commonly used devices are pulse oximetry, ultrasonic Doppler, digital thermometry, and the laser Doppler.[91] Each of these devices can help identify an early vascular occlusion, but each has its shortcomings. While temperature measurements are inexpensive, variations such as room temperature can affect the accuracy. Laser Dopplers have a high sensitivity and specificity. When compared to thermometry, the sensitivity of the Doppler is 93% while that of thermometry is 84%. Specificity is 94% with the laser Doppler and 86% with thermometry.[92]

Clinical tips

The best monitor of the replanted digit is a well-trained nursing staff. The surgeon should examine the replantation with the nursing staff and ask to be called at any change in appearance. Shift change handoffs should be made at the bedside, so that all care members know the physical appearance of the replantation.

Postoperative therapy

Therapy is essential to regaining function. During the first few days after surgery the therapist fabricates splints, and initiates gentle range of motion to the non-affected joints. At postoperative days 5–7, a formal therapy program is initiated; this includes dressing changes, passive splinting, and instruction regarding activities of daily living. Blood vessel and nerve repairs are protected for 3–4 weeks. Tendon therapy initially involves immobilization to prevent injury, but early active and passive mobilization can be initiated if there is rigid bone fixation and a solid multistrand tendon repair. After 6–8 weeks, the therapy program is increased to include strengthening and full range-of-motion programs. Sensory re-education is initiated after any nerve injuries. Desensitization programs start using fabric textures and progress to vibratory sensory re-education.[93] Patients who started therapy before day 14 postoperatively have better recovery of motion than those who start therapy later.[24]

Psychosocial aspects of replantation

The surgeon treating a patient with an amputation must not only treat the amputation, but the whole patient, and the family. The psychological implications of amputation and replantation must not be overlooked when caring for these patients. The hand has a significant role in a patient's identity and psyche. The hands are an individual's second most visually prominent structure, second only to the face. Most individuals view their hands far more than they view their own faces. The hands are not only a source of contact with the world, but a means of communication and an instrument of sexuality. Injury or disfigurement to the hands can be a source of tremendous psychological difficulty. The psychological consequences of amputation may not correlate with the degree of injury.[94] The consequences of a distal single-digit injury in one patient may be more severe than that of a major limb amputation in another individual. Despite

common misconceptions, the presence or absence of worker's compensation or litigation does not seem to correlate with the patient's psychological reaction after injury.[95]

The psychological response to amputation may take various forms, including anxiety, depression, anger, guilt, fear, frustration, and sadness. All of these emotions are normal after an injury, but their prolonged manifestation may be pathological and lead to full acute stress disorder and post-traumatic stress disorder (PTSD). PTSD symptoms may include flashbacks, nightmares, sleep disturbances, avoidance, and detachment.

The physician should convey hope but also give the patient realistic expectations prior to surgery. Patients need to be reassured that everything possible will be done to make them whole again.

Nightmares and flashbacks are commonly seen after traumatic injuries. Flashbacks are an almost universal component of the traumatic hand injury. These can be "replay flashbacks" where an individual replays the entire traumatic event, or an "appraisal flashback" where the patient sees a snapshot of the injured hand. Patients may also have "projection flashbacks" where the injury is seen as more severe than it actually is. The type and persistence of flashbacks are strong prognostic factors in predicting PTSD and the eventual return to work and function. Psychological care of the patient with a traumatic hand amputation begins immediately in the emergency room. The patient is asked two questions: how did this accident occur, and what do you perceive was responsible for the injury? Whether patients take responsibility for the injury or attribute it to something out of their control is an important prognostic sign. Patients who see the accident as under their control, e.g., I knew I should not have removed the blade guard, do significantly better than those who believe they lack control, e.g., the machine intermittently malfunctions.

Patients are also asked how the injury appears to them and their emotional reaction. Finally they are asked about flashbacks. After discharge from the hospital, patients should be followed up with psychological treatment. Patients who are experiencing signs of PTSD are begun on a course of desensitization and systematic exposure training. Grunert *et al.*[95] were able to achieve over 90% return to work with a graded return-to-work exposure program in patients with PTSD.

Children with traumatic injuries are a special challenge to the surgeon. Rusch *et al.* found that 98% of children with traumatic injuries had symptoms of PTSD, depression, or anxiety 1 month after injury. Twelve months after injury, 21% still met the criteria for PTSD.[96]

Outcome, prognosis, and complications

Outcome after replantation and revascularization surgery can be measured in many ways. The simplest of these is survival of the replanted part. Overall survival can be expected in over 90% of digits. The largest single-institution study found a success rate of 92.9%.[25] Several factors are associated with worse prognosis. The most significant of these is mechanism of injury. Crush and avulsion injuries have a poorer anastomotic success rate than clean amputations. The anastomotic success after a clean amputation approaches 100%.[25,97]

Other factors associated with poorer success rates include the total number of anastomosed vessels. The more vessels anastomosed (whether arteries or veins) improved survival. Even in very distal replantation where anastomosis of a vein is not possible, a high success rate of over 60% can still be obtained.[28] A positive correlation exists between the number of vessels anastomosed and the mechanism of injury; crush injuries generally reduce the number of anastomosed vessels and veins.[33] The use of vein grafts is not associated with a poorer outcome. Cigarette smoking leads to a poorer outcome, but alcohol consumption does not affect survival.

A better indicator of outcome is objective measurement of hand function. Standard measurements include range of motion, grip strength, and sensation. These measurements can be compared to non-injured hands or to hands with amputations. Long-term follow-up of 59 successfully replanted digits showed that average active range of motion was 44–56% of the normal contralateral hand. Grip strength was 67% of the contralateral hand. Only three digits had normal two-point discrimination. Over one-half achieve 10 mm or less two-point discrimination.[98]

The best measurement of outcome is the use and function of the hand. A variety of tests are available to judge outcome, including the short-form 36 (SF36), upper extremity functional test (UEFT), and the Disability of the Arm, Shoulders and Hand (DASH). Outcome assessment after major upper extremity replantation is difficult.[99,100] Outcome of replantation can be compared to amputation, the normal hand, or other surgical reconstructions.[58] Various scales have been devised to try to assess and predict functional recovery after mutilating hand injuries and replantations; these include the Tamai scale, the Chen scale (Table 11.6), and the Campbell hand injury severity scale (HISS).[56,101–103] The HISS performed at the time of injury can be predictive in assessing return to work and functional recovery of the patient. The more proximal level of injury and the more injured fingers predicted poorer functional outcome.[104] A comparison of four commonly

Table 11.6 Chen classification of functional results after replantation/revascularization

Grade	Return to work	AROM (%)	Sensation	Cold intolerance	Grip strength (five-grade scale)
I	Same profession	>60	Normal	–	4–5
II	Other profession	40–60	Satisfactory	–	3–4
III	Not returned to work	30–40	Protective	Yes	Slight
IV	The limb survived, but is functionally severely disabled				

AROM, Active range of motion.

used scales, the Tamai, Ipsen, Chen, and DASH, found a high correlation between the Ipsen, Tamai and DASH. The Chen had a moderate correlation with the others.[105] Despite results of functional outcome, patient satisfaction after replantation is high; long-term follow-up in successfully replanted digits shows good satisfaction by a majority of the patients.

Replantation distal to the FDS insertion offers excellent functional results. Hattori *et al.* compared the functional results of single fingertip amputations versus replantation in regard to symptoms of pain, paresthesias, cold intolerance, and DASH scores. Grip strength did not differ between the amputation group and the replantation group. Range of motion of the proximal interphalangeal joint was better in the replantation group. Replantation patients had significantly improved DASH scores. Ninety-six percent of patients obtained protective sensation. Less than 10% of replantation patients complained of pain, 60% of patients with amputation complained of pain, half of these patients rarely or never use their affected fingers for activities of daily living. All patients with successful replantations were highly or very satisfied. Only 60% of patients in the amputation group were highly or very satisfied.[97] Patients with primary amputation revisions have a higher incidence of painful and uncomfortable sensation in their amputation stumps. Patients with replanted index and middle fingers have improved use and function of these fingers compared with patients with amputation revision. When cost was compared, a successful replantation cost 20% more than unsuccessful replantation and 300 times more than primary amputation revision.[106] The level of injury had a significant influence on the final function, with the worse function in amputations in flexor tendon zone II. In this area, repairing the profundus stump to the superficialis had improved outcome.[25]

The surgical success rate for major limb replantation ranges from 36% to 100% depending on the level of amputation, etiology of amputation, and age of the patient.[98] Using the Carroll Quantitative Test of Upper Extremity Function, the Louisville group compared the outcomes of replantation to prosthesis in adults with amputations proximal to the wrist. In injuries between the wrist and elbow, good to excellent outcomes were achieved in 50% of replantation patients. No patients in the prosthetic group had good or excellent function.[106] Better outcomes were seen in younger patients and those with more distal injuries. Outcomes for injuries proximal to the elbow were significantly worse in both groups.

Replantation, even after significant mangling injuries, is still worthwhile. Avulsion amputations in the forearm were evaluated based on the patient's overall satisfaction, recovery of motion, and ability to perform daily activities: 100% success rate of replantation was achieved. Postoperative function was rated as excellent to good in 40%, but poor in 30% of patients.[107]

Amputation at the transmetacarpal level is an intermediary between the digital amputation and major limb replantation. A review of 10 patients with transmetacarpal-level replantations showed 90% salvage of the replanted hands. Intrinsic muscle function was weak or absent in all patients. Only one patient was able to resume his prior occupation. Despite this fact, all patients were satisfied with their replantation.[108]

Complications

The most devastating complication after replantation and revascularization is anastomotic failure. Re-exploration to correct arterial insufficiency can be successful in over 50% of patients with a failing replantation.[103,109] Close observation of the patient postoperatively for signs of thrombosis and urgent re-exploration of the vessel is the essential first step in successful re-exploration. In the patient's room, the dressing should be removed and if skin sutures appear to be constricting venous outflow, they should also be removed. The patient is given a bolus of intravenous heparin and the operating room is readied. The anastomosis is opened and clots are atraumatically evacuated. The use of a Fogarty catheter may be considered; however, a catheter can cause significant intimal damage. If white thrombus or intimal injury is present, a vein graft should be utilized. Intravascular tissue plasminogen activator is considered; however, there is very limited clinical data and outcome of its effectiveness. After establishing flow, prophylactic therapy with aspirin or heparin should be strongly considered.[85,110]

Cold intolerance is common in varying degrees in almost all replanted digits; it usually resolve in 1–2 years but may be permanent.[98] Eighty-one adults from Norway were evaluated for cold sensitivity after successful replantation or revascularization. Twenty percent were severely or extremely cold-hypersensitive. Cold-hypersensitivity is significantly higher in replantations as compared to revascularizations.[111] Only 40% of children with replanted digits reported cold intolerance.[50]

Secondary procedures

The incidence of secondary procedures after digital replantation ranges from 15% to 80%.[108,109] Most series report an approximate 50% rate of reoperative surgery. Procedures include those performed immediately, mostly related to vascular anastomosis and skin closure, and late secondary procedures relating mainly to bony nonunion, or tendon adhesions.[112] Yu *et al.* reviewed a series of 102 secondary procedures in 55 patients with injuries in 79 digits. Ninety-two percent of the early procedures were for soft-tissue coverage and 67% of later procedures were for tendon function. Significant factors related to the need for secondary surgeries are avulsion or degloving injuries, and proximal replantations in zones 3–5.[113] In digital replantations proximal to the superficialis insertion, a high rate of secondary procedures can be expected. Many of these secondary surgeries have a poor outcome.[114] Tenolysis after finger replantation and revascularization is technically demanding, but the results can be rewarding (Fig. 11.21). Tenolysis in these digits may produce a modest total improvement in motion, but this functional improvement can be substantial. The risk of tendon rupture in these patients is significant.[115]

Revascularization and replantation remains one of the most challenging procedures in hand surgery. The surgeon must have a meticulous plan and exacting surgical technique. The postoperative management may be as complicated as the surgical procedure itself. Yet the rewards of a successful replantation for the patient and the surgeon are immeasurable.

Future directions

Replantation remains one of the most challenging surgeries performed. Microsurgery and "supermicrosurgery" is

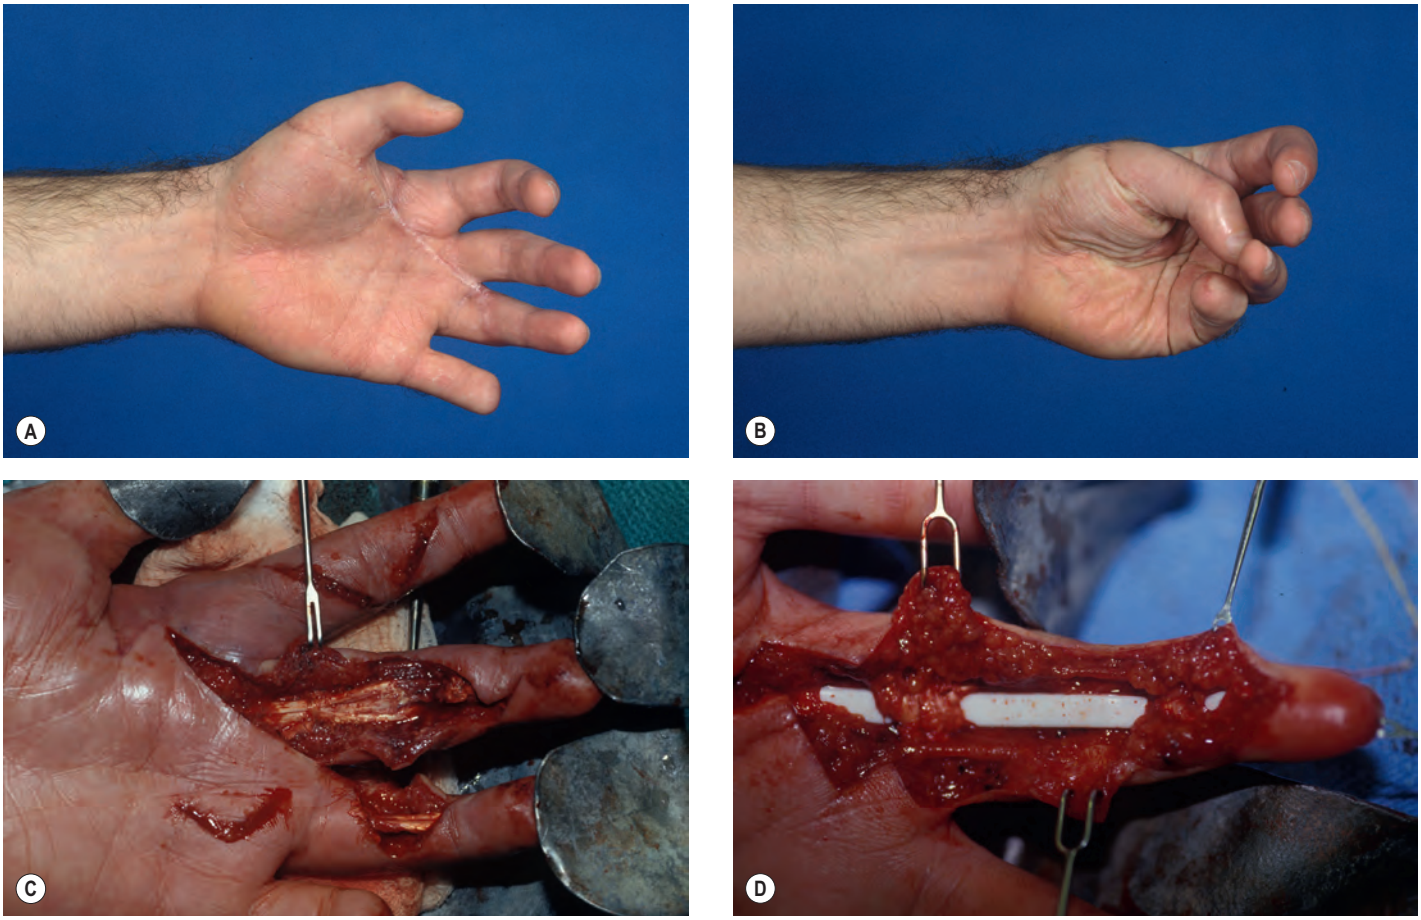

Fig. 11.21 **(A,B)** A 24-year-old status post five-finger amputation and replantation with stiff fingers. **(C)** Exploration at time of tenolysis shows severe scarring and attenuation of the digital pulleys. **(D)** Hunter rod inserted, and A2 and A4 pulley reconstruction.

allowing reattachment of more distal amputations. Newer procedures such as palmar pocketing allow successful reattachment of very distal amputations even without a venous anastomosis. Outcomes analyses generally show good to excellent satisfaction with replantation and revascularization surgery, yet there are few studies which compare functional and psychological results of replantation with that of amputation revision.[116] In this changing healthcare environment, economic and cost effectiveness studies of replantation are still lacking and are needed to establish the benefit of these procedures.[117]

The type of injury and the number of vessel anastomoses were the most significant predictors of successful outcome. Crush injuries had significantly worse outcome than sharp injuries. In distal replantations, an arterial repair even without repair of a vein can achieve a high success rate.*

Reconstructive surgery of the mutilated hand

William C. Pederson and Randolph Sherman

Access video content for this chapter online at expertconsult.com

SYNOPSIS

- Thorough debridement is essential in the management of these patients to decrease risk of infection and scarring.
- In cases of arterial insufficiency, provisional revascularization via a shunt or temporary vein graft should be considered.
- Adequate skeletal stabilization should be performed early and preferentially is done with internal fixation to allow definitive repairs of neurovascular structures and soft-tissue coverage.
- Definitive vascular reconstruction is usually delayed until after skeletal stabilization is achieved.
- Musculotendinous reconstruction should be done early if possible, to the point of performing early tendon transfers.
- Nerve repair is also best performed early, to allow proper alignment of nerves and to avoid having to dissect the nerve out of scar at a secondary procedure.
- Proper management of the soft-tissue envelope is essential to allow all of the other structures to be repaired as noted above. Proper flap selection allows early rehabilitation and facilitates secondary surgery when necessary.
- Postoperative management revolves around proper planning at the first stage of reconstruction. Every surgery should be performed with an eye to what will need to be done in the future.

Introduction

General

Management of the mangled upper extremity is complex, demands special skills and expertise, and is facilitated by a team approach with participation of all those dedicated to upper extremity surgery. When adequate facilities, equipment, and surgical expertise are not available to manage the patient's degree of injury, the patient should be transferred with the extremity splinted. If the limb is ischemic, or if part of the limb is amputated, the extremity should be cooled. The ischemic limb should be carefully covered in ice, with a protective barrier to prevent frostbite injury. The amputated part should be wrapped in a saline-soaked gauze, placed on ice, and sent with the patient. The ideal temperature is +4°C. Dry ice or alcohol should not be used to aid in cooling during transport of the part as this can cause actual freezing of the tissues.

Resuscitation of the patient is a priority over addressing the extremity injury. However, in the event of a coexisting life-threatening injury, the extremity injury must not be neglected. Assessment of vascularity, realignment, and splinting are not time-consuming and should be done as soon as possible. Provisional revascularization through shunting may be an option to quickly restore circulation to the extremity while the trauma team simultaneously addresses the coexisting injuries. Consent of the patient should initially be obtained for wide debridement of the wound; internal versus external fixation; repair or reconstruction as indicated of nerves, vessels, tendons, and muscles; use of vein grafts for arterial and venous reconstruction; possible donor sites for flap coverage; and primary amputation. The selected treatment is based on the intraoperative findings.

The initial treatment includes meticulous debridement, wound irrigation, wound culture, antibiotic administration, and tetanus prophylaxis. Copious irrigation of the wound coupled with debridement is important because it removes foreign bodies and decreases the bacterial load. High-pressure and/or pulsed lavage of the soft tissues is to be avoided in these types of injuries, as it may force debris and bacteria into the tissues and has a tendency to force fluid into the tissues, potentially creating more edema in the postoperative period. The cultures most predictive of later infecting organisms are the post-irrigation cultures. Antibiotics will help reduce infection and should be administered in the emergency department and continued intravenously for at least 72 hours. Antibiotic coverage should be effective against both gram-positive and gram-negative organisms. The authors currently prefer to use a first-generation cephalosporin and an aminoglycoside in combination. In cases of soil contamination, as in farm injuries,

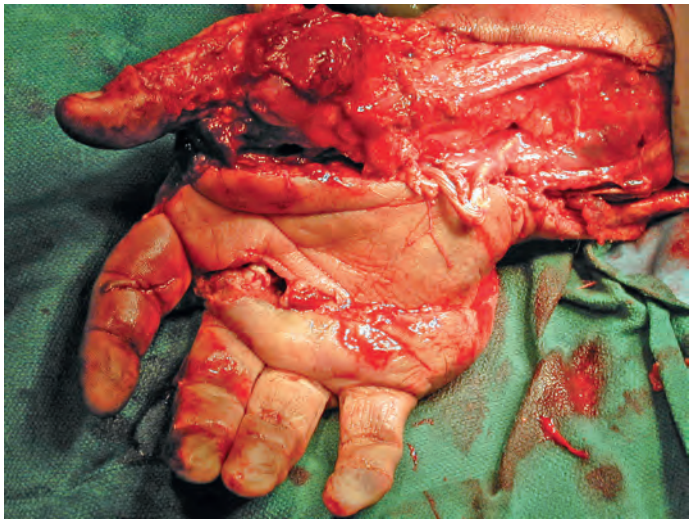

Fig. 12.1 43-year-old patient who suffered a crush injury to his hand when an airplane fell on it while under repair. This hand will require extensive debridement to delineate which tissues are viable and which are not.

coverage against anaerobic organisms should always be added. High-dose penicillin provides excellent anaerobic coverage. The possibility of gas gangrene should also be considered in these cases. The antibiotic regimen should subsequently be modified depending on the culture results. Tetanus prophylaxis should be administered in accordance with the status of previous immunization.

Debridement (Video 12.1 ▶)

Radical debridement with elimination of all nonviable tissue is *the crucial step* in the management of these injuries. This is performed under tourniquet control to provide the best visualization of the extent of injury and to prevent iatrogenic injury to intact structures. Once nerves and vessels are identified, the tourniquet may be released to better assess the viability of the remaining tissue (Fig. 12.1).

Skin and subcutaneous tissues are sharply debrided to bleeding edges. Muscle is debrided until bright red blood is seen. Color and twitch are used to assess muscle tissue; however, these characteristics are not totally reliable in determining viability. If the muscle does not bleed, it is dead and should be debrided. Small bone fragments devoid of soft-tissue attachments are avascular and should be discarded unless they constitute part of an articular surface. Contused or contaminated nerves are left in continuity. Superficial dissection above the epineurium can be carefully done to remove foreign material if it is present. Cut nerves are debrided to healthy-appearing fascicles. At the time of reconstruction, this is done under microscopic visualization because a primary repair or nerve graft will fail if the entirety of the injured segment is not resected.

The wound is copiously irrigated. Tissue margins are re-evaluated, and further debridement is performed as necessary. Hemostasis should be done cautiously. Do not cauterize vessels that may be needed for arterial or venous reconstruction. Side branches may be controlled with small sutures or vascular clips. Arterial debridement is performed for cut or thrombosed vessels. Definitive debridement of arteries that are to be reconstructed is done with the tourniquet released. At the completion of debridement, assess and record what structures remain intact and what the functional losses are. Some of the remaining intact muscles may be suitable for immediate tendon transfer to replace important functional losses.

Provisional revascularization

When the extremity is amputated or ischemic and the delay to surgery or anticipated length of time for debridement and definitive skeletal stabilization exceeds 6 hours, provisional revascularization can be done with use of a shunt, such as a Javid, Ishihara, or comparable segment of plastic tubing (Fig. 12.2). Another option is to rapidly perform reversed vein grafting between the arterial ends to re-establish arterial inflow. After definitive skeletal stabilization, the length of the vein graft can be adjusted and the anastomosis revised.

Skeletal stabilization

Definitive stable internal fixation should be done immediately when possible to allow therapeutic access to the extremity for wound care and early joint range of motion when applicable. In general, the use of external fixation is to be avoided. These

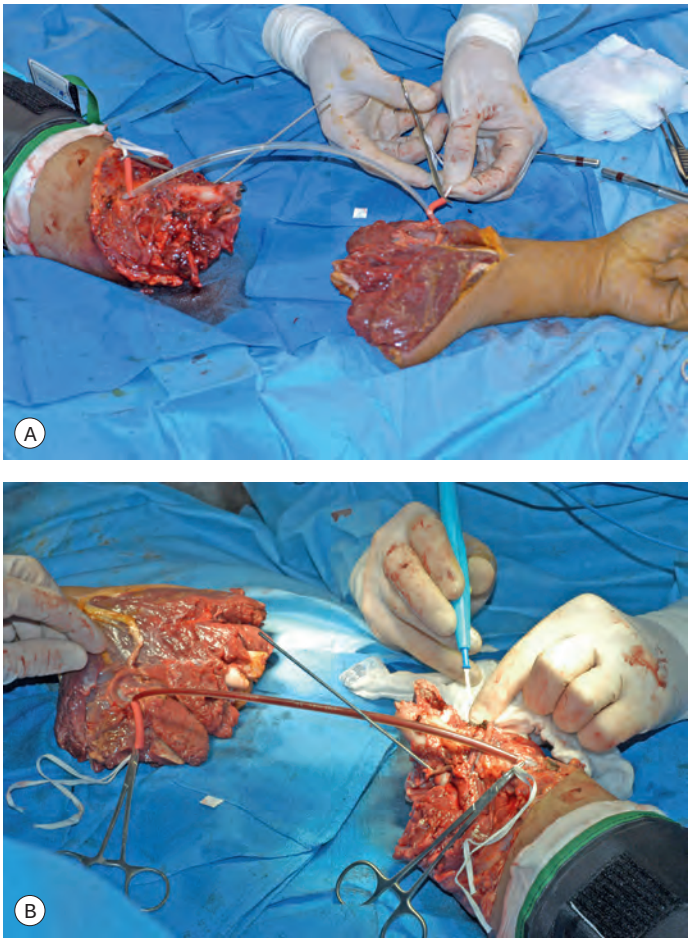

Fig. 12.2 **(A)** 24-year-old patient after mid-forearm amputation. Shunt placed from radial artery to radial artery to perfuse limb while debridement and bony fixation is performed. **(B)** View of shunt perfusing limb while debridement is performed.

devices carry the risk of neurovascular injury during pin placement, restrict circumferential access to the extremity, and may limit rehabilitation. They may be useful as a temporary solution for severely contaminated wounds with extensive soft-tissue injury, however. External fixation should not be used for the reason to avoid exposed hardware. Potentially exposed hardware should be addressed with appropriate soft-tissue coverage.

Diaphyseal fractures of the arm and forearm are usually amenable to plate fixation. If the fracture is segmental or comminuted over a large segment, a flexible interlocking intramedullary nail can be used. Fractures should be reduced anatomically with respect to rotational alignment. One must carefully check pronation and supination prior to final fixation to avoid placing the hand in a poor position. Comminuted bone fragments without soft tissue attachments should be removed. Shortening of the humerus up to 5 cm and of the radius *and* ulna up to 4 cm is acceptable. Indications for shortening include significant comminution over a segment with bone and soft-tissue loss and bony shortening has the advantage of allowing primary repair of vessels and, more important, of nerves.

Complex diaphyseal fractures include Galeazzi fractures (radial diaphyseal fracture with disruption of the distal radioulnar joint), Monteggia fractures (proximal ulna fractures with radial head dislocation or radial head or neck fracture), and Essex-Lopresti injuries (radial head fracture with associated rupture of the interosseous membrane to the level of the wrist). These fractures must be restored to anatomic length to restore joint congruity and alignment.

Diaphyseal fractures of the hand are fixed with Kirschner wires, with attention to maintaining rotational alignment. Shortening of the metacarpals or phalanges between 5 and 6 mm may be necessary in replantation. For other injuries, length can be restored or maintained with internal or external fixation and primary or delayed bone grafting. In general, initial use of plate fixation is not recommended in the hand, particularly in the phalanges. This requires more stripping of the periosteum and later has an adverse effect on functional outcome because of potential tendon adhesions around the plate.

In contrast to lower extremity injuries, primary bone grafting is acceptable and recommended in the upper extremity. Primary iliac crest bone graft or bone allograft may be used for defects up to 4 cm. For larger defects, vascularized bone grafts, in particular a vascularized segment of free fibula, should be considered (see below). With massive bone loss, creation of a one-bone forearm can be considered as a salvage procedure when other options are not available. The results of this procedure in trauma are not as good as in limb salvage surgeries for tumor reconstruction.

Intra-articular fractures should be anatomically reduced. Stable fixation is imperative to allow early range of motion. Fixation can be done with plates, screws, K-wires, or tension band wiring as dictated by the fracture pattern and location. Articular fragments free of soft-tissue attachments should be preserved to reconstruct the joint surface. Primary bone grafting should be done to address bone defects, to enhance the stability of the fixation, and to promote bone healing. If there is complex injury to the distal radius and/or wrist, spanning plates across the wrist may be used to provide excellent fixation and allow healing of complex bony and ligamentous injuries.[1] These have been shown to be an excellent option in the face of severe injury and soft-tissue dissection can be minimal, without the disadvantages of external fixation[2] (Fig. 12.3). When the joint surface cannot be reconstructed owing to severe comminution or bone loss, other reconstructive options are available. At the shoulder and elbow, a primary allograft or a prosthesis can be used. At the wrist joint, primary fusion should be the first treatment option. If wrist motion is critical to the patient, vascularized free fibula, retaining the proximal articular cartilage, can be used to reconstruct the joint surface. Prosthetic devices for total wrist arthroplasty are poor at present, and historically do not do well in post-traumatic wrists regardless.

In summary, the goal of skeletal stabilization is to achieve stable anatomic fixation to allow early range of motion and rehabilitation. Soft-tissue stripping of bone is limited to only that which is necessary for fixation. Comminuted fragments with attached soft tissue are retained. Bone defects are treated primarily whenever possible. The potential of exposed hardware should not limit the choice of fixation. Exposed bone, hardware, or joints are addressed with appropriate soft-tissue coverage, whether it be pedicled or free.

Vascular reconstruction

Definitive revascularization is done once skeletal stabilization is completed. Lacerated vessels are resected to healthy-appearing vessel wall both proximally and distally. Contusion along the adventitia suggests injury within the intimal layer as well. A "ribbon sign" (convoluted or tortuous course of the digital vessels) indicates injury to the media layer of the vessel and requires resection of the length of the involved area and reversed vein grafting (Fig. 12.4). Inflow is assessed, and if it is not adequate, the vessel should be resected more proximally until excellent pulsatile flow is achieved.

When possible, primary repair is preferred. However, it is better to resect appropriately and to use a reversed vein graft than to perform a primary repair under tension. Reversed vein grafts are available from several sites. The most commonly used for long segments in the upper extremity is the saphenous vein. For reconstruction in the hand, local grafts from the dorsal or volar forearm can be used.

Reconstruction of the superficial palmar arch and its multiple common digital arteries may be difficult. Branched vein grafts from the dorsum of the foot and use of the subscapular artery and its branches have been described for this. The descending branch of the lateral femoral circumflex artery may also be utilized as a smaller arterial graft to make use of its branches to reconstruct the arch. The conventional method is to harvest two Y vein segments from the volar forearm and to perform end-to-end or end-to-side anastomoses as necessary. Vein grafts should be routinely used to reconstruct venous outflow if primary repair cannot be achieved. There is almost no role for artificial grafts for vascular reconstruction in the upper extremity distal to the axillary artery, particularly in contaminated wounds.

When the need for coverage and vascular repair present themselves simultaneously, one can consider "flow-through" free flaps to both bridge the arterial defect and obtain coverage at the same time. The radial forearm free flap is very useful in this regard, as the radial artery offers an excellent choice for a long bypass.[3] Due to trauma to the

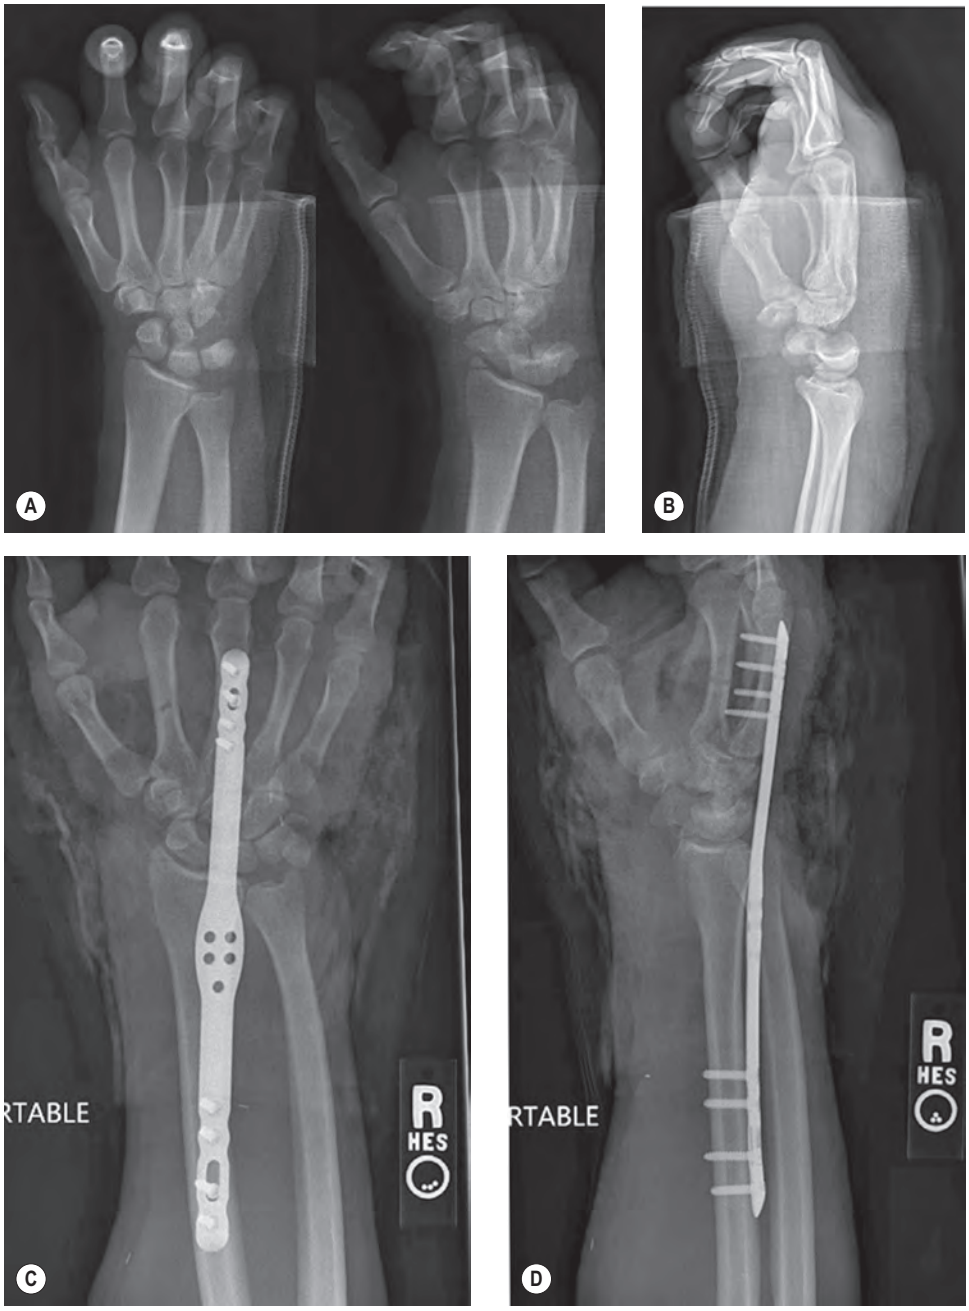

Fig. 12.3 (A,B) Preoperative X-rays of patient suffering crushing injury to the wrist. Note midcarpal capitate fracture/dislocation and radial styloid fracture. **(C,D)** After reduction and fixation with spanning plate. *(Courtesy of Dr. Ramesh Srinivasan, the Hand Center of San Antonio.)*

forearm, however, this may not be an appropriate choice of flap. In this case, the anterolateral thigh flap with its long segment of the descending branch of the lateral femoral circumflex can be utilized.[4,5] Small venous free flaps with arterialized segments of vein can be utilized to great utility for revascularization of fingers in the face of a soft-tissue loss volarly.[6]

Musculotendinous reconstruction

Primary tendon repair is preferred when permitted by the injury. There is often a crush or avulsive component to the injury, which may preclude primary repair. In these cases, treatment options include primary or delayed reconstruction with tendon grafts or Silastic tendon rods. Immediate reconstruction is favored with use of available donor tendons (palmaris, plantaris, local tendons that cannot be reconstructed, and toe extensors).

In flexor tendon injuries in the hand, priority is usually given to reconstruction of the profundus tendons. If there is trauma to the distal interphalangeal joint requiring fusion, priority is rather given to the superficialis tendon. The lesser priority tendon can be used for reconstruction of the other when necessary. It can be used as a donor tendon for other sites or for pulley reconstruction as necessary. One should pay close attention to the status of the pulleys in the fingers, and the A2 and A4 should be reconstructed with portions of tendon grafts when necessary.

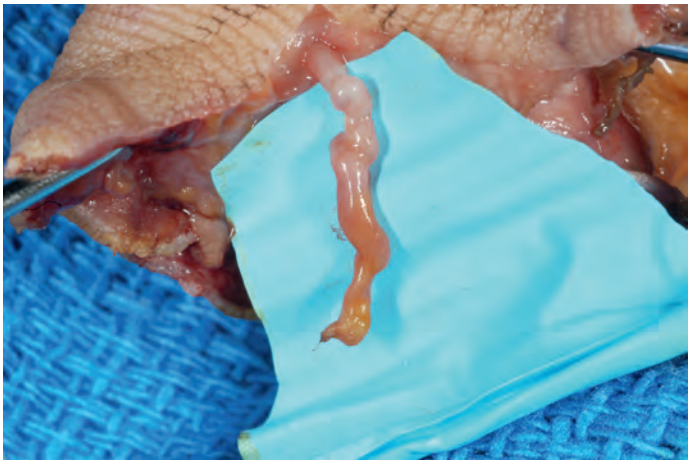

Fig. 12.4 "Ribbon" sign in an avulsed finger. Note corkscrewing of vessel which indicates severe avulsion damage to the adventitial layer.

Functional reconstruction of muscle deficits and tendon injuries should be done immediately whenever possible.[7] Unrecoverable muscle function can be treated with tendon transfer, and it is preferable to perform this as a primary procedure. However, this can also be performed at a later stage of reconstruction. Delayed transfers are generally more difficult because they have to be performed through a scarred tissue bed, and this requires additional surgical procedures and further delays the patient's rehabilitation and recovery. When no donor tendons are available for transfer muscle function can be restored with functional free muscle transfer. The gracilis is the most commonly used muscle for functional reconstruction and can actually provide both coverage and restoration of muscle function to the fingers. Again, this can be done either primarily or at a later stage of reconstruction, however primary reconstruction is favored as available nerves and vessels are easier to locate and one is not operating through a scarred bed of tissue. This procedure will be discussed in more length below and in Chapter 35.

Nerves

Nerves may have internal derangement without loss of anatomic continuity and they can be partially or completely disrupted. Severe contusion to the nerve with internal hemorrhage without actual division may mitigate against functional return, however contused or attenuated nerves are usually left intact. If lacerated, the nerve ends should be debrided serially under magnification until healthy-appearing fascicles appear. Do not compromise the resection to preserve length, as nerve regeneration will not occur through scarred nerve tissue, and nerves repaired under tension also do not recover well.

Mobilizing the proximal and distal stumps to achieve primary repair is not recommended because this results in devascularization of large segments of the nerve. Mobilization can be done over a 1- to 2-cm distance to allow repair, but to avoid repair under tension, nerve grafting is preferable. If a staged repair is planned, nerve ends are tagged with 6-0 polypropylene suture for later identification. Primary nerve grafting is recommended, however, as the orientation is much clearer at the time of injury rather than later and dissecting a nerve out of a scarred bed is technically challenging (Fig. 12.5). Common donor nerves include the sural or saphenous nerves, sensory branch of the radial nerve (if lacerated from the injury), medial or lateral antebrachial cutaneous nerves, and the posterior interosseous nerve. In multiple nerve injuries, primary nerve transfers can be performed.[8] These include transfer of the anterior interosseous nerve (distal to the branch to the flexor pollicis longus) to the motor branch of the ulnar nerve and transfer of the sensory branch of the radial nerve to the digital nerves of the thumb and index finger.[9] When a nerve defect is greater than 15 cm, an end-to-side neurorrhaphy of the distal stump of the injured nerve to a neighboring intact major nerve can be done, although functional outcomes of this procedure are generally poor.

Skin and soft-tissue reconstruction

Appropriate soft-tissue coverage is of paramount importance for coverage of bone, joint, tendons, neurovascular structures, and hardware. The selection of coverage should provide a gliding surface for mobile structures and enhance vascularity in the injured area.

Extensive skin and soft-tissue loss is one of the major problems in the mangled upper extremity. Isolated skin loss may be managed by split-thickness skin grafting (if not over a bony prominence, hardware, or exposed tendons). Local random skin flaps have limited utility even in superficial soft tissue defects owing to their restricted mobility, precarious blood supply, and frequent involvement in the injury.

Soft-tissue loss can be managed in a variety of ways. A simple approach is to leave the wound open and let it heal by secondary intention with granulation tissue. However, exposed tissues sensitive to desiccation, such as nerves and tendons, will become necrotic, scarring will be promoted, and function will be compromised. Local muscle flaps are usually not suitable because of their proximity to the zone of injury, the limited amount of coverage that they provide, and the resulting functional deficit. Two-stage distant pedicled flap procedures are avoided when possible; immobilization of the reconstructed area will lead to stiffness and swelling. If this means of coverage is required, the most common sources are the pedicled groin flap, cross-arm flap, thoracoacromial flap, and abdominal flap. In mangling injuries, the need for extensive coverage, reliable vascularity of the flap, and early mobilization usually necessitates use of axial flaps (local or regional), one-stage distant pedicled flaps, or free flaps. The type of coverage depends on site and extent of the defect. This is particularly important for bone, tendon, nerve, and hardware coverage, as well as for facilitation of future reconstructive procedures in planning a staged reconstruction. As discussed above, one should think one or two steps ahead in terms of what reconstructive procedures are potentially going to be performed later under or though the chosen flap.

Fasciocutaneous flaps or cutaneous flaps with subcutaneous tissue are recommended when tendons are exposed as this tissue facilitates tendon gliding. However, many fasciocutaneous flaps over time do not have a good cosmetic appearance (color match can be poor and they can be too bulky). The primary fasciocutaneous flaps used with acceptable cosmetic appearance include the radial forearm flap, as either a free or rotational flap; the lateral arm flap; and the

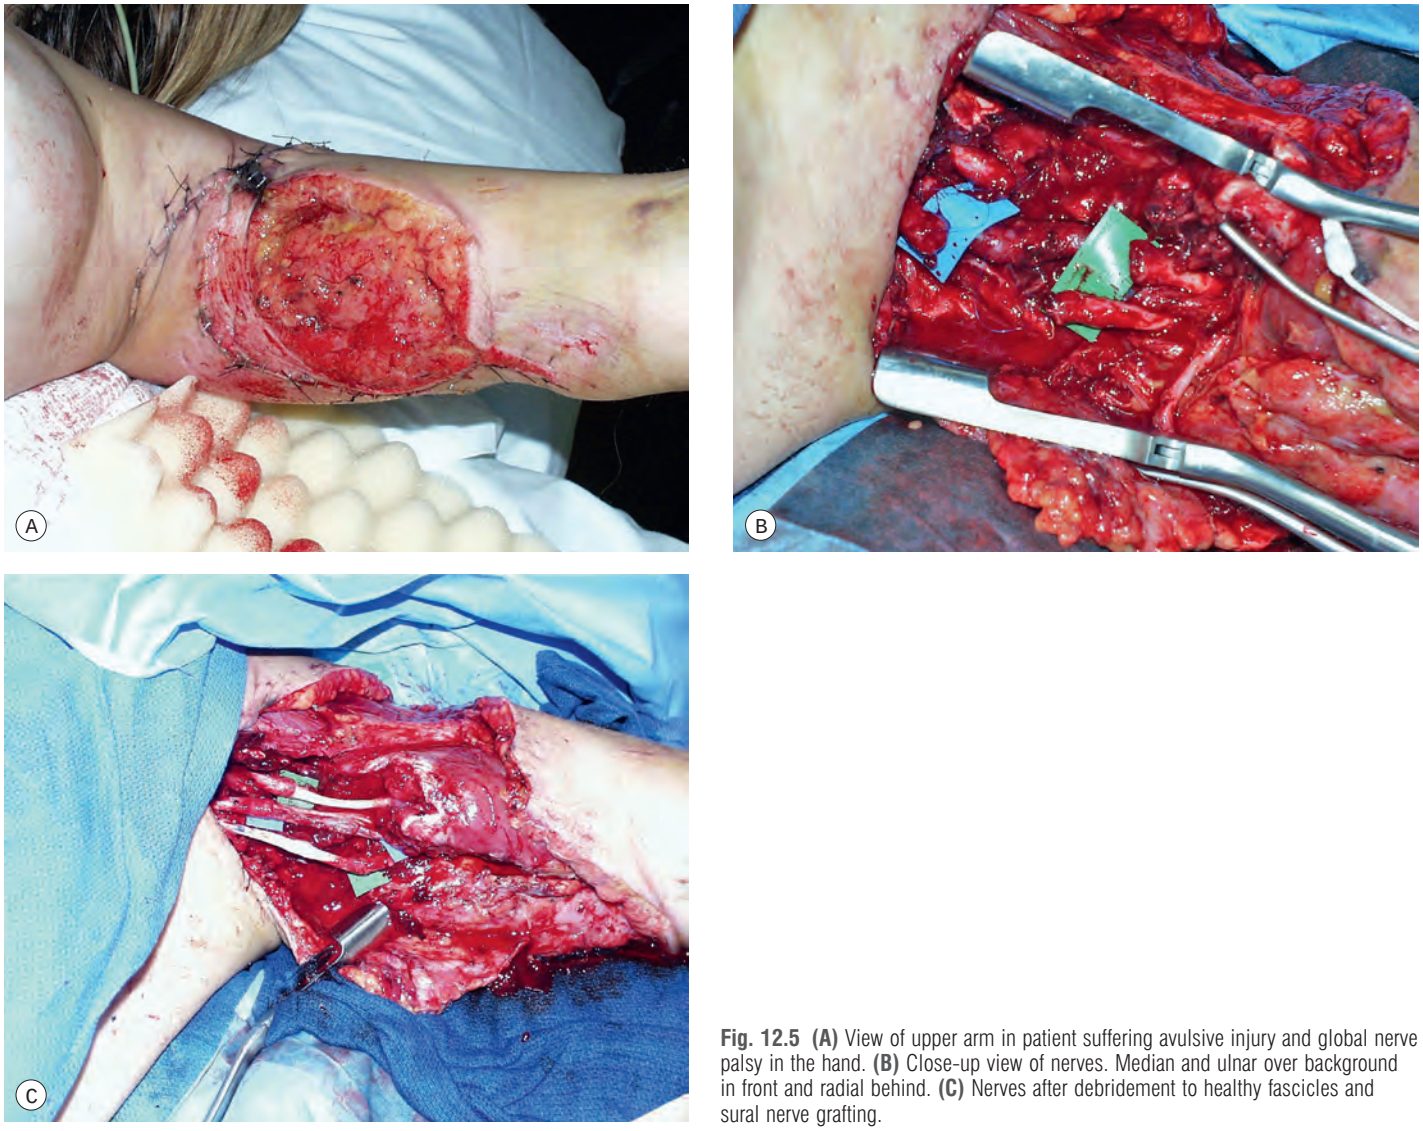

Fig. 12.5 **(A)** View of upper arm in patient suffering avulsive injury and global nerve palsy in the hand. **(B)** Close-up view of nerves. Median and ulnar over background in front and radial behind. **(C)** Nerves after debridement to healthy fascicles and sural nerve grafting.

groin flap. These can all be utilized as free flaps, but the groin flap is generally utilized today as a pedicled flap due to the small size and short available vascular pedicle. An alternative to the fasciocutaneous flap is a fascial flap. Donors for this include the temporoparietal fascia, the parascapular fascia, and the radial forearm fascia. The free fascial flap is placed on the defect and then covered with an unmeshed split-thickness skin graft. It has been our experience, though, that it can be difficult to lift a fascial flap later for tenolysis or other procedures.

Muscle flaps are used when a moderate to large soft-tissue defect is present. Although muscle flaps may be harvested with a skin component, harvesting of muscle alone is preferred. This is then covered with a split-thickness skin graft. In the arm and elbow, the latissimus dorsi can be used as a one-stage distal pedicled rotational flap. Most other reconstructions are done with a free muscle transfer using the gracilis, rectus abdominis, latissimus dorsi, or serratus anterior. When a functional deficit is present, consideration should be given to use of a functional free muscle transfer to provide both functional restoration and soft-tissue coverage. The gracilis is most commonly used for this transfer in the forearm as noted above.

Postoperative management

In the immediate postoperative period, the extremity is splinted in an appropriate position to prevent capsuloligamentous shortening and tension on repaired structures. Elevation is necessary to reduce edema and help control pain. The patient's pain and anxiety should be adequately controlled. The ambient temperature should be at least 25°C and adjusted to the patient's body temperature. Hydration should be sufficient to maintain urine output between 80 and 100 mL/hr. Anticoagulant therapy is used by many surgeons. However, the authors are selective in using heparin; aspirin is used daily for 4 to 6 days after surgery. Appropriate antibiotic therapy is continued in the postoperative period and later modified as necessary according to culture results.

Extremity and flap monitoring is critical. Early recognition of arterial hypoperfusion or venous congestion will occur only in a well-monitored environment with trained nursing

staff. If there is a question about tissue viability, the dressings are released and the entirety of the revascularized tissue is exposed for further assessment of perfusion, congestion, temperature, turgor, and color with Doppler examination. Release of the dressings alone may be sufficient to alter the vascular issue. If viability is still in question after 30 minutes, immediate re-exploration and further assessment may prevent failure of the revascularized tissue, whether it be the extremity or a free flap.

Early and motivated rehabilitation of the extremity is an important factor in achieving a successful outcome. Early motion reduces edema, adhesions, and scarring. It prevents muscle atrophy and facilitates healing of the soft tissues by remodeling of collagen fibers. The details of the rehabilitation program are determined by the existing injuries and the reconstruction procedure.

Basic science/disease process

Upper extremity function and facial appearance and expression are the two centrally defining features of our humanity. Movement of the hand through space along with precise grasp, pinch, and positioning allows us to perform the most rudimentary to the most highly complex tasks to actualize the entire range of our wishes, dreams, and ambitions. Man without hands is akin to a plane without wings. Nearly all tasks combine positioning of the hand with shoulder, elbow, and wrist motion followed by intricate manipulation of finger joint position with both intrinsic and extrinsic muscle force modulation.

Injuries to any part of the upper extremity, no matter how minor, may immediately compromise and chronically debilitate the user's ability to perform. Witness the enormously negative impact of work-related injuries on our economy. Productivity is reduced, medical costs are escalated, and the work environment is disrupted, not to mention the enormous personal and family suffering caused by pain and loss of function. Some have estimated the cost to our economy from upper extremity trauma to run in the hundreds of billions of dollars. In light of the significantly problematic consequences that result from extensive upper extremity injuries, it is paramount that early diagnosis and, more important, strategically sound treatment be instituted from the outset.

Extensive skin and soft-tissue trauma along with composite injuries involving multiple structures must be managed actively, there being few circumstances in the hand in which open wound management and healing by secondary intention play a role. Maximum preservation of motion and sensibility should be ever present in the mind of the reconstructive surgeon from the moment of first evaluation, with prompt wound closure given high priority.

The term *mangled* is commonly used to describe the hand and upper extremity after major trauma. Gregory *et al*. used the term *mangled* to describe a severe injury to at least three of the four organ and tissue systems of skin, bone, vessel, and nerve.[10] According to the *Oxford English Dictionary*, to mangle is "to reduce by cutting, tearing or crushing to a more or less unrecognizable condition". Each of these definitions implies a severe, high-energy injury that involves multiple anatomic structures, usually over an extended topography.

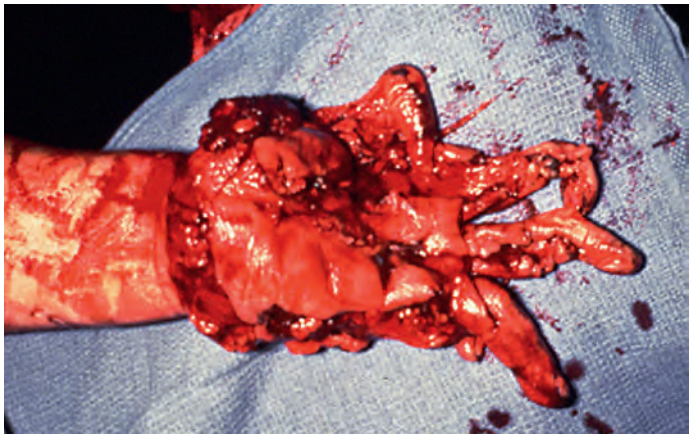

Fig. 12.6 View of hand after it was caught in a 9-ton press. This is the definition of mangled, however it was also unfortunately unsalvageable.

Mangling injuries are produced by high-energy forces. High-power equipment – agricultural (corn picker, grain auger), industrial (punch press, power saw), or household (lawn mower, snow blower) – may cause such an injury (Fig. 12.6). In addition, gunshot wounds, explosives, and motor vehicle accidents (especially with the arm of the patient being outside the car window[11]) account for many cases. The injury may have a combination of sharp, crushing, avulsive, and thermal components. The wound may be severely contaminated, depending on the location and mechanism of injury.

Types of injury

Amputation involves complete severing of a part from the body. This is common in the upper extremities, and ranges from fingertip amputation (an extremely common injury and one of the most common ones seen in emergency departments) to amputation of the entire upper extremity at the shoulder. While fingertip amputations may be managed in any number of ways (most by benign neglect) with excellent outcomes, management of major limb amputations can lead to significant functional and cosmetic deformity and present significant local and systemic problems in management. Replantation of amputated parts requires microsurgical skills and may necessitate other procedures to lead to final restoration of function.

Crush injuries may and may not lead to amputation, but involve significantly more damage to the involved structures than straightforward and sharp amputations. These injuries often lead to major loss of bony and soft-tissue structures and have much poorer results both in terms of survival (if replantation is required) and function. Familiarity with various options for bony and soft-tissue reconstruction, as well as nerve and musculotendinous reconstruction, is often required.

Avulsion injuries primarily involve the soft tissues of the upper extremity. The etiology of these injuries is often due to industrial accidents in roller press machines which cause both bone dislocations in the hand and can lead to loss of the entire soft-tissue envelope to the hand (Fig. 12.7). These injuries predictably lead to severe scarring and often poor function despite the type of reconstruction performed. Early motion is essential for reasonable outcomes in these injuries.

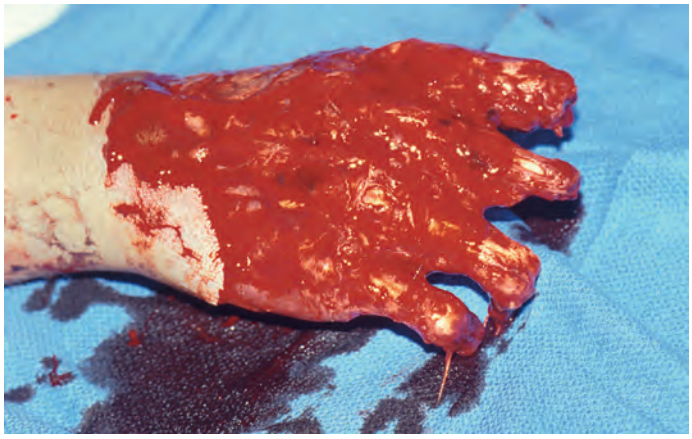

Fig. 12.7 Hand of 25-year-old male with avulsion injury of entire skin of hand and distal portions of phalanges. This is a devastating injury and will require a number of procedures for adequate reconstruction.

Roller injuries occur when the hand is caught between two rollers whose function is usually to compress sheets of metal. This can result in an array of injuries including degloving of the skin of the hand, fractures, and potentially crushing of all the tissues of the hand and forearm. These are devastating injuries and call on the entire armamentarium of the surgeon to manage the bony fractures, dislocations, and coverage and functional issues from soft-tissue damage (Fig. 12.8).

Careful evaluation of both the patient and the injury, formulation of a treatment plan, meticulous operative treatment by an experienced team, and early, motivated rehabilitation reduce the morbidity associated with these injuries.

Diagnosis/patient presentation

Evaluation of the patient in the emergency room

Evaluation of the patient with a high-energy injury includes a thorough trauma work-up, beginning with the basics of airway, breathing, and circulation. Whereas the mangled extremity is often the most apparent injury, careful evaluation of the entire patient for potential life-threatening or other associated injuries is critical to formulation of a treatment plan.

The patient's history focuses on the time and mechanism of injury and any associated chemical, electrical, or thermal components of the injury. The mechanism of and the time from injury, which is especially crucial when ischemia is present, are the most important factors in determining the zone of injury and predicting the ability to salvage the extremity. A medical history is taken to determine the patient's ability to tolerate a prolonged anesthetic with the potential for significant blood loss, fluid shifts, and release of metabolic byproducts after revascularization of ischemic tissue. Medical conditions such as diabetes, hypertension, vasculitis or other inflammatory diseases, and smoking history can adversely affect outcome and should be considered in developing a treatment plan. Similarly, the occupational history and social

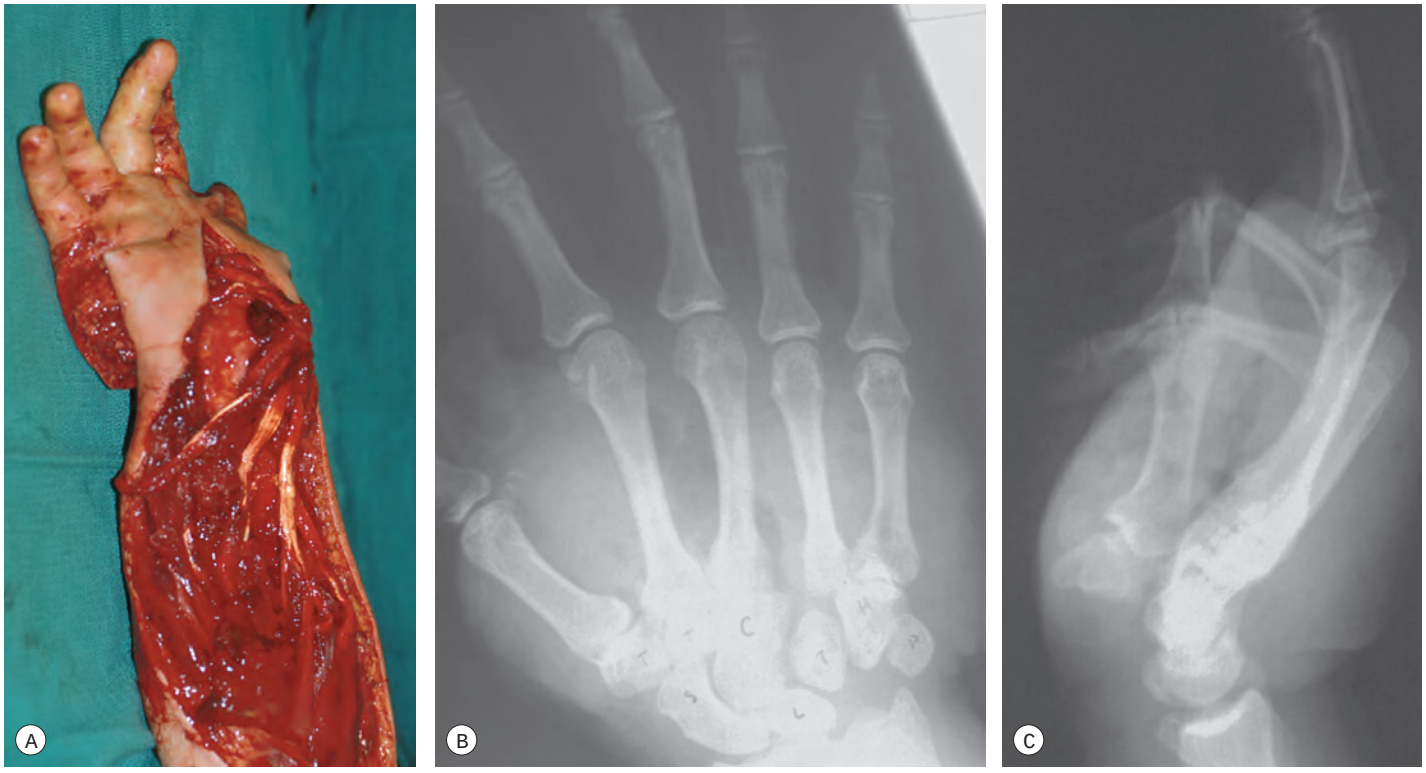

Fig. 12.8 **(A)** 27-year-old male who got his hand caught in a roller press. Note avulsion of muscles and position of hand. **(B)** AP X-ray of hand and wrist. Patient has a longitudinal dislocation between the 3rd and 4th rays (a "peri-hamate peri-pisiform" injury) which is typical of crushing injuries to the hand. **(C)** Lateral X-ray of the hand and wrist. Note the carpometacarpal dislocation of the thumb in this view, also fairly typical of crushing injuries to the hand.

history are important in determining postoperative compliance and in addressing the reconstructive goals. The presence of one or several adverse factors is not an absolute contraindication to salvage of an extremity or to microvascular repair and/or reconstruction. However, these factors should be considered in selecting the type of reconstruction to be used and in better predicting outcome.

Examination of the mangled extremity should be systematic and address vascular status, skeletal stability, motor and sensory function, and soft-tissue loss. The vascular status is evaluated by assessment of peripheral pulses, color, temperature, and capillary refill time in the distal extremity. Pulse oximetry is generally readily available in the emergency department and is helpful in assessing ischemia in the fingers. Doppler examination and angiography can also be used. Arteriographic exam in the mangled extremity may simply delay revascularization, however, and should be utilized very selectively. Skeletal injury is assessed clinically by the presence of deformity, crepitance, or bone tenderness. Radiographs should be taken of the entire extremity – particularly to evaluate the joints above and below the level of injury. A motor and sensory examination should be documented. The examiner should be aware that motor or sensory loss can result from muscle, tendon, or nerve injury as well as from ischemia. The ultimate assessment of the mangled extremity occurs in the operating room, however, after the debridement of nonviable tissue.

In the case of limb-threatening ischemia in a mangling injury, evaluation of the status of the vessels is generally performed in the operating room without the delay necessary for an arteriogram. An intraoperative angiogram may aid in determining the level and extent of arterial injuries, however. Radiographs taken in the operating room are usually of better quality than those taken in the emergency department because the extremity can be positioned without causing the patient discomfort. Traction radiographs allow better delineation of the fracture pattern and number of fragments, especially in evaluating intra-articular fractures about the wrist and elbow. Photographic documentation of the injury should be done throughout the course of treatment from initial evaluation to conclusion of treatment.[12]

Clinical tips

Initial management

- Debridement of all nonvital tissue is essential
  - Save intact vessels, nerves, and tendons
  - May need to return in 24–48 hours to reassess
- Fixation is important in management
  - Internal fixation is superior
  - Consider "spanning" plates across joints
- As you clean up, consider timing and type of coverage
  - May need a flap early to cover neurovascular structures
  - Can re-debride under flap
- Consider single-stage reconstruction when appropriate
  - Reconstruct tendons with grafts
  - Reconstruct nerves with grafts
  - Consider delayed bony reconstruction or vascularized bone transfer

Emergency room to operating room – making a plan

Planning in patient management starts when the patient is first seen in the emergency room. As a general rule, however, multiple examinations of the extremity by multiple physicians (emergency physician, intern, resident, fellow, etc.) is to be avoided. In the unanesthetized patient this is painful and leads to further anxiety which can lead to vasospasm and further problems. The quality of circulation in the extremity must be assessed, and a rough idea of the soft-tissue deficit should be obtained in a single examination. X-ray studies of the extremity (and of the distal portion in cases of amputation) done in the emergency room can also give an idea of what might be necessary in terms of bony fixation. Consent must be obtained for whatever might be necessary to include bony fixation, revascularization (including potential vascular graft donor sites), and coverage. While an emergency free flap is rarely indicated, the patient should be informed of potential soft-tissue flap donor sites as well. The patient and family should also be informed of the need for further surgery, including second looks/wash-outs which should be performed in the first several days.

Planning for reconstruction

In deciding how best to treat the mangled extremity, a variety of factors are considered. They can be broadly classified as patient and extremity factors. Pertinent *patient factors* include the general condition, age, handedness, occupation, functional requirements, and socioeconomic background of the patient. Associated injuries resulting in cardiopulmonary or hemodynamic compromise as well as pre-existing medical problems will mitigate against a lengthy salvage procedure, especially in a patient of advanced age. Conditions adversely affecting the blood vessels, such as diabetes mellitus, vasculitis, or smoking, will increase the risk of anastomotic failure and should be taken into consideration. Psychiatric disorders may be a contraindication to reconstruction because of possible repeated suicide attempts or anticipated noncompliance with the rehabilitation program. A morose patient may be temporarily incompetent to participate in determining treatment. Because time is a critical factor in treatment, it may be better to err in attempting to salvage an extremity than to perform a primary amputation.

Important *extremity factors* include the time since the injury, the severity of the injury, and the previous functional status of the extremity. Warm ischemia time longer than 6 hours results in progressively irreversible changes in cellular structure of muscle. Even if vascularity is re-established, tissue necrosis will not be avoided. Systemic risks of revascularizing a limb with prolonged ischemia must also be considered and addressed. These include acidosis, hyperkalemia, and rhabdomyolysis. In amputations of digits, where no muscle is present, the delay until reperfusion with use of cold ischemia may be extended to 20 hours. Finally, the previous condition of the extremity is considered. A history of major trauma, neurologic disease, or congenital deformity resulting in impaired function may not justify a salvage attempt.

The multitude of factors and the complex interrelations among them make reaching a decision a difficult task, even for experienced surgeons. Specialized scoring systems have

been developed on the basis of lower extremity injuries. These may offer valuable guidelines for evaluating the lower extremity but cannot be applied well to the upper extremity.[13] Each case is unique, however, and the final decision should be an individualized one based on assessment of the patient and extremity parameters as well as sound judgment. The patient's knowledge of the potential risks and benefits of surgery and the possibility of early or later amputation is important.

A third factor which is rarely discussed is the surgeon factor. The skill and experience of the surgeon managing the patient is extremely important in determining the outcome.[14] While obviously the experienced surgeon is more likely to have a more favorable outcome, reasonable results can be obtained by others if they follow basic principles and stick to what they are comfortable doing. The surgeon who only occasionally performs microsurgical tissue transfer may better serve his patient by performing a pedicled flap for initial coverage than attempting an esoteric and complex microsurgical procedure that he read about once. It is always better to perform an initial reconstruction using a technique that you are familiar with rather than attempting to perform a procedure that has a high potential for failure. In any case, it is preferable to refer a patient with a complex extremity injury to a center which routinely deals with these problems rather than attempt reconstruction if one is not familiar with these types of problems.

The single most important factor in planning reconstruction of a mangled extremity is to in fact have a plan and to know what you are going to need to do next. While the merits of early reconstruction and primary vs. delayed reconstruction will be discussed below, the surgeon must have a plan and be ready to alter this depending on the findings at surgery and potential problems as they arise. The reconstructive surgeon must always think at least one or two steps ahead of where he is today in order to maximize his reconstructive efforts. *Anticipation of what will need to be done in the future is the primary determinant of what needs to be accomplished today.* If one decides to delay bone grafting but proceed with soft-tissue coverage (which is often applicable) the soft-tissue reconstruction should be done in such a manner to make the secondary bony reconstruction both feasible and easy. If there is a large bony defect which may potentially require vascularized bone grafting, the soft-tissue flap should be performed in such a manner as to facilitate performance of the vascularized fibula transfer later. This may mean that a pedicled soft-tissue flap is a superior choice to a free flap (to save recipient vessels for the later bone transfer), but if this type of coverage is not feasible, then the anastomosis for the soft-tissue transfer should be performed in a location and to a vessel which will not make a second microsurgical bone transfer technically more challenging that it already is. The same philosophy applies when one anticipates later toe transfer(s) for thumb or digital reconstruction. Another example is the potential need for later tenolysis or tendon grafting under a soft-tissue flap which is placed at the initial surgery. There is no question that it is much easier to re-operate through a soft-tissue flap than it is under a muscle flap. Muscle flaps scar rather severely underneath when placed on a wound, while soft-tissue flaps do not. Tendons also glide much easier under a fascia or fatty tissue flap than they do under a muscle flap, thus it is preferable to cover exposed tendons (or wounds with gaps in tendons) with some type of fascial or fasciocutaneous flap.

Timing of reconstruction

Definitive reconstruction of the mangled extremity may be undertaken either early or late. In both reconstructive plans, the initial treatment includes aggressive debridement, skeletal stabilization, revascularization, and soft-tissue coverage. Early soft-tissue coverage is of paramount importance to limb salvage.[15] This improves the vascularity to the traumatized area, limits exposure to hospital pathogens, and reduces the risk of infection. Coverage is technically easier to perform early; with delay, edema obscures tissue planes, vessels become friable, and vascular grafts may be needed to perform microanastomoses out of the zone of injury.[16]

Reconstruction of bone, tendons, and nerves can be performed either early or late. Early reconstruction implies repair or reconstruction of all injured structures during the initial phase of treatment, up to 10 days from the initial injury. Delayed reconstruction implies staged repair of bone, tendon, nerve, and soft tissue at different periods in the course of treatment. The choice of the reconstructive approach depends on the characteristics of the injury and the preference and expertise of the treating surgeon.

Early reconstruction (single-stage)

This approach requires debridement of the wound followed by reconstruction of all structures: bone, tendon, and nerve. This is done ideally within 24 to 72 hours. Primary corticocancellous bone graft or vascularized bone grafts, nerve grafts, tendon transfers, tendon grafting, and free functional muscle transfer are performed at the time of soft-tissue coverage. Reconstruction can be delayed up to 10 days in the event of a severely contaminated wound, which requires several debridements to reduce the contaminant load.

Primary reconstruction of all structures is technically easier to perform when the tissue bed is fresh rather than later through a scarred soft-tissue bed. It decreases the number of subsequent procedures, total hospitalization time, and cost. Also, rehabilitation can begin earlier. The development of adhesions is decreased, and the functional outcome is improved.[17,18] This type of reconstruction by its nature, however, usually mandates experience and skill with microsurgical repair (nerves) and tissue transfer (for complex and composite tissue loss).[7] If one lacks experience in this type of reconstruction, it is usually best to get primary soft-tissue coverage by whatever means is best and delay the reconstruction of the other structures until a stable soft-tissue bed is obtained.

Delayed reconstruction (multiple stage)

In the past, delayed, staged reconstruction was the primary method of treatment of severe injuries with multiple structural defects. In this treatment plan, vascularity is established, and the soft-tissue injuries are treated with serial debridements performed at 24- to 72-hour intervals. Appropriate wound coverage is performed when the wound is clean and all necrotic tissue has been debrided. This should be within the first 10 days from injury, regardless of the technique chosen. Bone, tendon, and nerve reconstruction is delayed until "soft

Fig. 12.9 **(A)** Hand of 38-year-old male after saw injury with amputation of index and middle fingers with mangling injury to thumb. Thumb is not replantable. **(B)** View of index finger after debridement and identification of structures for replantation. **(C)** Hand after replantation of index finger in thumb position.

tissue equilibrium" is achieved. This is when the tissues have healed and are free of infection, edema has resolved, scar tissue has matured, and the joints are supple and have achieved their maximum passive range of motion. Delayed reconstruction is a good option when the patient's comorbidities or a severely contaminated or infected wound prevents early definitive treatment.

Salvage versus amputation

The surgeon may be confronted with the decision to attempt salvage or to amputate a mangled, nonviable upper extremity. The appropriate decision is difficult because recovery of function in a salvaged extremity may be limited or absent.[19] Thus, multiple reconstructive procedures with associated morbidity, prolonged hospitalization, disability time, psychological distress, and financial demands may be too expensive a price to pay for the end result of a useless and painful limb. In contrast to prostheses for the leg, prostheses for the hand and forearm offer limited restoration of function. Even with the most advanced prosthetic devices available today, there is no sensory feedback from the prosthesis, and for most purposes, this makes a prosthesis less functional than a sensate yet injured hand. Thus, most mangled upper extremities should be considered for salvage. Nevertheless, serious associated injuries or diseases, ischemia time longer than 6 hours, and parts that are severely crushed, avulsed, contaminated, or injured at multiple levels constitute unfavorable conditions for a replantation or revascularization attempt. In this setting, amputation is not a failure but rather a step toward stabilization of the patient and rehabilitation of the extremity.

Spare-parts utilization

In some instances in severe injury to the upper extremity, there may be uninjured tissues, which while not salvageable in their native position, may be utilized for coverage and/or reconstruction of the defect. This is certainly the case in multiple digital amputations when the thumb is severely damaged and another finger can be placed in the thumb position to reconstruct this important function (Fig. 12.9). Likewise, the tissue from an amputated finger or forearm can be utilized for coverage of another defect, or even an amputation stump, to salvage length and preclude the necessity for another flap. One should remember to salvage whatever may be useable for reconstruction from parts not deemed suitable for replantation, and this can include skin (grafts or flaps), bone graft, joints (vascularized or not), nerves and tendons.

Treatment/surgical technique

Options for bony reconstruction

Mangling injuries to the hand and upper extremity usually involve the bone structure as well as the soft tissue. This can

Fig. 12.10 X-ray of patient shown in Fig. 12.7 after reduction and pinning of dislocations using Kirschner wires.

range from dislocations to significant bone loss. Each of these must be managed primarily to allow stabilization for vascular and soft-tissue repairs. Dislocations are generally managed with relocation and pinning with Kirschner wires, which usually require 6–8 weeks in place to allow for healing of ligamentous structures. Crushing and roller press injuries commonly lead to longitudinal dislocations in the metacarpal and carpal bones, most frequently between the 3rd and 4th rays (axial loading dislocations or "meat cleaver" injuries). One may also see the thumb ray dislocated with the trapezium on the radial side of the hand. Ligament repair is rarely possible in these injuries, and the bony injury can be missed due to the fact that the soft-tissue issues are often quite dramatic (see Fig. 12.8B,C). Management of these injuries is appropriate reduction of the dislocations and/or fractures and pinning (Fig. 12.10). Immobilization is needed for 6–8 weeks. Other wrist dislocations are usually managed in a similar manner.

Fractures of the hand are often best managed with simple K-wire fixation, as this is a rapid and reliable technique. Taking a great deal of time to perform plate fixation in the case of severe injuries in the hand is often counter-productive, especially if the distal extremity is ischemic. This type of fixation usually will not allow early motion, but this is frequently difficult to do in any case in mangling injuries. On the other hand, fractures of the radius and ulna are best managed by internal plate fixation. This can be performed relatively rapidly, and gives very stable fixation. We prefer to utilize stainless steel locking plate fixation, and ideally there should be three screws placed on either side of the fracture. The state of the soft tissues should not be a deterrent to plate fixation, as providing good soft-tissue coverage (with an appropriate flap) should be part of the initial plan. The bone must be thoroughly debrided and contaminated fragments with no blood supply should be discarded, however. In the case of severe contamination, a second wash-out at 48–72 hours should be planned with elevation of the soft tissues, further debridement, and irrigation.

Bone loss may or may not present a problem. Small segments may not preclude healing, but large segments may need reconstruction. Bones should still usually be placed in proper relationship with internal fixation whenever possible, and as noted above, with the ends in anatomic alignment around the gap. In heavily contaminated wounds, primary bone grafting (with non-vascularized grafts) is not indicated, as the bone graft could be lost to infection. Soft-tissue coverage should be obtained first and the gap dealt with by either standard bone graft (if the defect is less than 6 cm) or vascularized bone grafting (usually a free fibula transfer in the upper extremity). In cases where a significant amount of bone has been lost in both bones of the forearm, an external fixator may be required until adequate soft-tissue reconstruction can be performed and internal bony stabilization applied.

Options for vascular reconstruction

Ideally, primary repair of vascular injury will be possible, but if there is any doubt about potential injury to the ends of the vessels, one should rapidly perform a bypass graft. For most purposes in the upper extremity, this is going to involve the use of vein grafts. Artificial conduits smaller than 6 mm (primarily expanded PTFE or Gore-Tex) have extremely poor patency rates, and are not indicated for bypass grafting. That leaves primarily venous grafts and in some instances arterial grafts. For long segments in the upper arm or forearm, the preferred vein graft is the saphenous from the medial thigh or lower leg (Fig. 12.11). The lesser saphenous, located on the posterior-lateral portion of the ankle and running up the midline of the calf, presents another option if the saphenous is absent or severely varicose. Arm veins (the basilica or cephalic) can be utilized for bypass in the arm, but in the face of severe injury, these may not be available and in fact may be needed for venous outflow (particularly in the face of replantation).

For reconstruction of injuries distal to the wrist, small vein grafts from the volar forearm or dorsal foot may be used. The use of arterial grafts in reconstruction of the ulnar artery and arch has some advocates, and donor sites for this include the subscapular–thoracodorsal axis from the axilla and the descending branch of the lateral femoral circumflex artery in the lateral thigh.[4] Both of these give a reasonable size match for the vessels of the arch, and may offer multiple side branches to anastomose to the common digital vessels as they come off of the reconstructed arch. In cases of traumatic injury with ischemic distal tissue, however, the time it takes to dissect these arterial grafts out (as compared to subcutaneous veins) is probably not worth it. To date, we are not aware that there is any proven benefit to utilizing arterial grafts over venous grafts.

Another option in the face of a moderately large wound with the need for arterial bypass grafting is the use of "flow-through" flaps. As noted above, several flaps are available for this, and the radial forearm free flap, anterolateral thigh, temporoparietal fascia,[20] and omentum have all be utilized as arterial flow-through free flaps. One can also utilize arterialized venous flaps, which have a great deal of utility in digital revascularization to cover small volar defects and provide

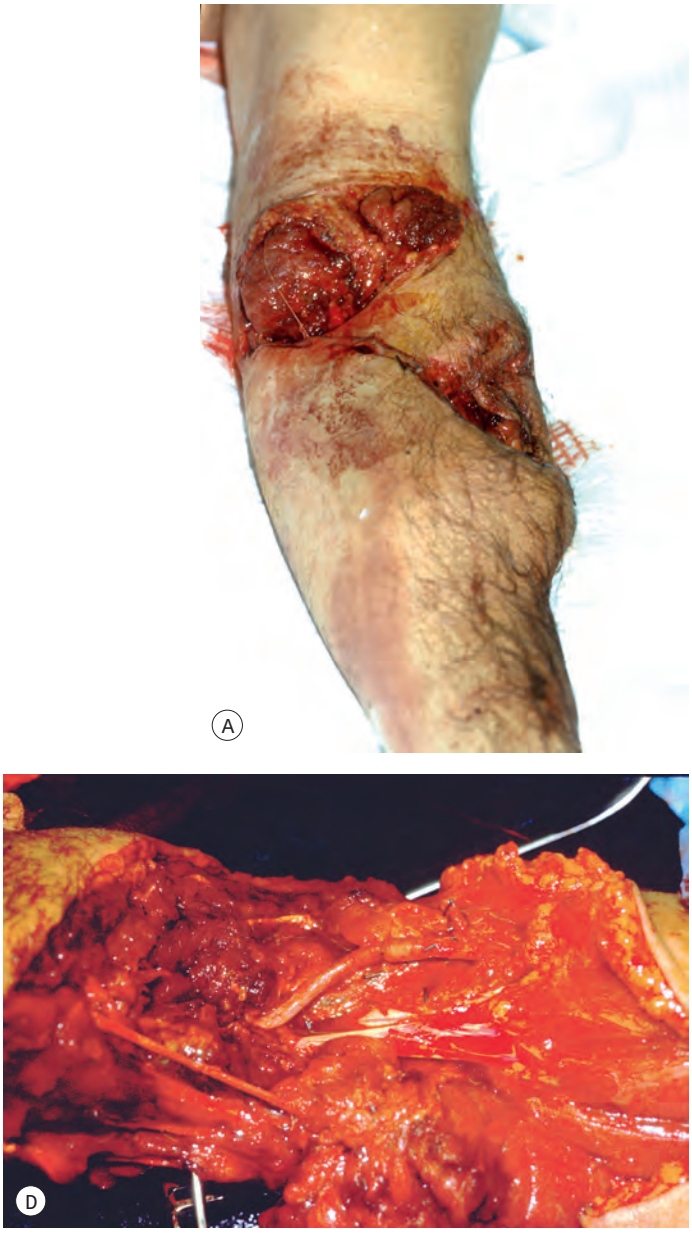

Fig. 12.11 **(A)** Arm of patient after vehicle roll-over with crush-avulsion injury. There were no palpable pulses in the wrist and the hand was cool. Surgeons at an outlying hospital planned to amputate the limb. **(B)** View of brachial artery after excision. Note severe intimal avulsion injury in mid-portion. **(C)** Portion of saphenous vein harvested for revascularization. arterial inflow at the same time, while larger flaps based on the saphenous vein with large skin paddles have been successfully utilized.[21] Another option in the case of large segments of amputated tissue is to provide both coverage and salvage of length utilizing all or a portion of the amputated tissue as a flow-through flap. The use of all of these flaps for both coverage and bypass is unusual, but the surgeon dealing with severe extremity injuries should be familiar with the options.

Nerve reconstruction

The ideal time for nerve reconstruction is usually at the time of injury, because it is easiest to determine level of damage (by observing bruising of the nerve), and dissection and orientation of the nerve are obvious prior to the onset of scarring. Nonetheless, the goal should be repair of nerve damage at the time of initial treatment with the caveat that nerve repairs and/or grafts should be surrounded with well-vascularized tissue. This may require the use of vascularized flap transfer to maximize nerve recovery, however a flap may be needed regardless. Nerve repairs and nerve grafts should not be done if there is inadequate soft tissue surrounding the repair and should certainly not be placed under skin grafts.

Primary repair of damaged nerves is the ideal, but if this cannot be achieved, the nerve should be grafted. Small gaps of smaller, sensory nerves may be treated with any of the number of "tubes" available,[22] however their utility in larger nerves and in longer gaps remains unproven.[23,24] The recently approved nerve allograft has shown some possible application in nerve gaps, but the results in larger nerves have not proven to be the equal of autologous nerve grafts.[25] Autologous nerve grafts remain the gold standard, and a number of donor sites are available. The most commonly utilized is the sural nerve running from the posterior knee to the lateral ankle, but other peripheral sensory nerves can be utilized as

well. These include the saphenous nerve, the medial and lateral antebrachial cutaneous nerve, the radial sensory branch, and the medial brachial cutaneous nerve. These secondary sources of nerve graft are all limited by their diameter and available length compared to the sural. When nerves are grafted, an attempt must be made to line up similar areas of fascicular bundles on the nerves to maximize functional recovery.

As noted above, nerve transfers may be the best option when multiple nerves have been injured.[8,9] The reader is referred to Chapters 32 and 33 in this text for more information on these subjects.

Muscle and tendon repair and reconstruction

As with other structures, primary repair of muscles and tendons is desirable. Tendons and tendon repair will also require good, vascular soft-tissue coverage in order to both survive and have maximal function. Flexor tendons in the hand and fingers should be repaired with a double core suture whenever possible, with the addition of an epitenon stitch of fine monofilament suture to aid in gliding.[26] In the case of injury to both the flexor digitorum superficialis and profundus tendons in the finger, one may opt to simply repair only the profundus, particularly if the cut ends are untidy. If the ends cannot be brought together, one must consider either primary tendon grafting or the possibility of tendon transfer to provide the missing function if it is essential. Primary tendon grafting should not be performed in a bad wound bed, as the odds of success are small. In these cases, one might also consider placing silastic tendon rods along the course of the tendon requiring reconstruction. Grafts can then be placed in the tracts of the rods. This scenario would most commonly accompany flap coverage, however, and in general cutaneous flaps are a much better bed than muscle for placing tendon grafts. Direct injury to muscles can often be sutured, but with severe injury the damaged muscle will often require debridement. Loss of function from removing muscle can be reconstructed with tendon transfers on occasion but may require free innervated muscle transfer to repair the loss.

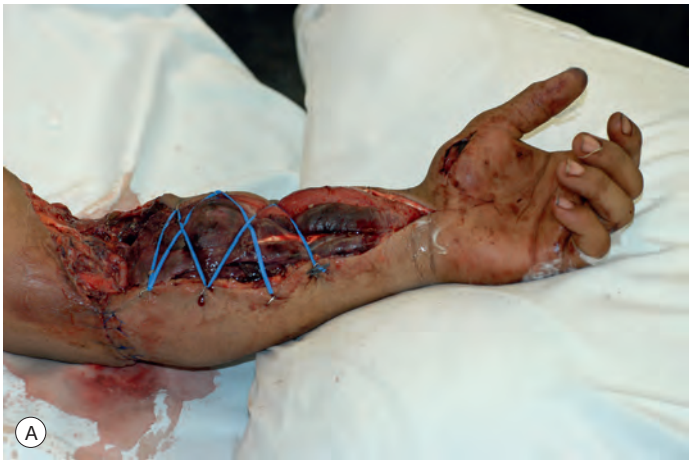
Soft-tissue reconstruction

The approach to wounds of the upper extremity should follow the usual parameters of soft-tissue reconstruction, the so-called reconstructive ladder. In complex wounds, however, this concept is being replaced by that of the "reconstructive elevator", which proposes bypassing simple reconstructions and providing the best functional coverage available (despite the fact that a wound might "get by" with a skin graft.) Many wounds nonetheless can be covered with a split-thickness skin graft or with regional flaps, particularly in the hand. The ultimate morbidity of any local or regional flap must be considered, however, especially in relation to later hand function. Because the hand is highly visible, the cosmetic aspect of certain local and regional flaps must be considered as well. Although certain wounds may be adequately covered with a flap from the same extremity, one should consider what offers the best coverage in terms of the overall reconstruction.[27] This will often lead to use of a free flap for many hand and upper limb wounds. The selection of flap coverage for a clean wound allows use of composite tissue in many cases.[28–30] Whereas many smaller wounds in the upper extremity are amenable to small local or regional flaps, this discussion centers on the use of major axial-based pedicle or free flaps for the management of larger wounds.

Wounds should be definitively closed as soon as the wound bed is clean. This applies equally to flap coverage as well as simple primary closure. As discussed above, wound debridement is essential to provide control of tissue necrosis and infection. If the status of the tissue is in doubt, serial debridements should be performed to avoid removal of viable tissue and yet assure a well-vascularized wound with minimal bacterial contamination. In patients with vital structures exposed, it is often best to place a muscle flap (usually a free muscle flap), with the plan to return to the operating room every 48 hours. The flap is not definitively sutured down, and is lifted at each subsequent procedure and debridement and irrigation is carried out. Once the muscle flap starts becoming adherent to the underlying tissue and there is a decrease in cloudy fluid under the flap, it is ready for definite insetting and coverage with a skin graft (Fig. 12.12). Vacuum-assisted wound closure provides an excellent temporizing measure between debridements,[31,32] and may be utilized in the upper part of the arm to optimize a wound bed prior to skin grafting. This wound management technique has the advantage of removing edema and exudates from the wound and tends to keep swelling down in our experience. It should be utilized with caution in the hand, however, as extended use can lead to increased scar (in the form of granulations) and a great deal of stiffness. When utilized for a relatively short period of time, however, it can be advantageous.

Types of flaps – cutaneous vs. muscle

Wounds of the hand and upper extremity can be covered by either cutaneous flaps or muscle flaps. Myocutaneous flaps are not utilized as much today as in the past, because surprisingly they are not generally as cosmetic as a simple muscle flap covered with a split-thickness skin graft. Muscle flaps have always been thought of as superior for coverage of untidy and/or infected wounds,[29] however fasciocutaneous flaps (at least with inclusion of the well-vascularized fascia) are actually equally applicable to these wounds in terms of the ability to manage infection.[30] For hand coverage, we prefer cutaneous flaps whenever possible, as it is usually easier to re-operate through skin and subcutaneous fat than muscle. While the muscle has the advantage that it atrophies over time, there tends to be a fairly severe amount of scarring under a muscle flap, which makes it more difficult to raise for secondary procedures and mitigates against tendon gliding. Thus, in general, we prefer to utilize any of the number of fasciocutaneous flaps when covering the hand. In severe injuries and in the face of a large dead-space needing to be filled, however, muscle is probably superior. There has been a great deal of interest in the so-called "perforator flap" based on septal perforators supplying the skin.[33] In the case of a severe injury to the hand most perforator flaps available in the upper extremity are probably too small to provide adequate coverage. The severity of injury would also likely render many of these flaps unavailable. While the hand and upper extremity affords a large number of local and regional flaps, this chapter will deal primarily with larger flaps and emphasize free tissue transfer for coverage of the hand.



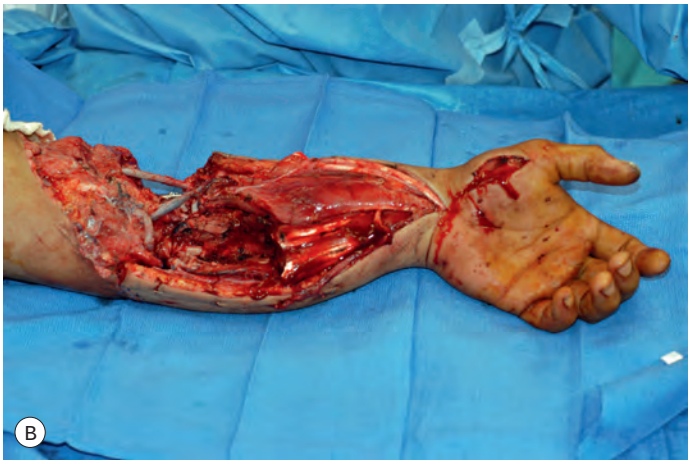


Fig. 12.12 **(A)** Forearm of young patient 48 hours after replantation at proximal forearm level. Note necrotic-appearing muscle in forearm. **(B)** View of forearm after debridement. Note exposed vein bypass grafts. (Patient and family refused amputation at this point.) **(C)** Patient at same surgery after placement of rectus abdominis muscle free flap to cover vessels and bone. **(D)** View of forearm at time of re-exploration 48 hours after last debridement and flap cover. **(E)** Nonviable muscle debrided at this surgery. Note rectus muscle flap flipped back to allow debridement and wash-out and nonviable muscle in basin. **(F)** Forearm at third wash-out, 6 days after injury. There was no further muscle necrosis noted on this exploration, and the muscle flap was becoming adherent to the underlying tissues. **(G)** Forearm at fourth wash-out, 9 days after injury. The wounds were very clean and the muscle flap was sutured down and a split-thickness skin graft was placed. This patient never developed evidence of sepsis and no infection developed in either the soft tissues or bone, despite severe contamination at the time of injury.

Pedicled flaps – the groin flap

The pedicled groin flap remains one of the workhorses for hand coverage. It provides a very large portion of soft tissue which can cover many large defects in the hand and forearm. This flap was the first axial-pattern flap described, and was the first flap transferred microsurgically. Its use as a free flap has been supplanted by many flaps with better vasculature, but it should be a part of the armamentarium of every hand surgeon. The blood supply is based on the superficial circumflex iliac vessels, which exit the femoral vessels in the groin and run approximately two centimeters below and parallel to the inguinal ligament (Fig. 12.13). This artery can be located with a pencil Doppler and can be mapped out roughly to the level of the anterior superior iliac spine (ASIS). This flap can (and should be) taken out beyond the ASIS to allow the proximal portion to be tubed to allow some shoulder and elbow motion. It can be radically defatted, especially the more distal portion (which will be placed on the hand), and contours very well on the hand. It can be utilized for coverage of the dorsal hand, forearm, first webspace, and has great utility as a first step prior to toe transfer for thumb or digital reconstruction.

The flap is first marked out with the vessel in the center axis of the flap (which we prefer to locate with a Doppler) (Fig. 12.14). Dissection proceeds from lateral to medial. Care should be taken to avoid leaving a great deal of the fat from the iliac area on the deep surface of the flap, as this will have to be removed regardless. The landmark to look for as dissection proceeds medially is the sartorius, as the artery pierces the fascia of the sartorius at its medial edge. We prefer to incise the fascia at the lateral edge of the muscle and stop the dissection short of the space medial to the muscle, which obviates damage to the vascular pedicle. Once the flap has been dissected up, the donor site is closed. The edges of the donor site *should not be undermined*, as this simply makes the wound larger. Closure is facilitated by bending the hip and placing a pillow under the knee. Once the donor site is closed, the proximal portion of the flap is usually sewn into a tube. The distal flap to be placed on the hand is defatted centripetally, avoiding defatting the central portion too much to avoid damage to the pedicle. Once this is done, the flap is sewn in place in the defect on the hand (Fig. 12.15).

We have not seen a patient pull the flap off the hand once they are fully awake, but it is prudent to either strap the arm down to the torso or put a very large suture between the wrist and the body until the patient is fully awake and on the ward. If the arm is strapped, this should be removed once the patient is cogent as it can lead to swelling and congestion in the hand. In the postoperative period, the patient is instructed how to move the shoulder and elbow through their available range based on the tubed portion of the pedicle. The flap can usually safely be divided at around three weeks, but this is dependent on how well the flap is healed on the hand. If healing has been delayed or there has been a partial dehiscence, division may need to be delayed. The flap can also be "delayed" prior to division, which is accomplished by either making a small incision in the tubed portion and dividing all the deep tissues (i.e., the pedicle) or conversely by incising the tube

Fig. 12.14 Locating the groin flap pedicle (superficial circumflex iliac artery) with a pencil Doppler.

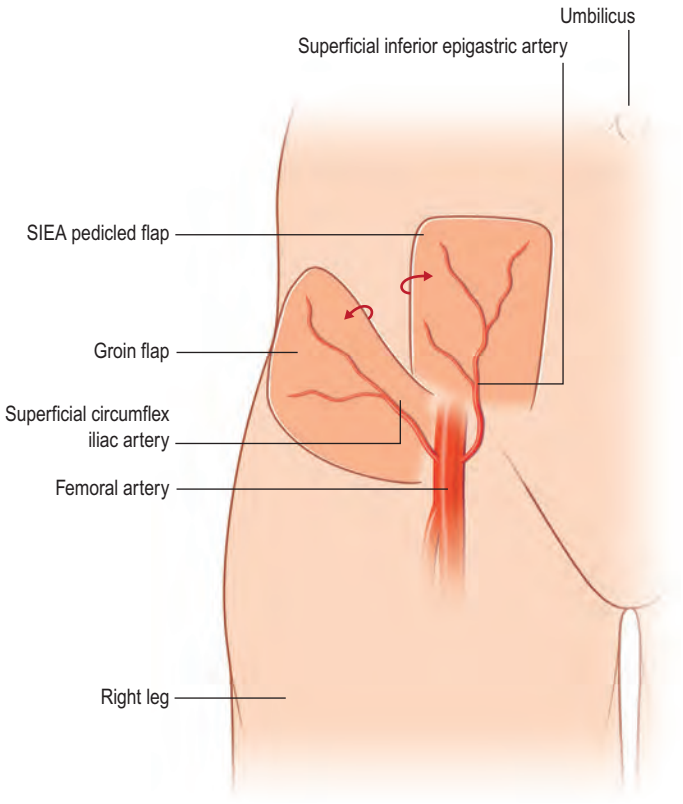

Fig. 12.13 Anatomy of groin flap and superficial inferior epigastric artery (SIEA) flap. Note that superficial circumflex iliac artery runs approximately 2 cm (or two fingerbreadths) below the inguinal ligament. These two flaps can provide coverage of very large wounds of the hand.

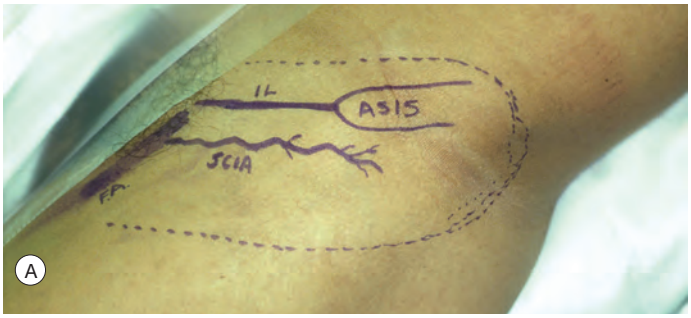

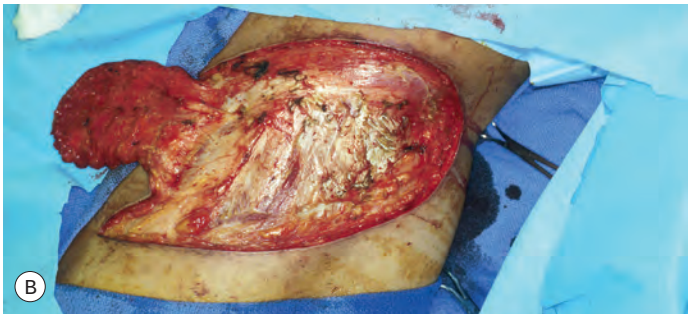

Fig. 12.15 **(A)** Markings on groin of patient for pedicled groin flap. Patient had failed replantation of thumb and flap is to prepare for later toe transfer for thumb reconstruction. **(B)** Flap elevated. Note size of donor defect after elevation. Be aware that undermining these edges simply makes this defect more difficult to close. **(C)** Donor site has been closed primarily and flap has been tubed. **(D)** Flap after placement on hand. **(E)** Final view after three and a half weeks at time of division and insetting of flap.

circumferentially to interrupt the subdermal plexus. Once this has been done, the flap can usually be safely divided in 5–7 days.

At the time of division, the donor site is closed and the flap is gently inset on the hand. Some advocate leaving the tubed portion dangling on the hand to allow for potential demarcation of the flap into viable and nonviable portions. Our experience has been that if the flap is well healed on the hand, the flap can usually be safely trimmed and inset. The patient is begun on a rigorous physical therapy program to regain shoulder and elbow motion, as well as motion in the hand. The pedicled groin flap can usually be contoured (defatted) adequately when first placed on the hand, but on occasion will require secondary procedures to inset and decrease the bulk later. The primary advantage of the pedicled groin flap is that it does not require microsurgical expertise, while the primary disadvantage of this flap is that the hand is placed in a dependent position and may lead to stiffness in the shoulder. One caveat concerning the donor site is that if this area gets infected, is it unwise to remove all the sutures. This will lead to a gigantic wound which can be quite difficult to manage (Fig. 12.16). It is much better to treat this by removing a few

Fig. 12.16 Patient who suffered infection and dehiscence of groin flap donor site after 3 weeks of wound care, prior to placement of split-thickness skin graft. This can be avoided by treating the wound carefully in the postoperative period and avoiding leaving it open.

sutures and irrigating the area under the sutures daily which will rid the area of infection without the morbidity of a massive wound on the hip.

Free flaps – fasciocutaneous flaps

The radial forearm flap

This flap offers almost ideal characteristics for hand reconstruction.[3] Its primary application is as a pedicled flap, based on reversed flow through the distal radial artery and venae comitantes.[34] It may be elevated on a proximal vascular pedicle to cover wounds in the forearm or about the elbow. Nonetheless, it may be used as a free flap in certain instances and affords excellent hand coverage. This flap can be raised anywhere along the course of the radial artery, and a skin island from very small to quite large may be taken (Fig. 12.17).

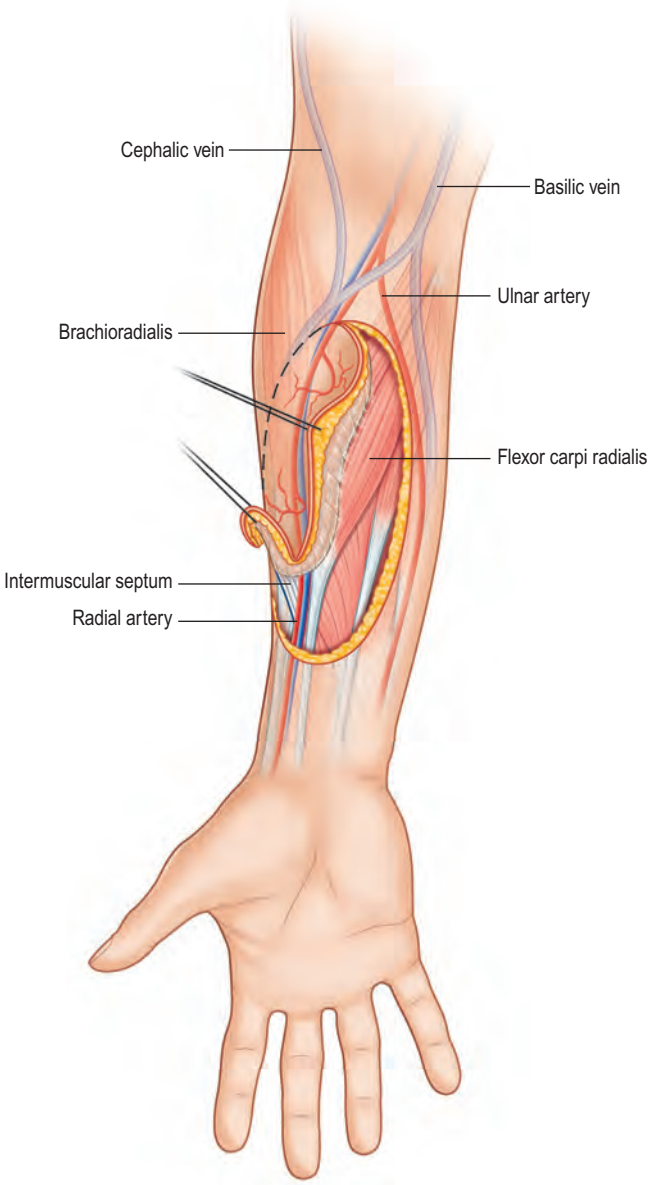

Fig. 12.17 Anatomy of radial forearm flap. This flap can be taken anywhere over the radial artery in the forearm, and can include skin, fascia, tendon, and bone.

The radial artery provides a large-caliber vessel for anastomosis and may be used for revascularization of the distal limb if necessary as a "flow-through" free flap. The venous drainage is through the dual concomitant veins of the radial artery; larger flaps can be drained by cutaneous veins. There has been some controversy as to the primary venous drainage of these flaps, but the venae comitantes offer reliable drainage even in the absence of superficial veins. This flap may be innervated by anastomosis of the lateral antebrachial cutaneous nerve, part of which is invariably in the flap. The quality of sensation in such reinnervated flaps is not great, but it may be useful. If the patient has a palmaris longus tendon, it may be taken in the flap as well and offers an excellent option for tendon reconstruction, especially on the dorsal hand. Because the tendon is taken with its surrounding tissue, it has excellent gliding when transferred as part of the flap. A portion of the volar radius may be harvested with the flap as well and is particularly useful in reconstruction of missing segments of metacarpal[35,36] (Fig. 12.18). The radial artery can be taken with the fascia only, which offers a thin flap that is particularly useful in reconstruction of the palm.

The advantages of this flap as a free flap are its thinness, its reliability (based on the radial artery), and the multitude of other tissues that may be harvested with it. The main disadvantage of this flap is the resulting donor site, which must usually be covered with a skin graft. The donor site is usually aesthetically unpleasing but causes few functional problems. Another relative contraindication to this flap is the loss of the radial artery, but studies have shown that significant problems are unusual. Cold sensitivity is seen but may be related to other factors. Whereas the radial forearm flap is an excellent free flap, it can usually be used as a distally pedicled island flap for hand reconstruction (Fig. 12.19). If this flap is not available for some reason as a pedicled flap, a skin flap is usually selected from another area, and a radial forearm flap is not taken from the contralateral uninjured arm.

Lateral arm free flap

This fasciocutaneous flap from the lateral distal upper arm is based on the posterior radial collateral artery, a branch of the profundus brachii.[37] This vessel runs with the radial nerve in the spiral groove and comes to lie in the posterior intermuscular septum between the brachialis and lateral head of the triceps (Fig. 12.20). It gives arterial supply to the skin overlying the septum as well as the underlying humerus (Fig. 12.21). Distal to the intermuscular septum, the posterior radial collateral artery has a rich system of anastomoses with vessels in the proximal lateral forearm, which will allow extension of the flap onto the proximal forearm. This flap can also be based distally for coverage of small to moderate defects of the elbow (Fig. 12.22). The pedicle for this flap is relatively short (5 to 7 cm), and the proximal artery has a small diameter (1.5 to 2 mm) compared with the flaps previously discussed. The length of the pedicle is limited by the fact that it exits the spiral groove with the radial nerve, and damage to this nerve must be avoided in the dissection. Acland and Shatford, in unpublished video demonstrations, have demonstrated a safe and effective method to significantly lengthen the pedicle through an alternative proximal dissection. The skin paddle can be based directly over the intermuscular septum for a smaller flap or extended distally for a larger one. Donor sites up to

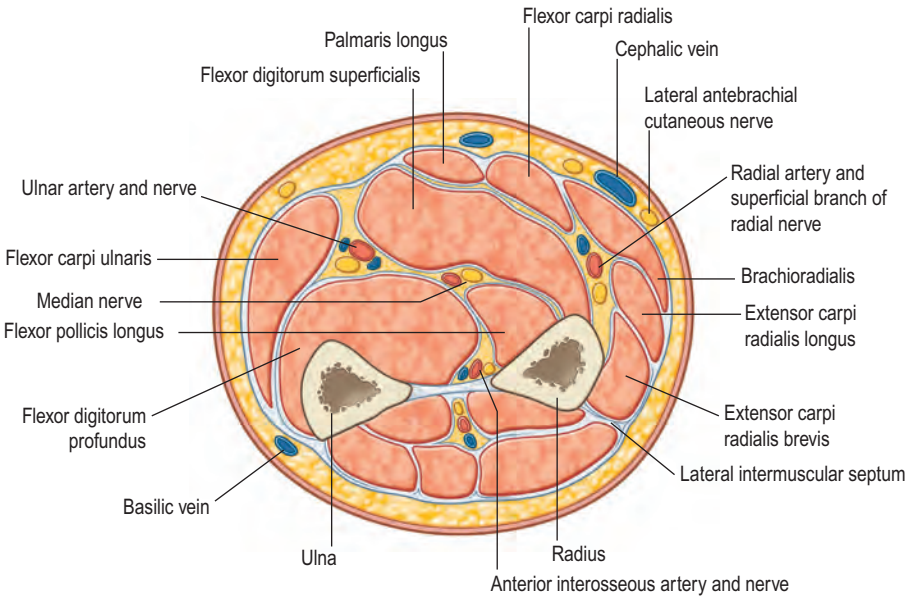

Fig. 12.18 Cross-section anatomy of the forearm. The radial forearm flap is based on the radial artery as it runs between the flexor carpi radialis muscle and the brachioradialis muscle. Muscle and/or bone may be harvested with this flap.

7 cm in width can be closed primarily, but larger ones require a skin graft.[38] When closed primarily, the donor site can be cosmetic, but the scar will widen significantly in some patients. The posterior cutaneous nerve to the arm may be taken to innervate the flap; the posterior cutaneous nerve to the forearm may be used as a flow-through vascularized nerve graft.[39] A portion of the lateral humerus can be taken with the flap for bone reconstruction, based on its vascular supply from the overlying pedicle.[40] The lateral arm flap is purported to be a "thin" flap, but because of the tissue in the intermuscular septum, it is a bit bulky when placed on a flat recipient site (i.e., the back of the hand). This problem can be avoided by using the fascia only, which also decreases donor site problems.[38,41] The primary advantages of this flap are that it can be taken from the ipsilateral arm (of injury) (Fig. 12.23), it avoids the sacrifice of a major vessel, it has the potential to serve as a multicomponent composite transplant, and the donor site can often be closed primarily. The primary disadvantages of the lateral arm free flap are its somewhat limited size, the short and small-diameter pedicle, the resultant contour deformity in the arm, and forearm dysesthesias. It is useful in coverage of small defects of the hand and works well in the first webspace (Fig. 12.24). In thin patients, it can be used to cover a degloving injury of the thumb with the added benefit of reinnervation through the cutaneous nerve. It has served nicely as a composite osteocutaneous flap to reconstruct multicomponent defects about the antecubital fossa and elbow.

Scapular flap

The scapular and parascapular flaps offer a versatile large skin flap for coverage of defects in the upper extremity.[42] The vascular supply is based on the circumflex scapular vessels that branch from the subscapular system.[43] The pedicle for this flap is long (4 to 6 cm) because the subscapular vessels can be taken if necessary, and this provides vessels of large diameter at the takeoff from the axillary artery. The vessels lie in the fascia with branches to the overlying skin. There are two primary branches, giving rise to the "transverse" scapular flap, which is sited transversely across the back, and the "parascapular" flap, which is sited obliquely down the back (Fig. 12.25). Based on this vascular supply, a large skin flap can be designed that will cover most defects of the forearm and arm.[44] Although a number of cutaneous nerves enter the skin, there is not a dominant nerve to this area, and thus this flap has poor potential for innervations. Branches from the primary pedicle feed the lateral surface of the scapula, and a portion of this bone can be taken to repair bone defects. This bone is flat, however, and its primary indication is reconstruction of smaller defects in the hand. Donor sites in the 8 cm range can usually be closed primarily, but this is usually limited to the parascapular design of the flap.

The primary advantages of this flap are the length and diameter of its pedicle along with its potential large size. The primary disadvantage of this flap is the need for turning the patient to harvest it. The scapular flap is an excellent choice for coverage of large wounds of the forearm and can be used in place of a pedicled groin flap for hand coverage (Fig. 12.26). It can be combined with the latissimus dorsi and serratus anterior muscle flaps on a single pedicle to provide a huge amount of tissue and for coverage of different surfaces of the hand and arm.[44] Fascia alone can be harvested if back skin and subcutaneous tissue is deemed too bulky for an effective transfer.

Temporoparietal fascia flap

The temporoparietal fascia offers a flap of specialized tissue that has great utility in reconstruction of the hand.[20] This flap is supplied by the superficial temporal artery and vein and has a pedicle in the 2- to 3-cm range, which is about 1.5 to 2.5 mm in diameter[45] (Fig. 12.27). The temporal fascia lies on the temporal region of the skull, beginning on the zygoma and running superiorly. There is a larger superficial layer as well as a deep temporal fascial layer, and both may be taken with this flap. The use of both layers of fascia has been promoted for wrapping adherent tendons on the dorsum of the hand

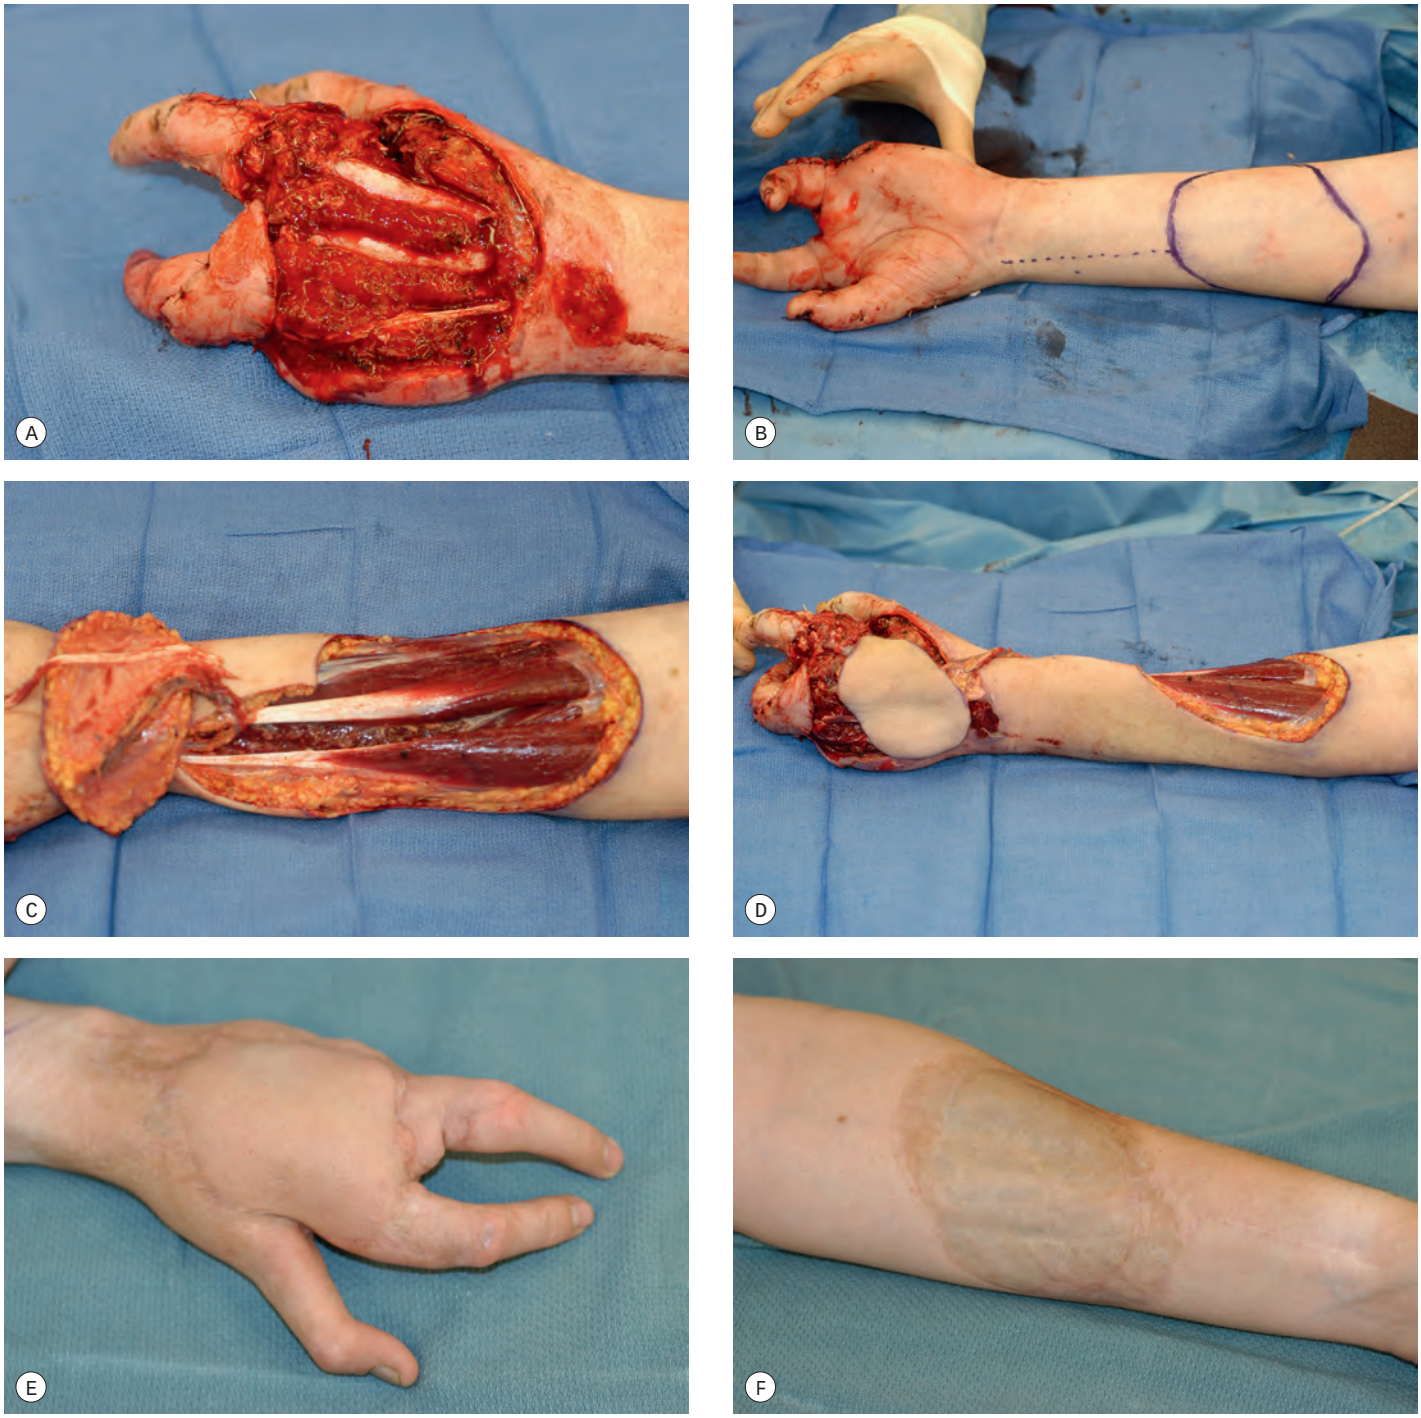

Fig. 12.19 **(A)** Degloving injury in 13-year-old boy after automobile roll-over injury. Patient and family refused pedicled groin flap coverage. **(B)** Outline of distally-based pedicled radial forearm flap for coverage of wound. **(C)** Flap elevated. Fig. 12.21 Dissection of lateral arm free flap.

after tenolysis in a scarred bed. The deep fascia can provide tissue for reconstruction of small tendons on the dorsal hand as well. A flap of moderate dimensions may be taken, in the 8- to 10-cm range. The potential for harvesting vascularized bone with this flap exists, but the thin, outer table bone available has little indication in the hand. Although the donor scar is one of the best in terms of cosmesis, the problem of alopecia exists because the superficial fascia must be dissected from just beneath the hair follicles of the scalp.

The primary advantages of this flap include the potential to provide a gliding surface and a donor site that is one of the best in terms of cosmesis. The primary disadvantage of this flap is that it is thin and must be covered with a skin graft. The frontal branch of the facial nerve can be injured in its dissection. Temporoparietal fascia offers nice coverage for defects of the fingers and hand, but the size of the flap is limited.[46] This tissue does seem to improve the gliding ability of tendons, particularly on the dorsum. When covered with a split-thickness skin graft, the temporoparietal fascia flap offers the thinnest coverage available (excluding other fascial flaps) (Fig. 12.28).

Anterolateral thigh flap

The anterolateral thigh flap is a more recently popularized flap which has application in reconstruction of wounds in the hand. It is based on the descending branch of the lateral femoral circumflex artery in the thigh, and can be taken with a large skin paddle, fascia, and potentially muscle (Fig. 12.29). This flap was originally thought to be a septal perforator type of flap, but it is well-recognized now that most of these flaps are supplied by intramuscular perforators through the vastus lateralis muscle.[47] Donor sites in the 6–7 cm width range can be closed primarily, but larger flaps will require a skin graft for the donor site. This flap can supply a large amount of tissue for coverage, and the fascia may be useful in reconstruction of tendons (i.e., the distal triceps tendon). It can also be utilized to revascularize the distal extremity as a flow-through flap via the descending branch which also supplies the flap.[48] When placed on the hand, the flap can be thinned rather radically to obviate a too-bulky piece of tissue.[5]

The flap is designed by marking a line from the anterior superior iliac spine to the lateral border of the patella. This should roughly follow the septum between the rectus femoris and the vastus lateralis. The primary perforators are located roughly half the way down this line. While some design the flap without identifying the perforators,[49] we prefer to utilize a pencil Doppler to locate the primary perforators along the medial border of the vastus lateralis. Once the central axis of the flap is laid out, the dissection begins by raising the medial aspect of the flap. This is raised over to the intermuscular septum between the rectus femoris and vastus lateralis, which is inspected to see if there are any perforators present. The dissection then proceeds from medial to laterally over the vastus, and great care must be taken to lift the flap very carefully and identify and preserve any and all perforators coming through the muscle and fascia lata into the skin paddle. Once these perforators are identified, the lateral edge of the flap can be incised and the remainder of the flap lifted. The perforators are then carefully dissected out of the muscle down to the level of the descending branch of the lateral femoral circumflex vessels. Once these

Anastomosis was to radial artery in anatomic snuffbox.

are dissected out, the flap pedicle can be ligated and the flap moved.

The primary indication for the anterolateral thigh flap is in large defects of the forearm and/or hand (Fig. 12.30). As noted above, it can be utilized for distal revascularization as well. The donor site is generally well-tolerated, even if it has to be grafted.[50] The primary downside of this flap is that it tends to be bulky, particularly in obese patients.

Free flaps – muscle flaps

Latissimus dorsi

The latissimus dorsi muscle is a large muscle of the back and shoulder, and its vascular supply for free transfer is based on the subscapular–thoracodorsal system[51,52] (see Fig. 12.25). The pedicle is lengthy (8–11 cm) and has a relatively large diameter proximally (up to 6 mm). This is the largest single muscle available for transfer, and its area of coverage can be expanded by including a portion of the serratus anterior muscle by its nourishing branch that arises from the thoracodorsal artery.[53] It can be used as an innervated muscle because of the single thoracodorsal nerve,[54] but the latissimus is generally used in the upper limb for coverage of large, degloving-type wounds (Fig. 12.31).

The advantages of this muscle are that it has a totally reliable vascular supply and is very large. Its primary disadvantage is that the patient must be turned in the lateral decubitus position for harvest of the muscle. If the contralateral muscle is taken, the patient can be turned on the side and the injured arm can be prepared simultaneously with muscle harvest (assuming that appropriate surgical assistance is available). It can be taken as a musculocutaneous flap or harvested with the entire subscapular axis to include up to two muscles (latissimus and a portion of the serratus anterior), a fasciocutaneous paddle, and vascularized bone; but for most indications in the upper extremity, the muscle only is taken and covered with a split-thickness skin graft. The donor site is easily closed, but seroma formation is a common sequela of this donor site. The functional morbidity from the loss of muscle is minimal in most patients, but its use should be avoided in patients who must adduct the arm strongly (crutch-walkers and paraplegics).

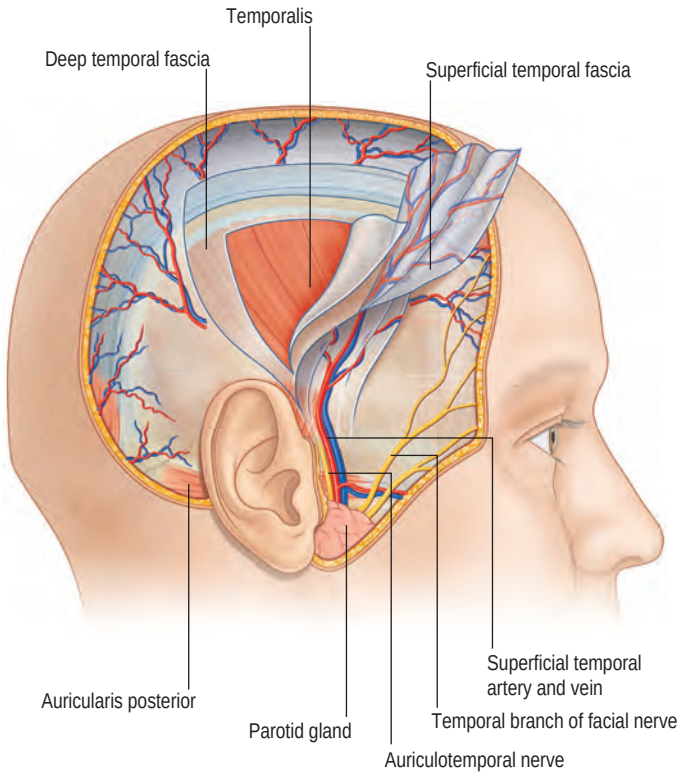

Fig. 12.27 Anatomy of the temporoparietal fascia.

Rectus abdominis

The rectus abdominis is a muscle widely used in microsurgery, primarily today as the transverse rectus abdominis muscle flap and perforator variants for breast reconstruction. This muscle is on the anterior abdominal wall and runs from the medial lower ribs to the pubis. It lies in a sheath composed anteriorly of continuations of the external and internal oblique muscle layers. The posterior sheath is a continuation of the transversus abdominis but is quite thin in the lower abdomen (below the linea semicircularis). It is a fairly large muscle and has a reliable vascular pedicle based on the deep inferior epigastric system. The pedicle is fairly long (5 to 7 cm) and the diameter fairly large (2.5 to 3 mm).

The rectus abdominis muscle will cover most defects of the hand and/or forearm,[55,56] and it will cover large defects of the forearm if most of the muscle is harvested and placed "barber pole" fashion around the arm.[57] The advantages of this muscle are that it has a reliable vascular pedicle and may be taken with the patient supine. The disadvantage of this muscle is that a hernia can result from its harvest if fascia is taken (for a myocutaneous flap) or if the anterior sheath is weak. For coverage of the upper extremity, this muscle is usually harvested without a skin paddle and covered with a split-thickness skin graft. The muscle can actually be harvested as a pedicled flap and placed on the forearm in rare situations where microsurgery might be difficult or pose other problems (Fig. 12.32).

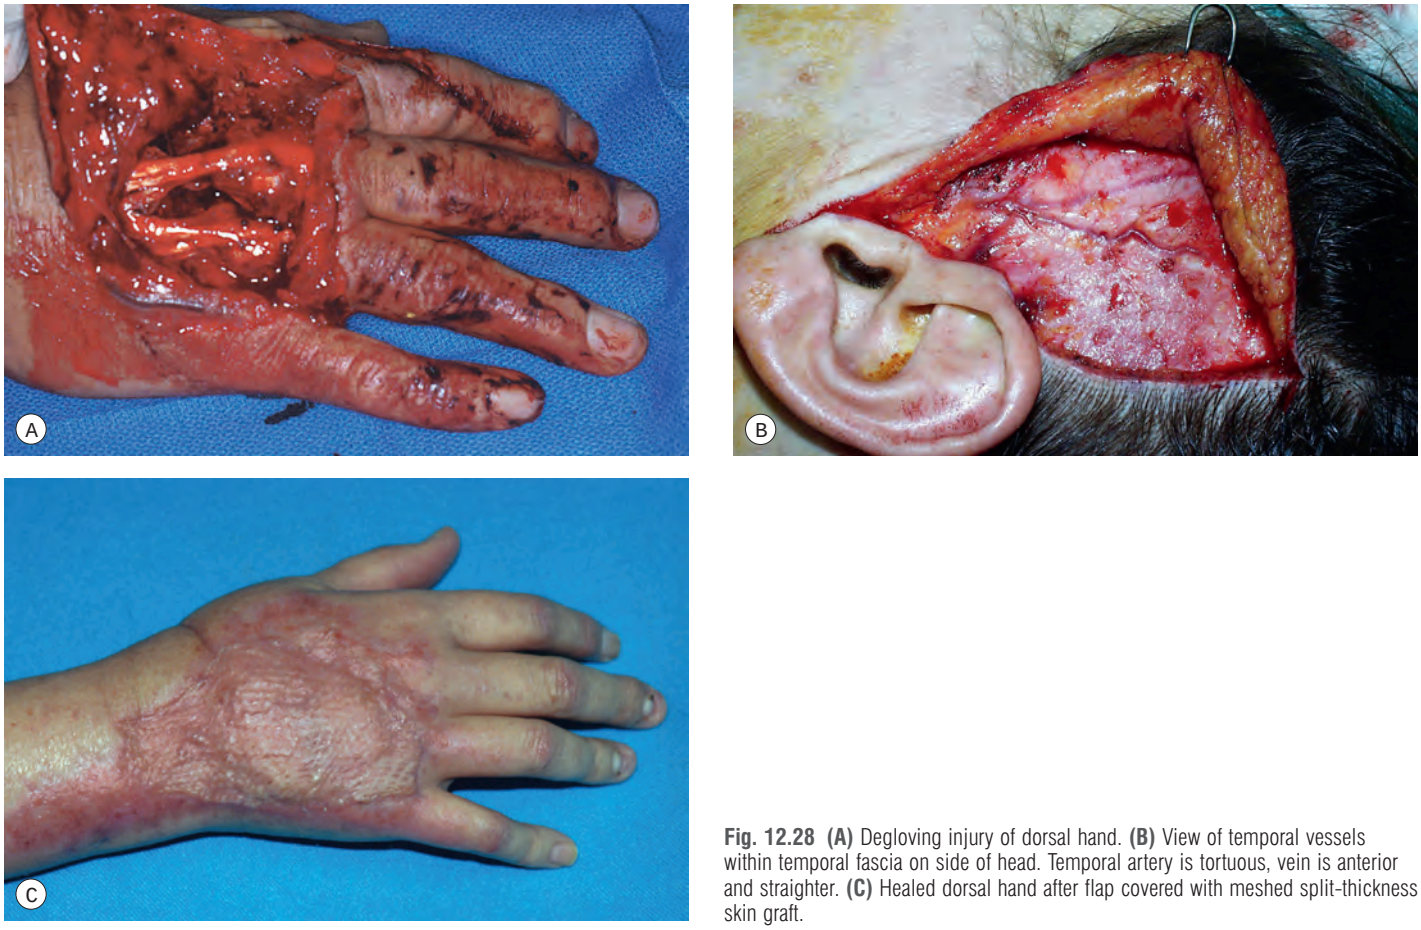

Fig. 12.28 **(A)** Degloving injury of dorsal hand. **(B)** View of temporal vessels within temporal fascia on side of head. Temporal artery is tortuous, vein is anterior and straighter. **(C)** Healed dorsal hand after flap covered with meshed split-thickness skin graft.

Serratus anterior

This muscle is useful for coverage of smaller hand defects.[53,58] It consists of nine slips of muscle that connect from ribs at the anterior axillary line to the tip of the scapula. The lower slips are vascularized by a branch coming off the thoracodorsal artery; the upper slips are vascularized by a branch of the lateral thoracic artery. The lower three slips may be taken individually or together as a free muscle flap based on the thoracodorsal pedicle. This dissection is tedious because branches of the long thoracic nerve may be intertwined with the vessels, and damage to the nerve supplying the remaining slips of muscle can lead to winging of the scapula.[59] The branch to the serratus is usually taken with the proximal thoracodorsal vessels, both for lengthening the pedicle and because of the larger diameter of the proximal vessel. This can give a lengthy pedicle (15 to 17 cm) with a large diameter (3 to 6 mm) (see Fig. 12.25).

The primary advantage of this muscle is its small size and lengthy vascular pedicle. The disadvantages of this muscle are the potential for long thoracic nerve injury and the decubitus position necessary for harvest. This flap can be used for coverage of the dorsal or palmar hand and first web space. It has the potential for innervation through a branch of the long thoracic nerve, but this application would be limited in the upper extremity.

Clinical tips

Flap selection

- Wound factors
  - Is the wound clean or relatively dirty?
  - Will you need to perform further surgery through or under flap?
- Patient factors
  - What donor site morbidity is acceptable to the patient?
  - Soft-tissue reconstruction only vs. composite tissue transfer
- Surgeon factors
  - Which flap(s) are you comfortable with and can you transfer reliably?

Postoperative care

In the immediate postoperative period, the extremity is splinted in an appropriate position to prevent capsuloligamentous shortening and tension on repaired structures.

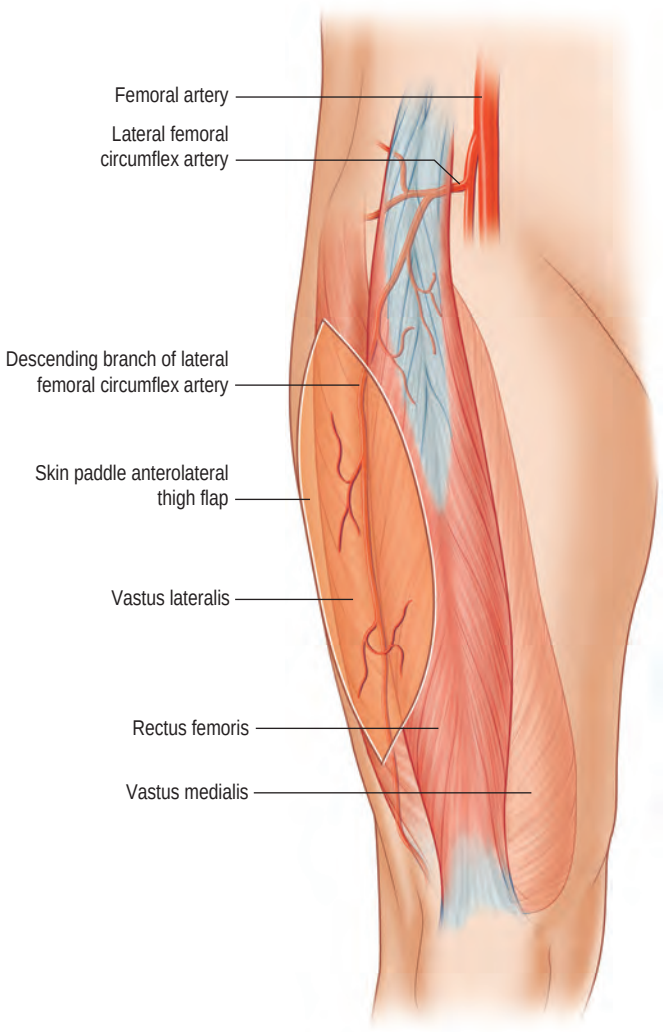

Fig. 12.29 Anatomy of descending branch of lateral femoral circumflex artery and anterolateral thigh flap. This flap offers one of the largest cutaneous free flaps available, and can be taken with vascularized muscle and/or fascia.

Elevation is necessary to reduce edema and help control pain. The patient's pain and anxiety should be adequately controlled. The ambient temperature should be at least 25°C and adjusted to the patient's body temperature. Hydration should be sufficient to maintain urine output between 80 and 100 mL/hr. Anticoagulant therapy is used by many surgeons. However, the authors are selective in using either heparin or dextran;[60] aspirin is used daily for 4 to 6 days after surgery. Appropriate antibiotic therapy is continued and later modified according to the culture results.

Flap monitoring is critical. Early recognition of arterial hypoperfusion or venous congestion will occur only in a well-monitored environment, with trained nursing staff. If there is a question about tissue viability, the dressings are released and the entirety of the revascularized tissue is exposed for further assessment of perfusion, congestion, temperature, turgor, and color and Doppler examination. Release of the dressings alone may be sufficient. If viability is still in question after 30 minutes, immediate re-exploration and further assessment may prevent failure of the revascularized tissue.

Early and motivated rehabilitation of the extremity is an important factor in achieving a successful outcome. Early motion reduces edema, adhesions, and scarring. It prevents muscle atrophy and facilitates healing of the soft tissues by remodeling of collagen fibers. The details of the rehabilitation program are determined by the existing injuries and the reconstruction procedure.

Outcomes, prognosis, and complications

Reconstruction of complex hand injuries remains a challenge. The ultimate desired outcome is "normal" function of the hand and upper limb, but this can rarely be obtained. Actual outcome studies in terms of the management of these injuries are very limited, however. Based on the few studies available, the primary determinants of the quality of eventual function are the severity of nerve injury and the need for emergency fasciotomy (which may lead to functional muscle loss).[61] Likewise, it is not surprising that outcomes have been shown to be better in younger patients, both from their ability to recover function and to adapt.[62] del Pinal has suggested that the initial goal in reconstruction of mutilating hand injuries should be the "acceptable hand", which he defines as a hand with three fingers, near normal length, near normal sensation, and a functional thumb.[14] This would seem to be a reasonable approach in these severe injuries, however it is not always obtainable.

There are many complications that can arise in the management of these injuries, with the early problems centering around infection. As noted above, this can be largely mitigated by early and thorough debridement, with return to the operating room frequently in the early period to re-assess the wound and to perform more debridement of nonviable tissues as necessary.[63,64] Appropriate antibiotic coverage is helpful, but is not a substitute for debridement. While the principle of "early" coverage in the first days after injury was proposed by Godina and has been the gold standard for nearly 25 years,[17] recent experience with the management of war wounds in the conflicts in the Middle East has proven that wounds can be safely and properly managed in a delayed fashion. These studies have shown that early debridement, followed by wound management with negative pressure therapy can temporize and decrease the infection rate in heavily contaminated wounds. The results of management of patients in this fashion is equivalent to that with early coverage in most instances.[65–67] These patients also suffer from the complications (or more properly labeled "sequelae") found in any injury to the hand or upper extremity, including tendon adhesions, poor nerve recovery, bony problems (malunion and/or nonunion), etc. These are managed by the surgeon in standard fashion, but particular problems will be addressed below.

Secondary procedures

Free fibula transfer

Most bone defects in the upper extremity can be managed with standard bone grafts; however, long defects (>6 cm) and

Fig. 12.30 **(A)** Forearm of patient who suffered severe electrical burn with loss of all volar musculature. Plan is for coverage with free anterolateral thigh flap and placement of tendon rods followed by innervated muscle transfer and tendon grafting. **(B)** Markings on leg for flap. Hip is to the right and knee to the left in this view. **(C)** Forearm and hand after placement of tendon rods and pulley reconstruction. **(D)** View after vascular anastomosis and insetting of flap. **(E)** Hand and forearm after three months prior to innervated gracilis transfer.

Fig. 12.31 **(A)** View of patient's elbow with wound breakdown after total elbow replacement for traumatic fracture/dislocation. **(B)** Patient after wound debridement, and pedicled latissimus dorsi for coverage. **(C)** Close-up of muscle in wound. Note that there is plenty of length to reach beyond the elbow proper.

those associated with recurrent nonunions may be candidates for microvascular bone transfer.[68] Whereas several flaps are available that can include a portion of vascularized bone (iliac crest, scapula, lateral arm, radial forearm, dorsalis pedis), the fibula osseocutaneous flap offers the best piece of bone for reconstruction of significant defects of the long bones of the upper extremity.[69,70] Smaller defects, such as those in the hand, can be managed by one of the previously discussed flaps with inclusion of a segment of bone. Larger defects of the radius, ulna, or humerus will usually require a piece of bone such as the fibula[71,72] (Fig. 12.33). The vascular supply of the free fibula is based on the peroneal vessels of the leg. These vessels run along the deep surface of the fibula from just below the tibioperoneal trunk to the level of the ankle. Whereas the peroneal vessels provide an endosteal nutrient artery to the medullary canal of the fibula, they also provide rich periosteal blood supply to the cortical surface. The proximal portion of the fibula can be taken for reconstruction of the radiocarpal joint, but this segment of bone gets its primary blood supply from a branch of the anterior tibial artery,[71] which must be taken to ensure viability of this segment. The proximal portion can be taken with the vascularized epiphysis in children to promote later growth,[73] and this application will be discussed further in Chapter 30.

A portion of the skin overlying the fibula can be taken with the bone, and thus compound defects can be managed with this flap. The perforators to the skin run around the posterior aspect of the bone, and thus it is best to include a cuff of muscle along the posterior surface of the bone if a skin paddle is to be included. If a skin paddle is taken, most donor sites will require a skin graft on the overlying muscles. The primary advantage of this donor site is the large amount of bone that can be taken. In adults, a total of up to 24 to 26 cm of bone may be harvested. The fibular head should be left in place at the knee level, and 6 cm of the distal fibula should remain to avoid problems with the ankle. In children, a screw should be placed across the distal fibular–tibial joint to avoid proximal migration of the fibula. The disadvantages of this donor site are few; the pedicle is relatively short (2 to 4 cm) and there is some morbidity from harvesting, but this usually does not present functional problems.

Fig. 12.32 **(A)** 33-year-old patient after forearm amputation and coverage with latissimus dorsi muscle flap. Hand is supplied by vein grafts as is latissimus flap. **(B)** View of rectus abdominis muscle being raised proximally as a pedicled flap. **(C)** Flap after insetting on arm. **(D)** Flap healed at four weeks. **(E)** View of flap at three months after division.

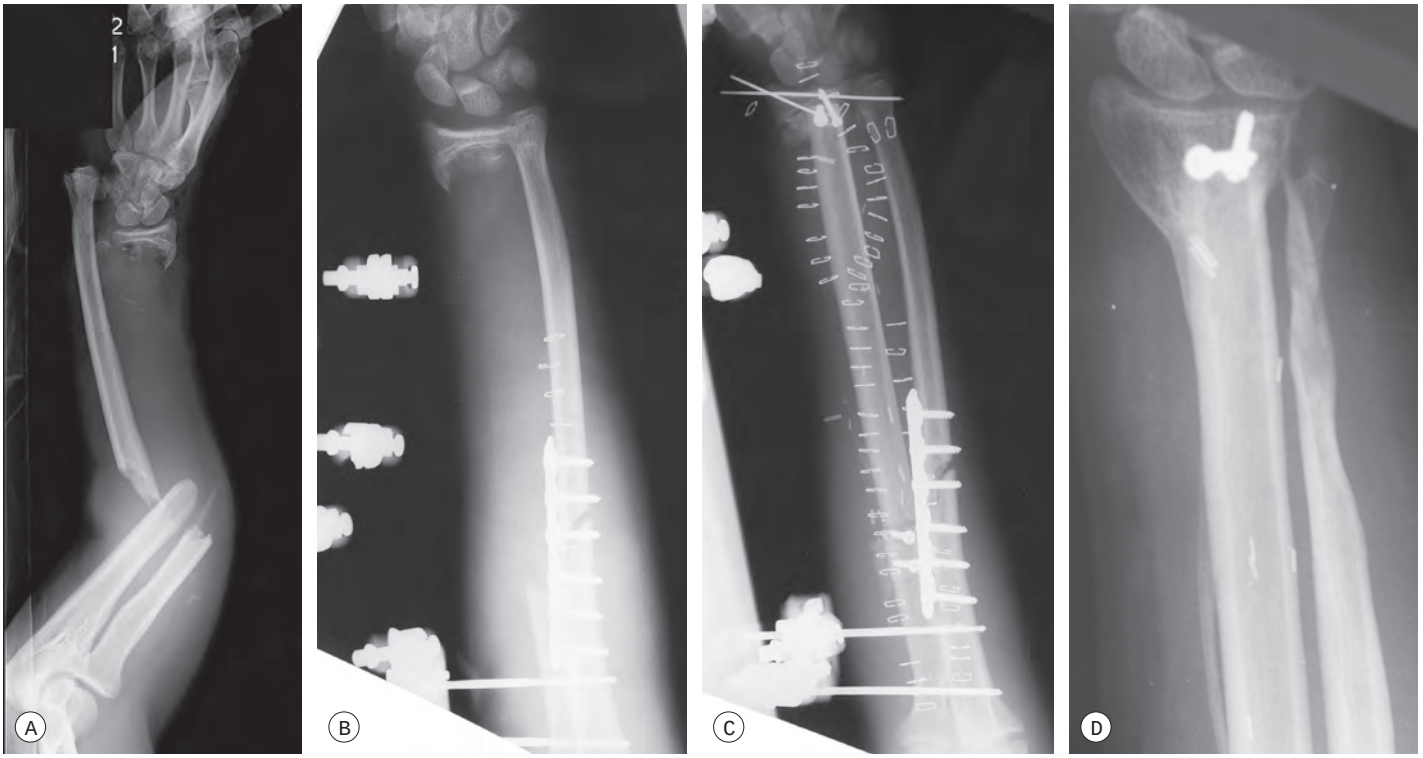

Fig. 12.33 **(A)** X-ray of forearm of 15-year-old male after automobile accident with loss of majority of radius through open fracture. **(B)** X-ray view of arm after external fixation to align bones. **(C)** X-ray after vascularized free fibula transfer to reconstruct defect of radius. **(D)** View of X-ray at six months. Note interface between fibula and distal radial remnant. (Patient developed osteomyelitis of distal ulna and required long-term intravenous antibiotics, but functionally had no problems from this.)

Digital reconstruction with toe transfer

Microvascular toe transfer represents one of the pinnacles of reconstructive surgery. The ability to replace in kind a missing digit with a mobile, sensate toe offers the best type of reconstruction available. Although this is a complex microsurgical procedure that should not be undertaken without experience,[74] it remains the benchmark for thumb and most digital reconstructions (Fig. 12.34). There are a number of variations of toe transfer, and almost any tissue needed for digital reconstruction can be transferred. These range from pulp-only transfers to double second- and third-toe transfers to reconstruct the metacarpal hand.[75,76] All great- and second-toe transfers ideally have their vascular basis on the dorsalis pedis–first dorsal metatarsal system. This anatomy is highly variable, however, and a thorough knowledge of this is the basis for safe harvesting of these flaps. The venous drainage is based on dorsal superficial veins of the foot; the deep system that accompanies the arterial supply is usually very small.[77] The flaps can be innervated by the proper plantar digital nerves to the toe as well as by the deep peroneal nerve that accompanies the dorsalis pedis–dorsal metatarsal vessels. The actual details of all the complexities of digital reconstruction with toe transfer is beyond the scope of this chapter, but

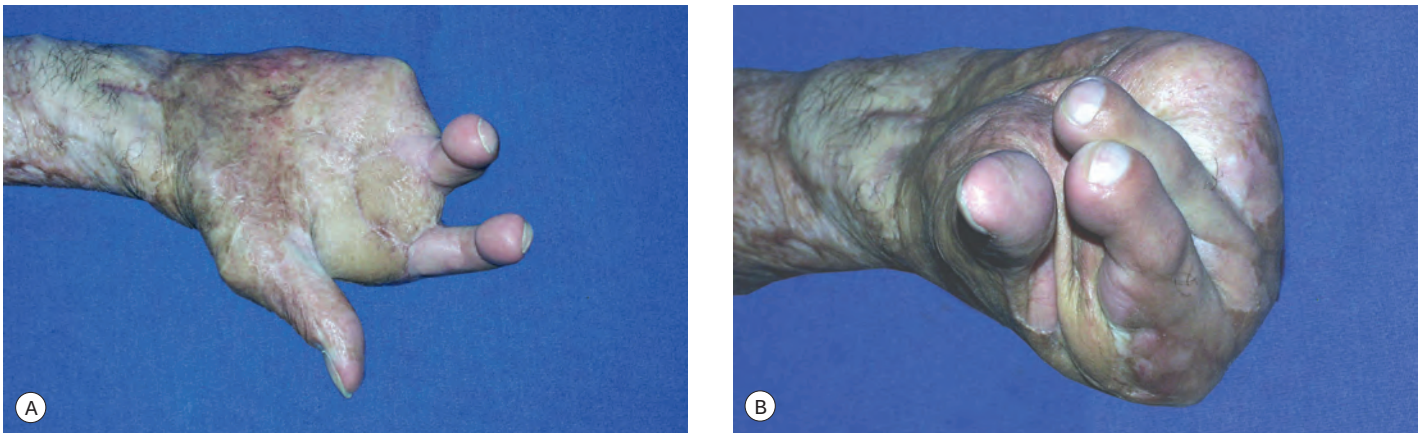

Fig. 12.34 **(A)** Hand of fireman, who lost fingers due to burn injury, after two second toe transfers for digital reconstruction. **(B)** Flexion of toes. Note good motion at native metacarpophalangeal joints but rather poor motion of interphalangeal joints of toes.

the reader is referred to several excellent review articles on this subject.[75–77] Toe transfer for thumb reconstruction is discussed in detail in Chapter 14.

Innervated muscle transfer

In the case of loss of functional muscle in the forearm, the options for reconstruction of this function are either tendon transfer or innervated microvascular muscle transfer. Although many losses can be adequately reconstructed with standard tendon transfers, patients with significant loss of muscle substance (such as those with Volkmann ischemic contracture) may benefit from reconstruction of function with a microvascular muscle transfer.[78] The muscles available for this include the gracilis, latissimus dorsi, and rectus femoris. The latissimus dorsi can be used in the forearm as a free functional transfer,[79] but it is not ideal. It is better suited as a replacement for elbow flexion when biceps function is lost. In this case, a pedicle transfer is perfectly adequate. The rectus femoris has been used for this in the past, but again, it is not the optimal muscle due to its short excursion. The gracilis muscle, on the other hand, is nearly ideal for reconstruction of the muscles of the forearm. It has adequate excursion to provide finger flexion or extension, it is of appropriate size (both length and width), and it has an excellent neurovascular pedicle. The reader is referred to Chapter 35 for the details of this procedure.

Future directions

Reconstruction of severe mangling hand injuries can be very frustrating, particularly if complications are encountered. Loss of replanted or transplanted tissues can lead to increased infection rates, fibrosis, and stiffness. These are all the enemies of the hand surgeon, but there are times when they cannot be avoided and/or adequately treated. Prevention of these injuries is undoubtedly the best approach, but this goal remains elusive. This is especially true when one considers that despite all of our technology, many industries (drilling for oil and heavy manufacturing come to mind) still rely on the versatility of the human hand to guide the machines. These hands are put in harm's way on a daily basis, and until such activities can be truly completely automated, mangling hand injuries will unfortunately be with us.

Probably the most promising development in the last several years has been the successful transplantation of hands and arms in patients. Most of these individuals have had bilateral amputations or injuries, and some have suffered the loss of their lower limbs as well. Despite early enthusiasm, this area has not grown particularly, and while many centers have set up "hand transplant" programs, few have proceeded. This is undoubtedly due to the relative lack of appropriate donor hands and ongoing concerns about immunosuppression. Despite the protestations of those who have performed hand transplants, the issues involving rejection, infections, and other systemic metabolic conditions related to the immunosuppression remain problematic. Barring a major breakthrough in immunosuppressive regimens to make these drugs less likely to cause side effects, the authors do not see hand transplantation as currently offering the best solution in *most* cases of mangling hand injuries.

Fortunately prosthetic options in the hand are improving, and with approaches including targeted muscle reinnervation and the work being done on allowing prosthetics to have sensory feedback, these may offer better solutions for missing digits and hands in the future. The primary issue with these advanced prosthetics is their cost, and the fact that the more sophisticated the prosthetic, the less able it is to withstand the wear and tear of daily use.

Tissue engineering may hold hope for the future, but engineering all or a portion of a hand (bones, tendons, nerves, soft tissue) from a scaffold of collagen or a 3D printer remains, the authors believe, a far distant hope.

Thumb reconstruction: Non-microsurgical techniques

Nicholas B. Vedder and Jeffrey B. Friedrich

Access video and video lecture content for this chapter online at expertconsult.com

SYNOPSIS

- Thumb reconstruction should aim to restore the cardinal thumb actions: mobility, stability, sensibility, length, and appearance.
- Level of thumb loss is divided into thirds: distal (tip to interphalangeal joint), middle (interphalangeal joint to metacarpal neck), and proximal (metacarpal neck to carpometacarpal joint).
- Distal third reconstruction typically requires only soft-tissue restoration.
- Numerous options exist for middle-third reconstruction, including increasing thumb ray length (metacarpal lengthening, osteoplastic reconstruction) and increasing relative length (phalangization).
- Proximal third reconstruction may be accomplished with pollicization or on-top plasty (pollicization of a damaged index finger). However, microsurgical reconstruction (discussed in Chapter 14) is preferred at this level.

Introduction

- When thumb loss occurs due to trauma, replantation is the best method of reconstruction for many patients. When replantation is not possible, thumb reconstruction is warranted.
- The level of thumb amputation guides the type of reconstruction. Determination of level of loss is based on physical examination and radiographs.
- Any thumb reconstruction method requires input and acceptance by the patient. The reconstruction should be tailored to the patient's personal and professional needs. Because significant rehabilitation may be required, the patient must be a willing participant in both the reconstruction and rehabilitation.
- Functional compensation following distal-third thumb loss is easily achieved; therefore, reconstruction at this level is chiefly soft tissue alone. Techniques such as the neurovascular advancement (Moberg) flap and the cross-finger flap remain reliable methods for reconstruction at this level.
- For losses in the middle third of the thumb, restoration of length is a priority. This can be done via absolute length restoration with metacarpal lengthening or osteoplastic reconstruction, or via relative length restoration using phalangization of the thumb.
- Proximal third thumb losses are best treated with microsurgical reconstruction. However, in some cases this may not be possible. In these situations, transfer of another finger can provide an excellent thumb replacement. A normal finger (typically the index) can be pollicized to become a thumb. A damaged index finger can also be transferred (on-top plasty) to become a stable post for opposition, pinch, and grip.
- Hand rehabilitation after reconstruction is absolutely necessary, especially following middle- and proximal-third reconstructions. Rehabilitation can last months, but allows the patient to regain motion and strength. For some procedures, such as neurovascular island flaps and digit transfer, sensory re-education is an important part of the rehabilitation.
- This chapter will provide a comprehensive description of non-microsurgical thumb reconstruction, including reconstruction decision-making, technical approaches, and post-reconstruction management.

Access the Historical perspective section online at http://www.expertconsult.com

Basic science/disease process

By far, the most common "disease process" necessitating thumb reconstruction is traumatic injury. The majority of these patients are working-age males. Within the larger trauma classification, thumb injury can be the result of a

Historical perspective

Littler extensively reviewed the history of thumb reconstruction, a field in which he has been a major contributor.[1] Nicoladoni introduced two techniques, namely, osteoplastic reconstruction and toe transfer through the pedicle method.[2] Guermonprez was among the first to pollicize a finger, a technique subsequently refined by the island principle, attributed to Littler and Gosset.[3–7] A mobile and sensate thumb was obtained, but at the price of sacrificing a finger. Matev originated the technique of progressive lengthening through distraction, maintaining good sensibility and improving length.[8,9] A major advance was the introduction of microvascular techniques, which led to microvascular free toe-to-hand transfer. First- and second-toe transfers were initially described, followed by refined techniques allowing the surgeon to improve the appearance of the reconstructed thumb while at the same time minimizing donor site morbidity.

variety of different mechanisms. These include sharp cut, avulsion, and crush. There are some mechanisms that have characteristics of more than one injury type. This phenomenon is best illustrated by saw and lawn mower injuries, which have both cutting and crushing components, resulting in a larger zone of injury.

Other insults that can result in thumb loss requiring reconstruction are infections and neoplasms. Because tumors are not acute events, thumb reconstruction planning can be more deliberate, and can even be performed at the time of tumor extirpation.[10]

Diagnosis/patient presentation

The diagnosis of thumb trauma is relatively straightforward, as there will be, in most cases, open wounds. It is important to obtain history regarding the mechanism and other details of the traumatic insult, time from injury to presentation, handedness, occupation, pertinent social issues (such as tobacco use), and pertinent medical problems (including problems that can compromise peripheral circulation and/or wound healing). If feasible, replantation of the amputated thumb will generally yield a thumb that is superior in appearance and function to any other type of thumb reconstruction. However, this is sometimes not possible, in which case, other reconstruction methods are employed.

Evaluation of the traumatically injured thumb requires complete evaluation of all tissues of the thumb including integumentary, neural, vascular, and musculoskeletal. The wound(s) on the thumb should be carefully inspected. The integrity of the sensory nerves supplying the thumb is assessed. Assessing any compromise in the circulation to the thumb is crucial, as is assessing the feasibility of arterial and venous reconstruction. Finally, assessment of the integrity of the thumb tendons and skeletal structures is performed. Radiographs are necessary to evaluate thumb skeletal structure.

Evaluation of the thumb following infection is similar to that following trauma. All tissues must be assessed, making particular note of the cutaneous defect requiring reconstruction.

Evaluation of a thumb affected by a tumor will be guided by the tumor itself. Specifically, tumor type and grade will determine the extent of extirpation that will need to be determined prior to reconstruction. This will also determine which procedures will be needed either intraoperatively (sentinel lymph node biopsy, lymphadenectomy) or perioperatively (radiation, chemotherapy).

Patient selection

Because there are many ways to reconstruct a deficient thumb, patients must be educated about the various options so that they may make an informed decision as to which type of reconstruction will serve them best in both the personal and professional settings.

Many thumb injuries occur in the workplace, and these patients will be affected by the injury because their work involves significant hand use. In these patients especially, it is essential to work toward a thumb that has adequate length for both gripping and pinching, is stable during activities, has reasonable motion, and, importantly, is sensate in order to give tactile feedback during these actions and to prevent recurrent ulceration or injury. That said, adequate length, stability, motion, and sensibility are the end-goals for any patient requiring thumb reconstruction, regardless of profession or vocation.[11]

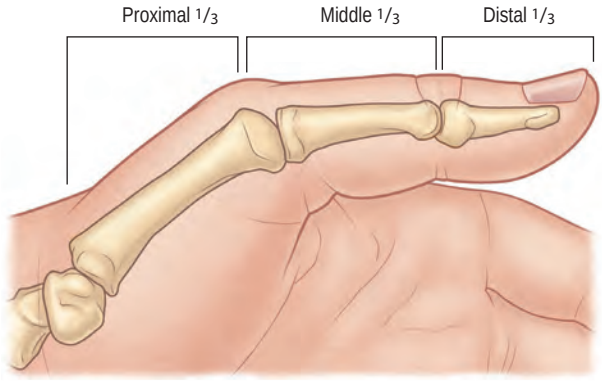

Fig. 13.1 Thumb loss classification, divided into thirds. Distal third is from thumb tip to interphalangeal joint. Middle third is interphalangeal joint to metacarpal neck. Proximal third is metacarpal neck to carpometacarpal joint.

In addition to patient input regarding reconstructive methods, the patient must also commit to the reconstructive process. Most of the reconstructive options will result in edema, stiffness, and pain in the near term; therefore, adherence to a supervised hand therapy program is critical to reconstruction success.

As with any type of reconstructive surgery, medical optimization prior to procedure(s) allows superior outcomes. This includes, but is not limited to, tobacco cessation, cardiopulmonary stabilization, and good diabetes control. If the thumb is being reconstructed following cancer extirpation, the physician must ensure adequate local disease control prior to reconstruction, and coordination of the patient's reconstruction with any systemic adjuvant therapies that will be required. Similarly, in patients for whom a thumb is deficient due to infection, infection control prior to reconstruction is paramount.

The most important factor in patient selection is the amount and nature of tissue loss that must be reconstructed. The level of amputation is the easiest way to classify thumb deficiencies, and is listed in thirds[12] (Fig. 13.1). The distal third extends from the interphalangeal joint to the thumb tip. The middle third is the portion between interphalangeal joint and the metacarpal neck, and the proximal third is from metacarpal neck to the carpometacarpal joint. Each amputation level presents unique challenges for patient and physician, and each level can be reconstructed with multiple modalities.

Treatment/surgical technique

Distal third

Thumb distal-third amputations rarely, if ever, require restoration of length, as a thumb amputated through the interphalangeal joint remains very functional.[12] Therefore, the chief goals of thumb tip reconstruction are soft-tissue coverage of

bone and length preservation. When there is no bone exposed at the tip of the thumb, closure can be achieved with either healing by secondary intention or skin grafting. Secondary healing of tip amputations has been shown to result in a stable scar and good two-point discrimination, and is therefore a relatively easy (and usually the preferred) method of achieving coverage.[13] Secondary healing by wound contracture has the advantage of bringing stable, sensate skin together to close the defect, as opposed to skin grafts, which remain insensate. Defects up to 1.5 cm in diameter with no bone exposure can be effectively treated with dressing changes. Daily dressing changes with petroleum or bismuth-impregnated gauze are relatively easy for patients. Larger defects with a stable base, however, require skin grafting. Full-thickness grafts are usually preferred, as they are more durable and stable, especially in the contact areas subject to pressure and shear. Small full- or split-thickness skin grafts can be harvested from the hypothenar eminence or the volar wrist crease. Larger skin grafts, however, are best harvested from the upper inner arm or groin crease.

When phalangeal bone is exposed at the thumb tip, vascularized coverage is required to preserve length, and there are several flaps that can accomplish these goals. The main criteria for flap selection are defect size and location of soft-tissue loss, specifically if it is volar, dorsal, or at the tip. The V–Y advancement flap described by Atasoy *et al.* provides good coverage of the tip of the distal phalanx when only a very small amount of bone is exposed[14] (Fig. 13.2). The technique involves incising the volar pulp of the thumb in a V shape. Scissors are then used to spread the subcutaneous tissue carefully. The subcutaneous attachments deep to the flap, which provide the neurovascular supply to the flap, are left intact. The flap is then advanced distally to close the defect and the proximal aspect of the V is closed side to side, thereby creating the Y shape of the final scar. In practice, there is limited application for this flap due to the limited advancement that is possible without devascularizing the flap.

The neurovascular volar advancement flap, which goes by the eponym of the Moberg flap, is well suited to cover volar and tip defects of the thumb.[11] It is often described as an advancement flap, but in reality, the amount of advancement achieved with the conventional rectangular Moberg flap is limited. Instead, the elevation of the flap allows flexion of the interphalangeal joint of the thumb, thereby allowing the flap to appear to "advance" distally (Fig. 13.3). To elevate the flap, one incises the mid-lateral lines on either side of the thumb, down to the base of the proximal phalanx. The flap is then elevated from the deeper tissues, directly off the flexor retinaculum, with sharp dissection. The flap includes both neurovascular bundles and all of the subcutaneous tissue down to the flexor tendon sheath. The interphalangeal joint is flexed, and the flap is inset at the tip. If necessary, a Kirschner wire can be placed across the interphalangeal joint to stabilize it, though this is seldom required. This flap can easily cover a defect of 1–2 cm^2 (Fig. 13.4). A variation of the Moberg flap is an island flap in which the flap is incised transversely across the proximal base, and the only remaining attachments are the two neurovascular bundles. The proximal gap at the base of the flap will then require a small skin graft. Alternatively, the proximal incision can be in the shape of a V, and following advancement, this can be closed in a Y, obviating the need for a donor site skin graft. Unlike the conventional Moberg flap, this method will allow a small amount of actual advancement, thereby covering more distal defects.[15,16]

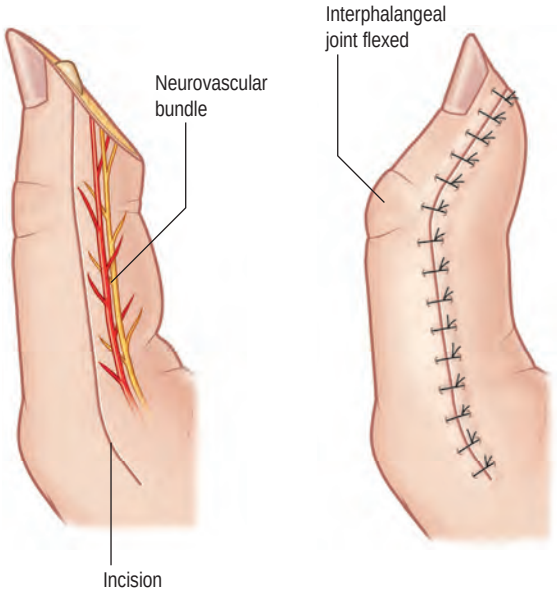

Fig. 13.3 Moberg thumb volar advancement flap. It is a sensate flap by virtue of the digital nerves remaining in the flap, and is perfused by the digital vessels.

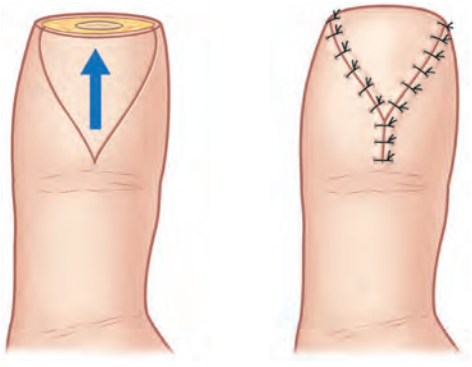

Fig. 13.2 Thumb tip closure via volar V–Y advancement flap. The flap is perfused by small vessels traversing the subcutaneous tissues immediately deep to the flap.

The cross-finger flap from the index finger is an excellent reconstructive technique for larger volar and tip defects of the thumb, up to 2–3 cm^2.[17] The tissue transferred is reliable and durable.[18] The chief disadvantages to this technique are iatrogenic syndactyly for 2–3 weeks, and the need for a skin graft on the index donor site. A radially based rectangular flap is marked on the dorsum of the index proximal phalanx that extends from the ulnar to the radial mid-lateral lines (Fig. 13.5). The flap is incised and elevated from ulnar to radial in the plane between the subcutaneous tissues and the extensor mechanism. It is critically important to leave the paratenon on the extensor to allow skin grafting. Upon reaching the radial aspect of the flap, one must release Cleland's ligaments along the length of the base of the flap to prevent kinking at the flap "hinge". The flap is then sutured to the thumb – this may require some trial and error to find the best flap orientation (Fig. 13.6). A full-thickness skin graft is then sutured to the dorsum of the index finger. A bulky thumb splint is

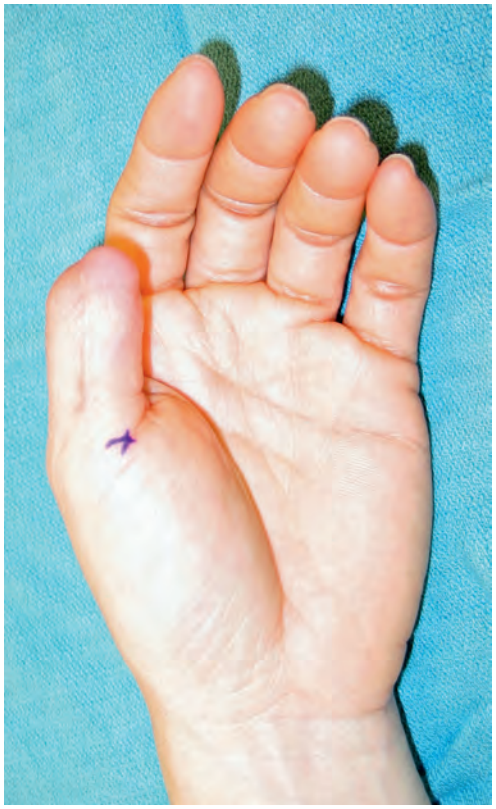

Fig. 13.4 Thumb reconstructed with a Moberg flap for a distal amputation. Note the flexed posture of the interphalangeal joint.

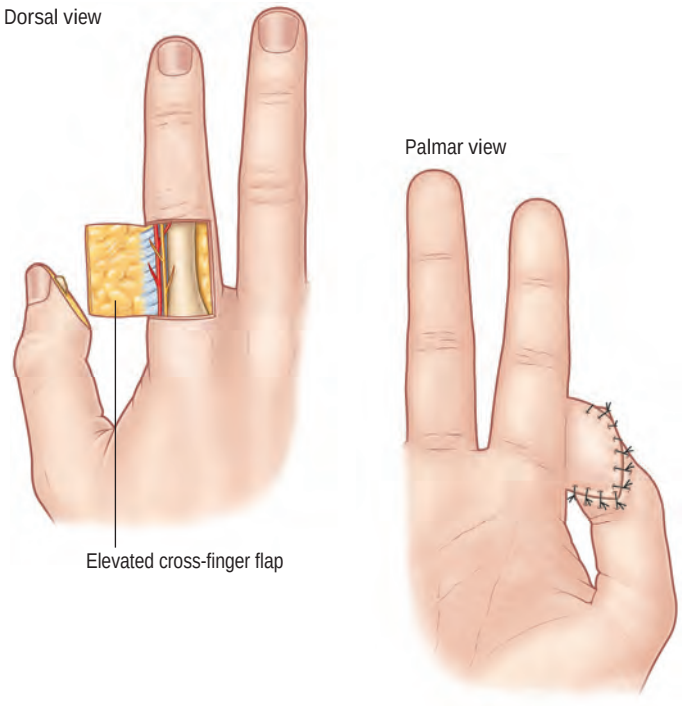

Fig. 13.5 Diagrammatic representation of the cross-finger flap to the thumb. The flap is elevated from the dorsum of the index finger proximal phalanx and inset to the thumb volar defect. Once elevated, Cleland's ligament of the index radial neurovascular bundle can restrain and kink the flap, therefore release of this ligament allows greater flap freedom.

Fig. 13.6 Thumb tip defect resurfaced with a cross-finger flap from the index finger.

applied. At 2 or 3 weeks, the flap is divided and the inset to the thumb is completed (Fig. 13.7). After division, aggressive range-of-motion therapy for both the thumb and index finger should begin.

The neurovascular island flap attributed to Littler is a valuable tool in thumb reconstruction.[19] It is rarely used as a primary coverage flap, although it is certainly possible to use it in that manner. Rather, its most common use is for the restoration of sensation to the thumb pulp following reconstruction.[19,20] The flap is based on the ulnar neurovascular bundle of either the middle or ring finger (Fig. 13.8). The ulnar side of the digit is chosen because its loss will have minimal effect on grip and pinch activities. The dimensions of the flap

Fig. 13.7 Reconstructed thumb following division of the cross-finger flap seen in Fig. 13.6.

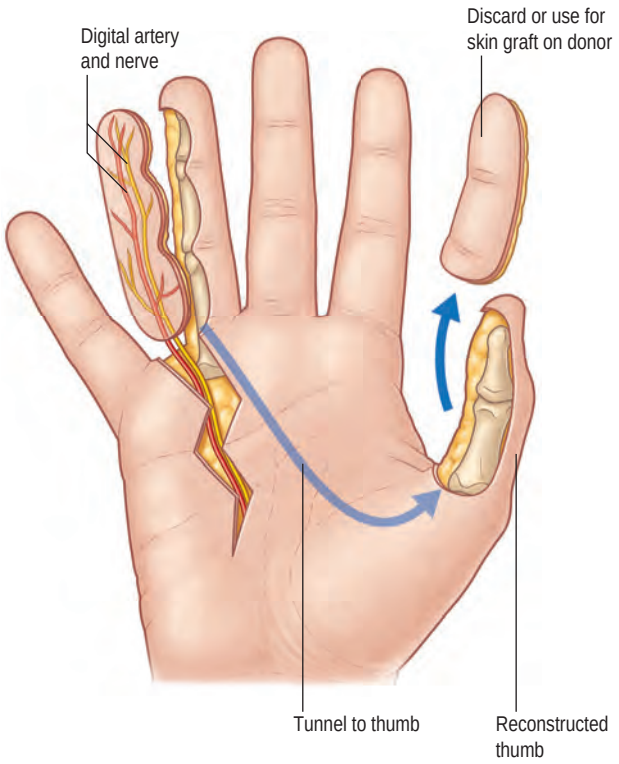

Fig. 13.8 Depiction of neurovascular island flap taken from ulnar side of ring finger. The flap will then be tunneled through the palm to the thumb to provide sensate reconstruction of volar thumb.

Fig. 13.9 Neurovascular island flap following dissection.

needed are marked on the ulnar pulp of the chosen donor finger. Often, the flap will require harvesting of skin over the distal and middle phalanges of the donor finger. The flap is incised, and a mid-lateral incision proceeding from the proximal aspect of the flap is made. The flap is elevated from distal to proximal, and the entire ulnar neurovascular bundle is elevated in continuity with the flap. It is critical to raise the neurovascular bundle with a fairly thick cuff of surrounding fatty tissue containing the vasa vasorum of the artery, as that is the only source of venous outflow for the flap. Failure to do this will result in flap congestion. One must dissect fairly proximally in the palm to allow adequate transposition to the thumb, and the other branch of the common digital artery (i.e., the radial digital artery to the ring or small finger) must be divided. The common digital nerve can be split along the fascicles to allow adequate flap mobility. The flap can then be transposed to the thumb either via subcutaneous tunnel, or a connecting incision from the donor site to the thumb can be made (Fig. 13.9). The flap is then inset into the volar defect of the thumb. The donor site is grafted with full-thickness skin. In addition to postoperative restoration of motion, patients must work with a hand therapist on sensory re-education of the thumb.

The proximally based first dorsal metacarpal artery (FDMA) flap is an excellent tool to achieve thumb coverage, although it is better suited for dorsal or lateral thumb defects than palmar defects[21,22] (Figs. 13.10–13.12 and Video 13.2 ▶). Its harvest causes virtually no donor site functional loss. The FDMA is found using a conventional Doppler device, beginning proximally with the radial artery at the anatomic snuffbox. The radial artery then branches into the princeps pollicis artery radially and the FDMA ulnarly. At approximately the metacarpal head level, the artery then becomes difficult to trace further distal. The flap is then centered over the FDMA (Fig. 13.13). The flap is incised and dissected from distal to proximal, leaving paratenon over the extensor mechanism for later skin grafting. To ensure inclusion of the FDMA with the flap, it is imperative to incise the thin fascia over the first dorsal interosseous muscle and include it with the flap. Once the flap is elevated and the proximal vascular leash fully mobilized, it can then be tunneled to the thumb in the subcutaneous plane, or a connecting incision can be made. The donor defect is then closed with a skin graft. It is critical to raise the vascular pedicle of the FDMA flap with a fairly thick pedicle of surrounding fatty tissue containing the venae comitantes of the artery, as that is the only source of venous outflow for the flap. It is possible to innervate the FDMA flap by suturing a branch of the radial sensory nerve in the flap to a digital or radial sensory nerve in the thumb (Box 13.1).

Middle third

Loss in the middle third of the thumb is more functionally limiting than that of the distal third. Therefore, the priorities are both soft-tissue coverage and functional restoration.

BOX 13.1 **Clinical tips: distal-third reconstruction**

Loss of the distal third of the thumb is minimal in terms of functional loss.[12] Therefore, the chief priority is soft-tissue coverage. The choice of soft-tissue reconstruction is determined by the location of loss. Volar defects can be reconstructed with secondary healing (wound contraction), full-thickness skin grafts, Moberg flaps, cross-finger flaps, and neurovascular island flaps, while dorsal defects may be dealt with using skin grafts or first dorsal metacarpal artery flaps.

Fig. 13.10 Dorsal ulnar thumb squamous cell carcinoma. The neoplasm was resected and reconstructed in one stage.

Commonly, the soft-tissue coverage of amputations at this level will have been achieved acutely by revision amputation in which the skeletal components are shortened to allow primary closure. Reconstruction then occurs weeks or months after the initial insult.

Phalangization is a set of reconstruction techniques that increases the effective, rather than the absolute, length of the thumb. The chief component of phalangization is first webspace deepening.[12] The webspace may be injured or not injured during the initial injury to the thumb. Webspace deepening allows better thumb excursion, specifically both palmar and radial abduction, thereby improving the thumb's oppositional function. First webspaces with mild or moderate tightness can be deepened with skin grafts or local tissue rearrangement (commonly Z-plasties). The main assessment of the webspace is whether the contracture is broad or is a discrete linear band. If it is broad, then scar contracture incision, followed by skin grafting, is warranted, whereas if the contracture is linear, Z-plasties are the preferred treatment. Full-thickness skin grafts are usually used for the first web, although a thick split-thickness skin graft can be used (Figs. 13.14 & 13.15). A single Z-plasty can be used for a linear scar band, although two combined Z-plasties are uniquely suited to this anatomic area. The four-flap Z-plasty (which is essentially two superimposed Z-plasties) (Fig. 13.16) and the double-opposing Z-plasty ("jumping man" flap) (Fig. 13.17) have been commonly used for the first web. In both cases, the scar band itself is the middle limb of both Zs, and the triangular flaps then are mobilized from the dorsal and volar sides of the scar contracture. When using either skin graft or Z-plasty for the first webspace, the adductor muscle is often tight due to scarring. A portion of it can be released to allow further thumb abduction prior to skin closure.

More significant first webspace contractures can require transposition of vascularized tissue into the space, rather than the less-complex local tissue rearrangement. Along with soft-tissue expansion of the first web, one should consider application of a first webspace external fixator or pinning of the thumb carpometacarpal joint in order to maintain the width of the first webspace while the reconstruction is healing.

The dorsal hand flap provides a good option for webspace deepening. This flap is proximally based on the dorsum of the hand and is vascularized by the metacarpal artery system (Fig. 13.18). Unlike the FDMA flap, it is not an island flap, and can include more than one metacarpal artery. The flap's distal extent is at the level of the metacarpal heads and is elevated in the plane between subcutaneous tissue and extensor tendon paratenon. The flap is then transposed radially into the first

Fig. 13.11 Thumb defect from Fig. 13.10, and the first dorsal metacarpal artery flap raised on its pedicle. Note that all tissues down to and including the first dorsal interosseous fascia are taken with the flap pedicle.

Fig. 13.12 (A,B) Healed thumb from Figs. 13.10 and 13.11 following reconstruction with proximally-based FDMA flap.

webspace, following release of all constraining structures in the space. The donor site is then skin-grafted.

If the dorsal hand skin has been injured, or if a larger amount of vascularized tissue is required to resurface both the first web and the thumb itself, then regional flaps will be necessary. The radial forearm flap and the posterior interosseous artery flap are good choices. The utility of the radial forearm flap has been repeatedly demonstrated in a variety of hand reconstruction settings, including the thumb. The major drawback to use of a reverse-flow radial forearm flap is that its use may compromise future thumb reconstruction. Specifically, if a microvascular toe transfer is being considered for thumb reconstruction, the radial artery is the preferred recipient vessel, and the transposition of a pedicled radial forearm flap will make later microvascular transfer difficult, if not impossible. It is, however, possible to

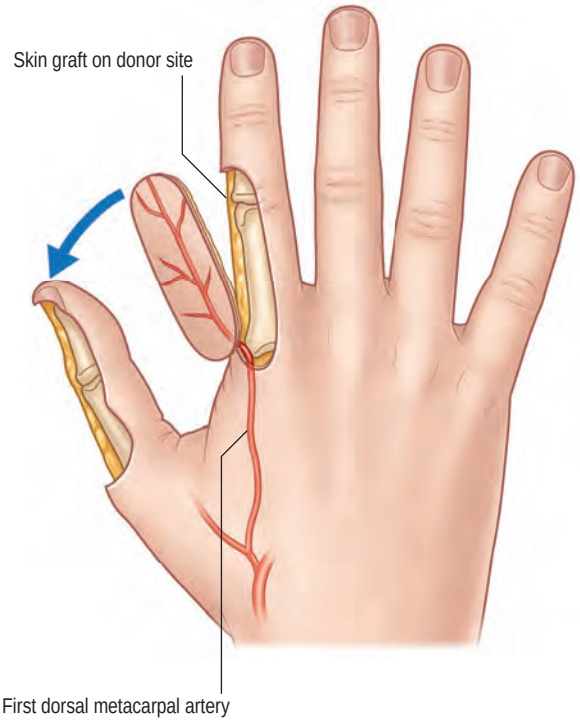

Fig. 13.13 Diagram of dorsal metacarpal artery flap ("kite flap") from index-finger dorsum. It is important to include subcutaneous fat and interosseous muscle fascia with the pedicle.

Fig. 13.15 First webspace from Fig. 13.14 that has been deepened with a full-thickness skin graft. Note improved thumb abduction.

harvest a radial artery perforator flap, leaving the radial artery intact.[23,24]

The radial forearm flap is extremity versatile, and can be harvested as a fascia-alone flap, fasciocutaneous flap, or a suprafascial skin flap. For thumb reconstruction, the use of the fascia-alone flap with skin grafts applied directly to the flap allows maintenance of the normal contour of the thumb[25] (Figs. 13.19 & 13.20). An Allen's test is always performed to ensure the digits will remain perfused by the ulnar artery. The pivot point of the flap pedicle is approximately at the radial styloid, although it can be more proximal than this. The flap should then be drawn on the forearm such that the pivot point is midway between the distal end of the thumb or first web defect and the proximal end of the radial forearm flap. The flap is elevated on the radial and ulnar sides. Upon reaching the ulnar edge of the brachioradialis muscle on the radial side of the flap, and the radial edge of the flexor carpi radialis tendon on the ulnar side of the flap, dissection then proceeds directly down toward the radius. The dissection then proceeds

Fig. 13.14 Severe wood chipper injury that later resulted in a first webspace contracture that prevented radial and palmar thumb abduction.

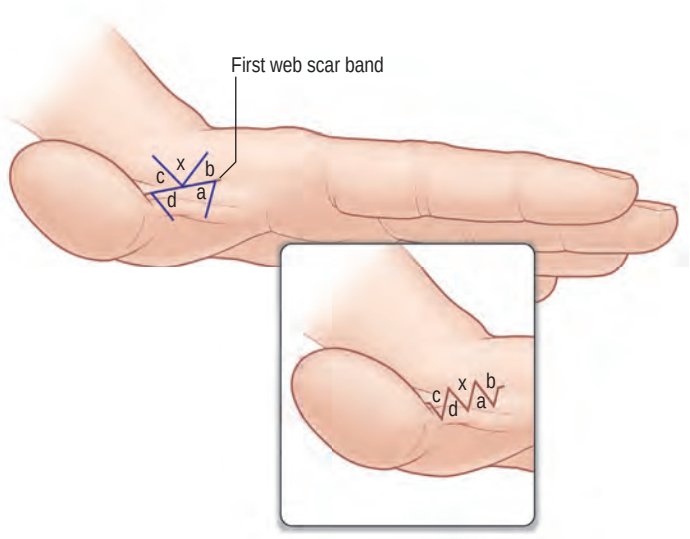

Fig. 13.17 Diagram of the double-opposing Z-plasty (known as the "jumping man" flap). This Z-plasty and the four-flap Z-plasty provide similar substantial amounts of first webspace release.

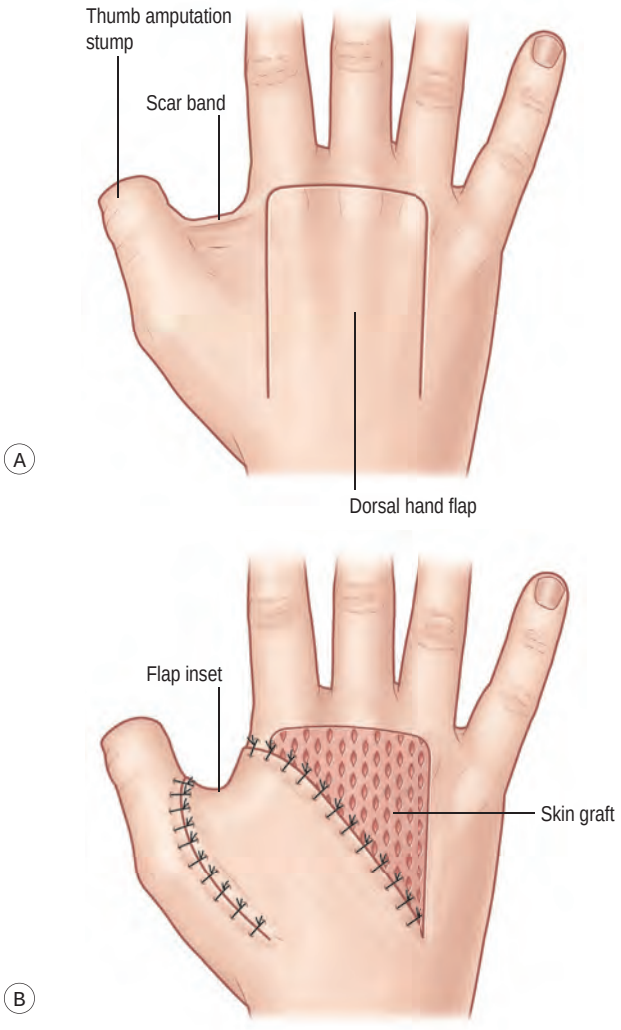

Fig. 13.18 (A,B) Diagram of the dorsal hand flap. This flap can provide a substantial amount of coverage for first webspace deepening.

Fig. 13.19 Severe dorsal thumb injury from a router. The fractures were stabilized, and the extensor pollicis longus tendon was reconstructed with a transferred extensor indicis proprius tendon.

under the deep aspect of the radial vascular bundle. Prior to dividing the proximal end of the radial artery, a microvascular clamp can be placed on the artery just proximal to the flap, and the tourniquet released. After several seconds, if both the flap and all the digits are well perfused, the proximal radial artery can then be divided. The flap is then transposed distally to the first webspace and/or thumb. Depending on the type of flap used, the donor site is primarily closed (fascia-alone flap) or skin-grafted (fasciocutaneous or suprafascial). Because venous outflow from the reverse radial artery flap is retrograde through the venae comitantes against the venous valves, venous congestion can occur. It is imperative to include the venae comitantes and surrounding fatty tissue with the arterial pedicle when raising the flap. Performing an antegrade venous microvascular anastomosis to a vein in the hand can reduce venous congestion and flap swelling.

The vascular supply to the posterior interosseous artery flap is both an advantage and a disadvantage: the flap is perfused by reverse flow-through in the posterior interosseous artery via anastomotic connections with the anterior interosseous artery just proximal to the distal radioulnar joint[26] (Figs. 13.21–13.23). This allows preservation of the radial and ulnar arteries to the hand, but the vascular supply can be compromised if the zone of injury is anywhere near the wrist. The posterior interosseous artery is found with a Doppler and the flap centered over it. The vessel is along a line drawn between the lateral epicondyle of the elbow and the ulnar head. The pedicle of the flap runs in the diminutive septum between the extensor carpi ulnaris and extensor digiti minimi (quinti) tendons. Dissection is performed from distal to proximal so as first to locate the anastomotic connection with the anterior interosseous artery and then include the

Fig. 13.20 Thumb from Fig. 13.19 satisfactorily reconstructed with a pedicled radial forearm fascia flap. The flap was skin-grafted and the donor site closed primarily as no skin was harvested from the forearm.

posterior interosseous artery with the flap as one dissects proximally. Once fully dissected, the flap is transposed to the first webspace, and the donor site is closed primarily or skin grafted. Another disadvantage of the flap is the appearance of the donor site, which is on the easily visible dorsal forearm.

Metacarpal lengthening allows increase in the absolute length of the thumb ray. This is usually performed for more proximal losses in the middle third of the thumb, and was popularized by Matev.[8,9] Matev reported that the only absolute contraindication to the procedure is less than 3 cm of remaining thumb metacarpal.[27] One should note that this reconstruction technique requires a long period of time with external fixation, and multiple outpatient visits, therefore patient acceptance of the technique should be established prior to reconstruction. The pins for the distraction device are placed

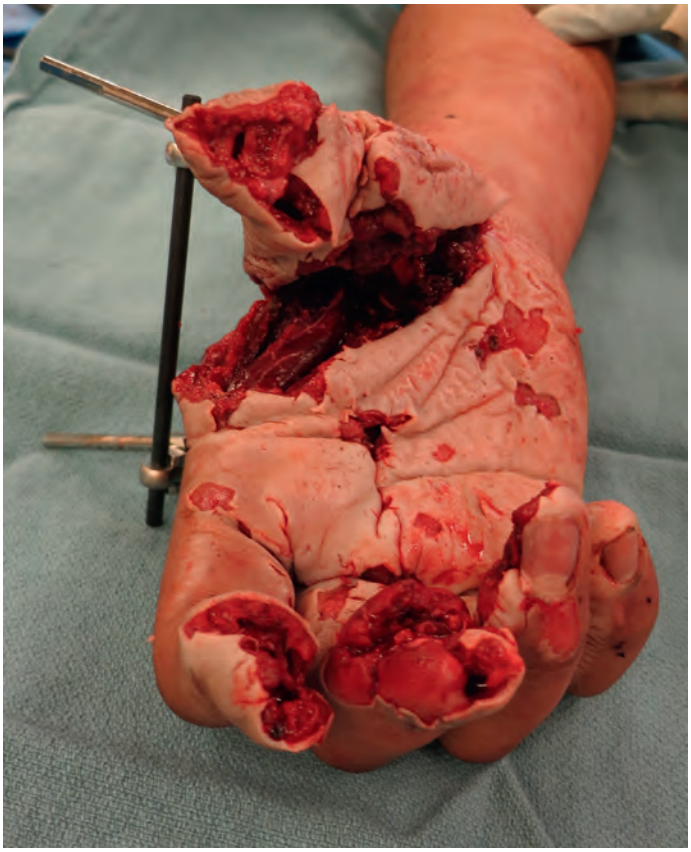

Fig. 13.21 Large first webspace defect following firework blast injury. An external fixator holds the space open.

distally and proximally prior to osteotomy (Fig. 13.24). Through a dorsal incision over the metacarpal, the distraction device is applied first, and the bone is then cut at the diaphysis and the skin closed. Distraction is initiated at 1 mm/day until the desired length is achieved. While some patients, especially children, will spontaneously ossify the bony gap of the metacarpal, many patients will require bone grafting at a second surgery. This bone can be harvested from the iliac crest, or with small defects, from the distal radius. While the bone graft is consolidating, the original frame may be left in place, or one may change to internal fixation. In Matev's experience, a number of patients had first webspace creep due to the distraction drawing the first web skin distally.[27] If this occurs, one of the first web deepening techniques described previously may be used (Box 13.2).

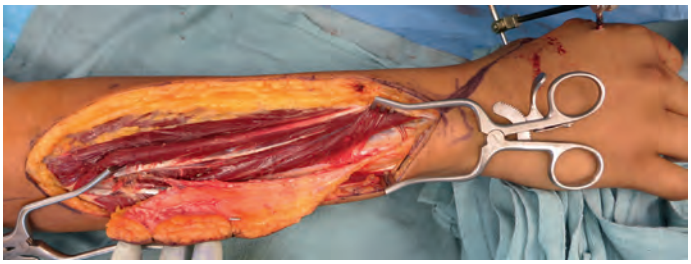

Fig. 13.22 Posterior interosseous artery flap elevated and attached only to the pedicle proximally and distally. Note the anastomotic vessels distally curving radially to join the anterior interosseous vessels.

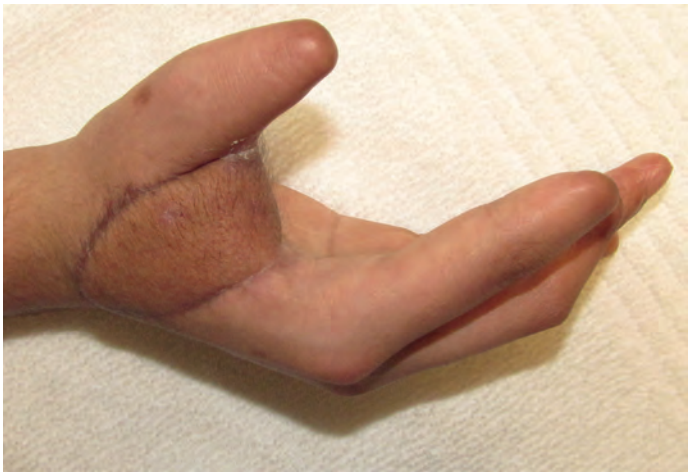

Fig. 13.23 Healed first webspace of patient from Figs. 13.21 and 13.22.

BOX 13.2 Clinical tips: thumb metacarpal lengthening

Metacarpal lengthening of the thumb is a good procedure and can achieve meaningful restoration of thumb length in patients who are not able or willing to undergo a toe transfer. However, it is an arduous process, most importantly for the patient.

1. Patient education is paramount. They must understand that the process involves at least two surgeries, multiple clinic visits, and a real potential for complications such as pin infection or distractor loosening
2. Pain is not a trivial issue with this procedure. Patients are in near-constant pain from the stretching of the soft tissues. Practitioners must be prepared to manage pain for a number of weeks.
3. Younger patients may ossify the bone gap, but older adults may require iliac crest bone grafting. This bone grafting procedure is a good time to place internal fixation. The internal fixation should be strong enough to prevent flexion of the lengthened metacarpal that often happens with these cases.

Osteoplastic thumb reconstruction allows restoration of good thumb length, and when combined with a neurovascular island flap, can result in fairly good thumb pulp sensation. While not absolute prerequisites, the osteoplastic thumb reconstruction method works best when there is intact and functioning thenar musculature and a working thumb carpometacarpal joint. It is generally accepted that osteoplastic thumb reconstruction is performed in three stages: (1) skeletal reconstruction with iliac crest bone graft wrapped with a flap (typically a groin flap); (2) groin flap division and serial thinning; and (3) pulp reconstruction with a neurovascular island flap.

The groin flap is a versatile and reliable flap.[28] It is an axial flap, perfused by the superficial circumflex iliac artery, which runs parallel to and 2 cm below the inguinal ligament. The flap is centered over this line. It is incised and elevated from lateral to medial just superficial to the muscle fascia. Upon reaching the lateral border of the sartorius, the sartorius muscle fascia is incised and elevated with the flap to prevent kinking of the pedicle. Typically, dissection to the medial border of the sartorius is sufficient length for a thumb groin flap. The proximal end of the flap is tubed upon itself. At this point, an iliac crest tricortical bone graft may be harvested from the lateral aspect of the groin flap incision. An oscillating saw allows rapid and neat harvest of the bone graft. The bone graft is then fixed to the distal end of the thumb stump (either proximal phalanx base or distal metacarpal). Fixation can be provided in a variety of ways; however, plate and screw fixation allows early motion (Fig. 13.25). Following bone graft fixation, the groin flap is then wrapped around the graft and inset to the thumb. The groin flap is usually divided 2–3 weeks after inset. Several stages of flap thinning are usually

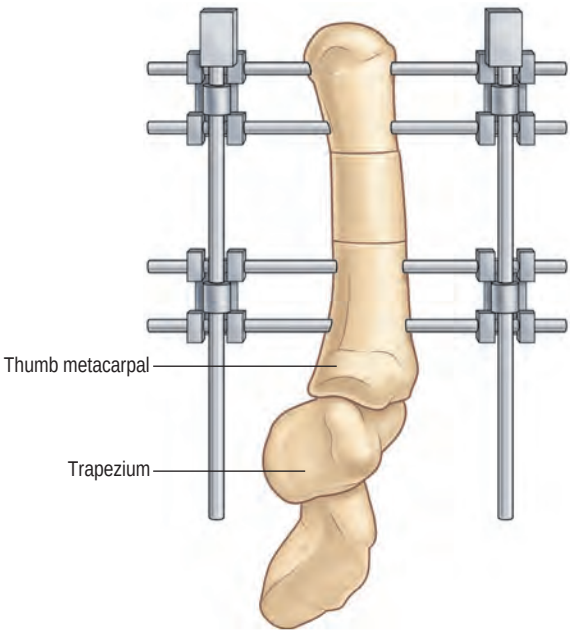

Fig. 13.24 Thumb metacarpal lengthening as described by Matev.

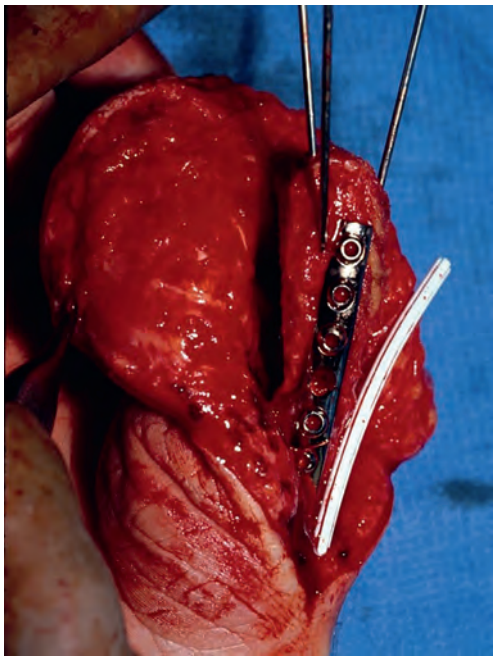

Fig. 13.25 Iliac crest bone graft used for osteoplastic reconstruction of a thumb. The fixation of the bone graft is in progress, and will be covered by a groin flap.

Fig. 13.26 Osteoplastic reconstruction from Fig. 13.25 following thinning of the groin flap.

required (Fig. 13.26 and Video 13.1 ▶). At approximately 3–6 months after skeletal and soft-tissue reconstruction, sensibility is achieved by transfer of the neurovascular island flap. The chief disadvantages of the osteoplastic reconstruction technique for the thumb are possible bone graft resorption, the multiple stages required, and the bulky appearance of the reconstructed thumb.

Osteoplastic thumb reconstruction is not necessarily performed only with the groin flap.[29] There are other flaps that can be used to cover a bone graft, most notably the reversed radial forearm flap. The other option with this type of reconstruction is to utilize an osteocutaneous radial forearm flap, rather than an iliac crest bone graft for the skeletal restoration. The flap may also be innervated by harvesting the lateral antebrachial cutaneous nerve with it, and then coapting it to the ulnar digital nerve of the thumb. While some authors tout this as a one-stage osteoplastic reconstruction, the flap often requires at least some debulking as it can be somewhat bulbous on the thumb.

Quite often, thumb amputations do not happen in isolation – there is often damage to other finger(s), especially the index finger. In the ultimate example of "spare-parts" surgery, the damaged/amputated index finger stump can be transferred on to the thumb amputation stump. This is an excellent reconstructive option for patients with a middle-third amputation of the thumb, especially at the proximal end of that zone.[12,30] The index transfer procedure has been variably referred to as "pollicization" and "on-top plasty". On-top plasty is probably more accurate as pollicization is most often used to denote transfer of a normally functioning index to the thumb. On-top plasty does not necessarily need to be accomplished with the index stump – the middle- or ring-finger stump may instead be used.

On-top plasty may be accomplished with a variety of skin incisions; however "racket"-type incisions at the base of the index and the end of the thumb stump are usually made. Perhaps the most important part of the surgery is the dissection of the dorsal veins. At least one vein must be preserved, but when possible, it is recommended that the majority of the dorsal vein arcade be taken with the digit. Volarly, both neurovascular bundles to the index are carefully dissected. Either before or after index dissection, the thumb is prepared for receipt of the transferred digit. This consists of soft-tissue elevation and metacarpal exposure for bone fixation. Internal fixation is preferred because it does not need to be removed, and early motion can be performed. At this time, a microvascular clamp is placed on the ulnar digital artery to the index, and the tourniquet released. If the index stump is perfused, then the ulnar digital artery is divided. Alternatively, the radial digital artery to the middle finger can be divided, and the common digital artery taken with the index. The ulnar digital nerve will need to be separated from the common digital nerve to allow transposition. As this is a damaged index stump, the flexor and extensor mechanisms are not usually transferred (in contrast to pollicization), and can be divided. The second metacarpal is cut at the appropriate length for the thumb reconstruction. The remainder of the second metacarpal (down to proximal metaphyseal flare) is removed to allow a full first webspace. Fixation of the index metacarpal neck to the thumb metacarpal shaft or base is then performed. In order to gain webspace closure and ensure an adequately deep webspace, a dorsal hand flap may need to be transferred to the webspace (Box 13.3).

Proximal third

Loss of the thumb at the level of the proximal third is a challenge for reconstruction, as this is essentially total thumb loss. While the divisions between middle-third and proximal-third loss are somewhat arbitrary, one chief difference is that loss at the proximal third can include loss of some or the entire cuff of thenar musculature. This muscle loss then precludes use of previously mentioned techniques such as osteoplastic reconstruction, distraction osteogenesis, and perhaps on-top plasty. Because of the paucity of local reconstruction options,

BOX 13.3 Clinical tips: middle-third reconstruction

For thumb losses in the middle third, length restoration becomes a primary goal. This is done by extending either the absolute length or the relative length of the thumb:

- Relative length ("phalangization"): restoring or deepening the first webspace. This may be accomplished as follows:
  - Small webspace deepening: either skin grafting or Z-plasties. If the patient has a linear scar band, Z-plasties; skin grafting is required for broader scar contractures
  - Large webspace deepening: vascularized tissue imported from another location, achieved by the dorsal hand flap, radial forearm flap, or posterior interosseous artery flap
- Absolute length: several techniques can increase absolute length of the thumb:
  - Metacarpal lengthening
  - Osteoplastic reconstruction: bone graft wrapped with a flap, most commonly the groin flap
  - On-top plasty: transposition of a damaged index finger on to the remaining thumb ray

microvascular techniques play a primary role in thumb reconstruction at this level. This primarily is performed with various types of toe transfer, and these techniques are detailed in a separate chapter.

There are some instances of proximal-third loss in which on-top plasty may be appropriate. As stated, if some or all of the thenar musculature is missing, mobility of the transferred index will be limited, and may need to be augmented by an opposition transfer at a later time. In the adult, this opposition transfer can be accomplished with either the ring-finger flexor digitorum superficialis tendon, or the extensor indicis proprius tendon. The technique of on-top plasty is performed the same way as discussed in the section on middle-third loss.

Short of microvascular techniques, index-finger pollicization is the only other viable technique for proximal-third thumb reconstruction (Figs. 13.27 & 13.28). The procedure's utility in children with thumb hypoplasia or aplasia is undisputed. Its use in adults is also fairly reliable, although it may be more difficult for adults than children to adapt to the new finger position. In Brunelli and Brunelli's description of pollicization in adults, the authors highlight one of the chief differences in pollicization between children and adults: in children, the thenar musculature and the adductor pollicis are entirely missing, whereas in adults, there may be at least a remnant.[31] This then slightly changes what is done with the index palmar interosseous (becomes the adductor pollicis) and the dorsal interosseous (becomes the thenar muscles). In children, these muscles are transferred with the index, whereas in adults, the muscles themselves are eliminated and their tendons sutured to the thenar and adductor remnants.

A variety of skin incision patterns can be used. Once the skin is incised, the dorsal veins are carefully dissected. Vein preservation is critically important, and is often the most tedious portion of the pollicization surgery. Next, the neurovascular bundles to the index are dissected. The palmar and dorsal interosseous tendons are divided from the muscles. The flexor and extensor tendons are dissected after opening the first and second annular pulleys. The thumb is then prepared by dissection of the soft tissue and exposure of the metacarpal remnant. The thenar and adductor pollicis muscles or their remnants are also prepared. At this point, the tourniquet is released. There are two possibilities for the ulnar digital artery of the index finger: it can be divided if the radial digital artery adequately perfuses the finger, or the radial digital artery to the middle finger can be divided and the common digital artery to the second webspace can be taken with the index finger. The second metacarpal is then cut at the neck. The remainder of the second metacarpal down to the metaphyseal flare is removed to open the new webspace. The index is transferred and rotated.

Fig. 13.27 Completed index-finger pollicization following traumatic thumb loss at the base of the thumb ray.

Fig. 13.28 Pollicization from Fig. 13.27 demonstrating good opposition of the pollicized finger and good tip pinch.

In general, the pulp of the new thumb should be facing the ring finger when bony fixation is completed. The tendon of the first dorsal interosseous muscle is sutured to the thenar muscle remnant (opponens pollicis if possible) and the tendon of the palmar interosseous muscle is sutured to the adductor pollicis muscle or its remnant. Some authors recommend no shortening of the extrinsic extensor and flexor tendons, whereas others advocate tendon plication.[12,31] The metacarpophalangeal joint is pinned for 6 weeks in slight flexion to counteract the tendency of the index metacarpophalangeal joint to hyperextend. The skin is then closed. If any of the skin closure appears tight, one should have a low threshold for placement of skin grafts to complete the closure. As with on-top plasty, the thenar musculature may be later found to be inadequate for functional opposition, and in these cases, opposition transfer (ring-finger flexor digitorum superficialis or extensor indicis proprius) can be performed at a later time (Box 13.4). Some authors have reported using a digit other than the index finger for pollicization, including one group who has studied transposition of the small finger into the thumb position.[32]

Prosthetics

Prosthetics for thumb loss are a viable option for patients who do not wish to undergo reconstruction. Prosthetics are generally aesthetic in nature, which is to say they have minimal or no function. Pillet has the largest experience with upper extremity prosthetics, and his aesthetic results are impressive.[33] There are scattered reports of osseointegrated digital

BOX 13.4 **Clinical tips: proximal-third reconstruction**

Losses in the proximal third of the thumb are not adaptable, and are challenging reconstructions for patient and surgeon. The entire thumb ray requires restoration. Microsurgical methods are now the standard for losses at this level. However, there remains a role for pollicization of the index finger, which can still be very functional. In cases where there is a concomitant damaged index finger, one can transpose the remaining index on to the thumb ray (on-top plasty) to restore a stable, mobile, and perhaps sensate thumb ray.

and thumb prosthetics, which would render them slightly more functional and durable.[34] In general, there must be at least a remnant of thumb proximal phalanx for an aesthetic prosthetic to remain on the thumb.[12] Otherwise, a hand-based extension may be required for prosthesis stabilization.

Postoperative care

Immobilization is the cornerstone of any hand postoperative care, and the thumb is no exception. Generally, distal-third thumb reconstruction is soft tissue alone and, therefore, immobilization in a postoperative plaster splint is only done for approximately a week. After that, the thumb can be supported with a removable splint, and normal showering and hand washing can begin. Sutures are removed at 2 weeks postoperatively.

More proximal reconstructions can involve skeletal reconstruction, in addition to soft tissue. Plate and screw fixation allows early mobilization, typically initiated at 1–2 weeks postoperatively. Kirschner wire fixation can be slightly less rigid; however, at least some passive gliding exercises can still be initiated at 2 weeks. Again, removable splinting allows hand washing and bathing.

At approximately 6 weeks, bony consolidation will have proceeded to the point that some resistive exercises can be started (provided that on radiographs the fixation has remained stable and there is at least some evidence of consolidation). It is also at this point that scar modification techniques can usually begin in earnest.

Outcomes, prognosis, and complications

Unfortunately, there is a scarcity of well-controlled outcomes studies related to the various types of thumb reconstruction.[35] There are, however, a number of large retrospective series for each of the above-listed reconstruction methods that, in general, demonstrate good results.[11,14–16,19,27,29]

There are five goals when reconstructing a thumb: restoration of (1) functional length; (2) stability; (3) mobility (especially opposition); (4) sensibility; and (5) aesthetic appearance. The treating physician should help the patient choose the technique that will allow restoration of (hopefully) all five of these aspects to the thumb. If all five are restored, then the prognosis for a functional thumb and a satisfied patient is good. If all five cannot be restored, then, at the least, restoration of a stable thumb with adequate length will allow some grip and pinch activities.

Secondary procedures

First webspace deepening is frequently required after thumb trauma and possibly after prior reconstructive procedures. This can be done with skin grafts or local tissue rearrangement, as discussed previously. Other scar contractures that are functionally limiting or aesthetically unpleasing can be treated with a variety of releases and transpositions, including Z-plasties and Y–V-plasties.

Tendon adhesions are also common after thumb reconstruction. The primary method of treatment of this problem is early and aggressive hand therapy to minimize their impact. If therapy cannot overcome the adhesions, then flexor and/or extensor tenolysis may be required. Following tenolysis, therapy should resume within 24–48 hours.

As mentioned in the section on metacarpal lengthening, bone grafting is often required. Nonunions in the hand are rare but may require later bone grafting. Malunions of the thumb ray are extremely well tolerated and compensated; however, severe malunions may require osteotomy and fixation.

Joint contractures in the non-thumb digits can be particularly detrimental, especially the proximal interphalangeal joint. However, in the thumb, these are less an issue, and in fact can help with thumb stability. If there is a severe flexion contracture of the metacarpophalangeal joint, this may need joint release.

Distal-third thumb loss may result in painful neuromas that require later excision. However, this can largely be mitigated by traction neurectomy of the digital nerve(s) at the time of initial reconstruction.

Future directions

One exciting development in the last several years is the development of perforator flap surgery. This has enabled soft-tissue reconstruction using local tissue that in the past may have necessitated use of a free flap. Some authors have dubbed this "microsurgery without the microscope". One group has described use of a princeps pollicis perforator flap for local thumb ray reconstruction, and it is likely that more hand-based perforator flaps will be described in the future.[36]

It was mentioned at the beginning of the chapter that perhaps the best thumb reconstruction is actually replantation of the amputated thumb when possible. The advent of super-microsurgery in the last decade has enabled replantation of more distal amputations, even at the nail bed level. Better replantation techniques will potentially allow salvage of more native thumb tissue.

Finally, advances in prosthetics for the upper extremity are occurring at an astounding pace. It is possible that more durable osseointegrated thumb prosthetics will allow more function without autologous tissue reconstruction, and one day, these prosthetics may even enable sensation.

Thumb reconstruction: Microsurgical techniques

Nidal F. Al Deek and Fu-Chan Wei

Access video content for this chapter online at expertconsult.com

SYNOPSIS

- Microsurgical toe-to-hand transplantation allows "like-with-like" reconstruction, achieving the best functional and aesthetic results in the hand that is missing digits.
- Preservation of neurovascular bundles, flexor and extensor tendons, mobile joints, and viable skin with minimal bone shortening in the amputation stump ensures optimal functional results and less morbidity at the foot donor site.
- Retrograde dissection of the vascular pedicle at the first webspace during toe harvest is a key technique to alleviate concerns regarding variations in the vascular anatomy of the donor vessels.
- A missing thumb, traumatic or congenital, can be successfully reconstructed with the second toe, great toe or modifications of the great toe including trimmed great toe, partial great toe, and great-toe wrap-around flaps.
- Missing fingers, traumatic or congenital, can also be successfully reconstructed with various configurations from the lesser toes, achieving good outcomes, especially in those distal to the insertion of flexor digitorum superficialis. Timing of toe-to-hand surgery does not have an effect on flap survival, complications, and secondary procedures.
- The "metacarpal hand" refers to a hand with amputations of all fingers proximal to their functional length with or without accompanying thumb amputations. Toe-to-hand transplantation can help restore maximal hand function to this once crippling condition, even for bilateral defects.
- The "metacarpal-like hand" is an ill-defined term and entity of debilitating condition that also benefits from toe-to-hand surgery.
- Our extensive experience of over 2200 cases of various toe-to-hand transplantations allows pioneering of new concepts and refinements of existing techniques, classification systems and strategic management algorithms, and patient-reported outcomes, which all shall improve how we think and perform toe-to-hand surgery.

Introduction

Microsurgical toe-to-hand transplantation is one of the earliest free tissue transfers dating back to 1966.[1–3] The technique was first developed to overcome functional deficits following fingers traumatic injury then congenital deformities but evolved to address even aesthetic concerns. Over 40 years of history, toe-to-hand transfer has already reached its zenith.

When confronted with digit amputations, replantation remains the standard of care.[4–6] However, in unreplantable cases or after failed replantation, toe-to-hand transplantation is the next best option superior to the use of prosthesis or other non-microsurgical techniques, fulfilling the "like-with-like" reconstruction principle without the need for immunosuppression.[7–13]

For replacing a mutilated or unreplantable thumb, microsurgical toe-to-thumb transfer is the gold standard; a surgery well-justified based on the fact that the thumb constitutes 40–50% of hand function.[14–17]

For multiple finger amputations, although the resultant disability is comparable to the loss of the thumb and drastically alters the appearance of the hand, indications for microsurgical toe-to-finger transplantation remain controversial.[8,18–21] It worth noting that toe transfer to the missing finger distal to the insertion of the flexor digitorum superficialis generally yields superior functional and aesthetic results compared with other techniques.[22–26]

Single finger amputation is not an exception to multiple finger amputation in controversy; although toe-to-finger transplantation could be indicated to help certain patients keep their jobs.[22–26]

The metacarpal hand, a more severe and extensive type of injury,[12,27,28] is a strong indication for toe-to-hand transfer, especially in bilateral injuries,[29,30] and in the era of hand allotransplantation its indication is more justified for amputations distal to the wrist given the good results at the price of prolonged immunosuppression.[31]

A critical look at the literature on toe-to-hand surgery may not reveal significant changes since the middle of the 1980s, but it does show slightly increased interest in toe-to-finger transplantation; a sign of change in surgeons' attitudes.[32] It also shows a growing interest in refining the appearance of the transplanted toe[33–40] and camouflaging the donor site.[41–43]

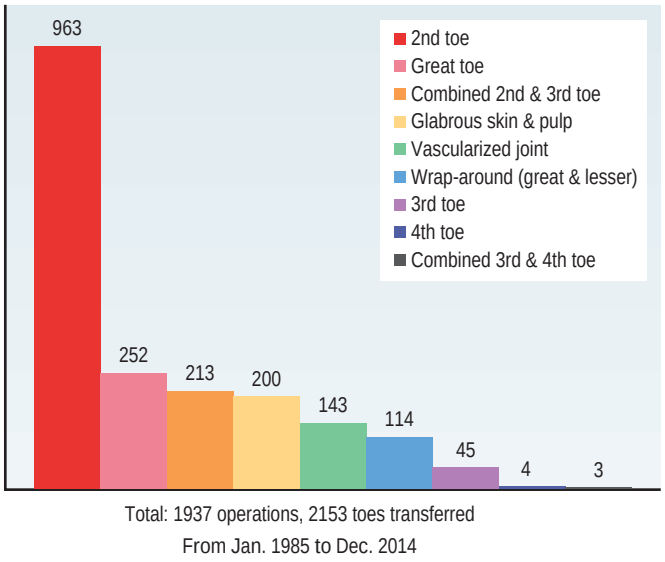

Fig. 14.1 Number of cases performed at Chang Gung University Medical College Hospital from 1985 to 2015.

Long-term outcomes have also been studied that shall further establish the safety and efficacy of the procedure.[44,45] This chapter outlines the current experience of toe-to-hand transplantations, drawing from the authors' experience of more than 2200 cases over a 30-year period at Chang Gung Memorial Hospital and Medical College (Fig. 14.1).

Diagnosis/patient presentation

The initial management of the potential toe-to-hand transplantation patient is similar to any other trauma or patient requiring digital replantation, with resuscitation and management of concomitant life-threatening injuries if necessary, and appropriate preservation of the amputated digits. Initial assessment of the injured hand allows preemptive discussion of toe-to-hand transplantation with the patient, especially when the possibility of a successful replantation is in doubt, such as in severely avulsed, crushed, or multiple amputations. In particular, patients whose occupation requires a high-demand use of their hands or those with special needs and hobbies requiring a fine degree of dexterity and ten fingers, e.g., musicians or athletes, should be given all information available concerning different reconstructive options. If there is significant tissue damage, or anticipated tissue lack following debridement, the use of pedicled groin flap with or without iliac bone graft to replace missing soft tissue and bone should be considered at the time of the initial operation and discussed with the patient (Fig. 14.2).

The initial operation

Anticipation of either primary or secondary toe-to-hand operations ensures careful preservation of all viable structures at the initial debridement or following failed replantation.[55,56] Excessive shortening of structures in order to achieve direct wound closure or the use of local and regional flaps should be avoided[10] and electively replaced by distant pedicled flaps such as the groin flap that allows for: (1) maintenance of all important structures in the amputation stump; (2) primary closure at the foot donor site; (3) enough soft tissue to create adequate webspaces and avoid skin grafts in the hand improving overall cosmetic appearance; and (4) preservation of potential recipient vessels in the hand for microsurgical toe transplantation. Although some reports have suggested other methods of additional soft-tissue harvest with the toe transplantation, either as a single-stage microvascular procedure with combined free flaps,[57] or the use of native foot tissue,[33,58] we still recommend the groin flap for the majority of cases; it is simple and reliable and leaves an almost negligible donor scar. In some severe cases of extensive soft-tissue loss, a pedicled anterolateral thigh (ALT) flap in sandwich technique fashion could be an alternative.

As the use of intraosseous wires is an effective method of osteosynthesis[59] and only requires 0.5 cm of bone for wire placement, as much remnant bone should be preserved as possible. In transjoint amputations, any intact articular cartilage and accompanying ligaments should be preserved to facilitate joint reconstruction with disarticulated toe joints.[60] Amputations at the level of the thumb metacarpals can be augmented with the use of bone blocks, thus avoiding the

Fig. 14.2 (A,B) Coverage of an injured hand with a pedicled groin flap before toe transplantation.

Historical perspective

The first ever report on toe-to-hand transfer was performed in a staged, pedicled manner on a 5-year-old child over a four-week period of time by Carl Nicoladoni in 1897. Unfortunately, the resultant transfer was stiff due to prolonged immobilization but still superior to the tubed pedicled flaps popular at that time.[46] Davis was the first to combine staged transfer with microanastomosis of the dorsalis pedis artery, opening the door for many innovations to follow.[47] But, it was not until 1967 that the first microvascular toe-to-thumb transplantation was performed by Yang and Gu[2] who transplanted the second toe to the thumb.[2] Notably, Buncke and Schulz's experimental work on monkeys[48] preceded Yang's operation by one year and probably inspired Cobbett, who successfully transplanted the great toe to the thumb in 1969.[3] Recent follow-up of Cobbett's first patient at 30 years showed good subjective sensation and no evidence of osteoarthritis.[49]

Partial toe transfer, another frontier in toe-to-hand surgery, was deemed feasible in 1979 after Buncke and Rose performed the first neurosensory pulp flap for finger tip reconstruction.[50] Koshima further pushed the limits of microsurgery by performing, for the first time, a free vascularized nail graft in 1988.[51]

The success of toe-to-hand transfer in adults encouraged pediatric toe-to-hand transfer with O'Brien first reporting the procedure for congenital absence of the thumb[52] and Gilbert[53] and Cooney and Wood[54] for the replacement of congenitally missing fingers.

The long and incredible history of toe-to-hand transfer has yielded it the current "state of the art" with the focus now on refinements of the functional and aesthetic results, long-term and patient-reported outcomes, and strategic guidelines. Toe-to-hand transplantations for traumatic and congenital hand defects will remain an important tool in the armamentarium of the reconstructive microsurgeon.

need for a transmetatarsal osteotomy in great-toe harvest, as preservation of the metatarsophalangeal joint is important for foot function and appearance.[12,61]

Avulsed or shredded extensor and flexor tendons should be debrided but never sacrificed for the sole purpose of obtaining wound closure. In fingers, preserving the native intrinsic extensor apparatus as far as possible, especially over the proximal interphalangeal joint, allows preservation of the arrangement of the intrinsic and extrinsic extensor systems[62] following reconstruction. Similarly, preserving the insertion of the flexor digitorum superficialis, wherever possible, has proved useful in achieving better functional results.[56,63]

Excessive shortening and the use of cauterization of arterial and venous ends are to be avoided in order to minimize intimal damage and preserve length, avoiding more extensive foot dissection and the need for vein grafts which prolong the operation and increase complications.[64] The same applies to nerves. Traditional teaching of the "pull and cut" method for prevention of neuromas in amputated stumps is to be avoided, as sensory recovery is much faster when nerve length is preserved and neurorrhaphy performed nearer to the transferred toe.[65] All neurovascular bundles should be tagged carefully with 10/0 sutures to ensure easier identification at the subsequent reconstruction.

Patient selection

Patient factors

Careful patient selection is the key to success. Age in itself is not a contraindication for microsurgical toe-to-hand surgery.[66] Instead, it may impact sensory recovery and range of motion with the best results achieved in younger patients.[67] Ideal patients should be highly motivated, clear about their needs with realistic goals and in good health. Decision-making for each patient is individualized not simply for the injury status but also to take into account the hand dominance and occupation as well as socioeconomic status.

Timing: primary versus secondary reconstruction

The time window once advocated by Godina for microsurgical reconstruction of lower extremity is not applicable in toe-to-hand surgery.[68] Acute, subacute, and chronic reconstructions cause confusion and have no significant impact on the result and, therefore, are better to be avoided; primary and secondary reconstructions should be used, instead. Primary refers to microsurgical reconstruction done at any time as long as the wound has not healed yet, while secondary refers to transplantation after the wound has healed. With that understanding, secondary toe-to-hand procedures may ensure better wound control and definition of the injury zone, while primary reconstruction allows one-stage procedure, earlier rehabilitation, and subsequent return to work, as advocated by several authors.[24,69–71] In our study of 26 primary cases versus 96 secondary cases, there was no significant difference in terms of flap survival rates, vascular re-exploration rates, recipient site complications including infection, or requirement for secondary revision.[71] In a well-informed and motivated patient without extensive soft-tissue loss or other significant injuries of the ipsilateral upper limb, primary toe-to-hand transplantation offers the ideal method of replacing digit loss. It is worth noting though that earlier transfer may also result in better sensory recovery than delayed transfer. On the other hand, the procedure should be postponed or not even performed in patients who are unsure about their decisions and who cannot undergo rehabilitation as expected.

Injury factors

Decision-making for the thumb

The functional thumb depends on adequate length, sensibility, stability, and the function of the thenar muscle group to perform opposition. Microvascular toe-to-thumb transplantations allow these four objectives to be achieved in a single stage with a superior aesthetic result. The function of the thumb decreases by 50% once the amputation level is proximal to the proximal interphalangeal joint and reaches 100% once it crosses the metacarpophalangeal joint.[72] Amputations distal to the interphalangeal joint are generally well tolerated but, in certain patients, the additional length, stability, and sensibility from a transplanted distal toe transfer should always be offered as an option.[65,73]

Various classifications and reconstructive algorithms exist for thumb defects,[74–76] although the underlying principles relate mainly to the types of tissue and the length of thumb missing.[77] Toe-to-thumb transplantations can be successfully reconstructed with various modifications of the great toe, including whole great toe,[73] trimmed great toe,[78] great-toe wrap-around flaps,[79] pulp flaps,[80] and the second toe.[29,58] The decision to use which toe or its variation should be individualized not only to the thumb defect and the patient's needs, but also with careful consideration of the donor site. In general, thumb reconstruction using the great toe or its variants provides better functional outcomes in terms of tripod pinch, side-to-side and pulp-to-side pinch, as well as appearance than the lesser toes do, although augmentation procedures for second toes to improve bulk have been described.[58] If the great toe is used, at least 1 cm of the proximal phalanx should be preserved in the foot to ensure better push-off and preservation of foot appearance; the great toe is therefore an ideal option for thumb amputation levels distal to the mid-metacarpal shaft. In a more proximal amputation, additional challenges are inadequate bone stump length and thenar muscle function. The first can be overcome by a transmetatarsal transfer of the second toe or preliminary distraction lengthening of the existing metacarpal ray or interpositional bone grafting between the transferred toe and the metacarpal without sacrificing the base of proximal phalanx or the metatarsophalangeal joint of the great toe.[12,30,65] The destruction of the thenar musculature and the subsequent loss of opposition, however, may necessitate pronation osteosynthesis, but is better corrected by primary opposition transfer in the authors' experience.[81]

Decision-making for fingers

Classification of finger defects is similar to the thumb and pertains to the type of tissue and length of finger missing, with the additional consideration of which finger is involved and whether there are single or multiple amputations. The

definition of proximal or distal amputations is determined by its relation to the insertion of the flexor digitorum superficialis tendon.[55,65,82] Toe transplantation to more distal finger amputations can be achieved by a wide variety of options, including the use of vascularized nail grafts,[51,83,84] pulp flaps,[85] wrap-around flaps,[35] and partial second toes,[23] depending on what tissues are missing. These operations are rewarding due to the restoration of high-density pulp sensation, fine pinch, and cosmetic appearance of the nail.[82,83,86] A partial second-toe flap which includes the distal interphalangeal joint or both the proximal and distal interphalangeal joints is indicated in amputations distal to the flexor digitorum superficialis insertion.[22,82,87,88] In contrast, a whole second-toe flap is indicated in carefully selected patients with more proximal amputations;[65] the ideal level, however, is distal to the middle of the proximal phalanx as reconstructions for more proximal amputations usually result in a slightly shorter finger.[89]

Decision-making for patients with multiple finger amputations are largely guided by the specific occupational and cosmetic needs of the patient. In general, two adjacent fingers should be reconstructed wherever possible to allow a stable tripod pinch or hook grip.[12,21,88] Preferential reconstruction of the radial two fingers should be recommended for patients who require fine pinch and the ulnar two digits for manual workers who require a strong grip.[19,90] However, multiple finger amputation could be too complicated to be addressed with toe-transfer alone, and additional procedures such as lengthening and ray amputation could be necessary, as well.[86]

Decision-making for the metacarpal hand

The term "metacarpal hand" refers to a hand injury with multiple finger amputations at the level of the metacarpophalangeal joint, or immediately proximal or distal to it. Delitala was perhaps the first to coin this term[91] and, since then, various classification systems have been proposed,[92–95] with varying levels of clinical usefulness. A classification system based on reconstructive options and different stages of injury has proved useful in our experience[12,61,91] (Tables 14.1 & 14.2). This takes into account the level of finger amputations and thumb involvement, and provides guidelines for the reconstructive technique as well as prediction of the functional outcome after reconstruction. Type I refers to four-finger proximal amputations without the thumb or only distal-thumb involvement (no thumb reconstruction necessary). In type IA where the amputation level is distal to the metacarpophalangeal joint, the focus is on the selection of two separate toes or combined second and third, or third and fourth toe transplantations depending on the presence of webspace (Fig. 14.3). To ensure that the different digits curve around an object more evenly in grasp prehension, the length of the remaining amputation stumps should not be longer than that of a normal little finger when considering a combined second- and third-toe transfer.[90] For type IB, where the amputation level is through the joints with intact articular surfaces, combined second and third toes are harvested as composite joint transfers. For type (IC) where the amputation level is proximal to the metacarpophalangeal joints, combined second and third toes as transmetatarsal transfers is indicated. Reconstruction of two adjacent fingers allows for a stable tripod pinch, although reconstruction of all four fingers is possible in certain selected patients with acceptable donor site morbidity (Fig. 14.4).[12]

Type II injuries refer similarly to four-finger proximal amputations but with various levels of thumb involvement proximal to the base of proximal phalanx. The reconstruction of fingers with toe transplantations follows a similar decision-making process as for type I defects, but reconstruction of the thumb is determined by the presence or absence of a functional thenar musculature. If the thenar muscles are intact or possess adequate function (types IIA and IIB), a one-stage procedure to reconstruct the thumb and two adjacent fingers is recommended. If the thenar muscles are missing or have inadequate function (IIC), the thumb reconstruction should follow finger reconstructions in a second stage and only after the thumb position is determined by the aid of prosthesis while the fingers assume their final positions (Fig. 14.5). Either

Table 14.1 Metacarpal hand classification for type I defects

Subtype	Thumb amputation levels	Finger amputation levels
IA	Amputation distal to the interphalangeal joint	Distal to the level of metacarpophalangeal joint
IB		At the level of the metacarpophalangeal joint
IC		Proximal to the level of the metacarpophalangeal joint

Table 14.2 Metacarpal hand type II defects and proposed reconstruction algorithm

Subtype	Thumb amputation level	Reconstructive options	Stage
IIA	Distal to the metacarpal neck	Whole or trimmed great toe	Simultaneous
IIB	Proximal to the metacarpal neck with adequate thenar muscle function	Whole or trimmed great toe ± lengthening or bone augmentation Transmetatarsal second-toe transfer	Simultaneous
IIC	Any level with inadequate thenar musculature	Same as in IIA or IIB Opponensplasty	Staged
IID	Any level with damaged carpometacarpal joint	Same as in IIA or IIB Immobile thumb post	Staged

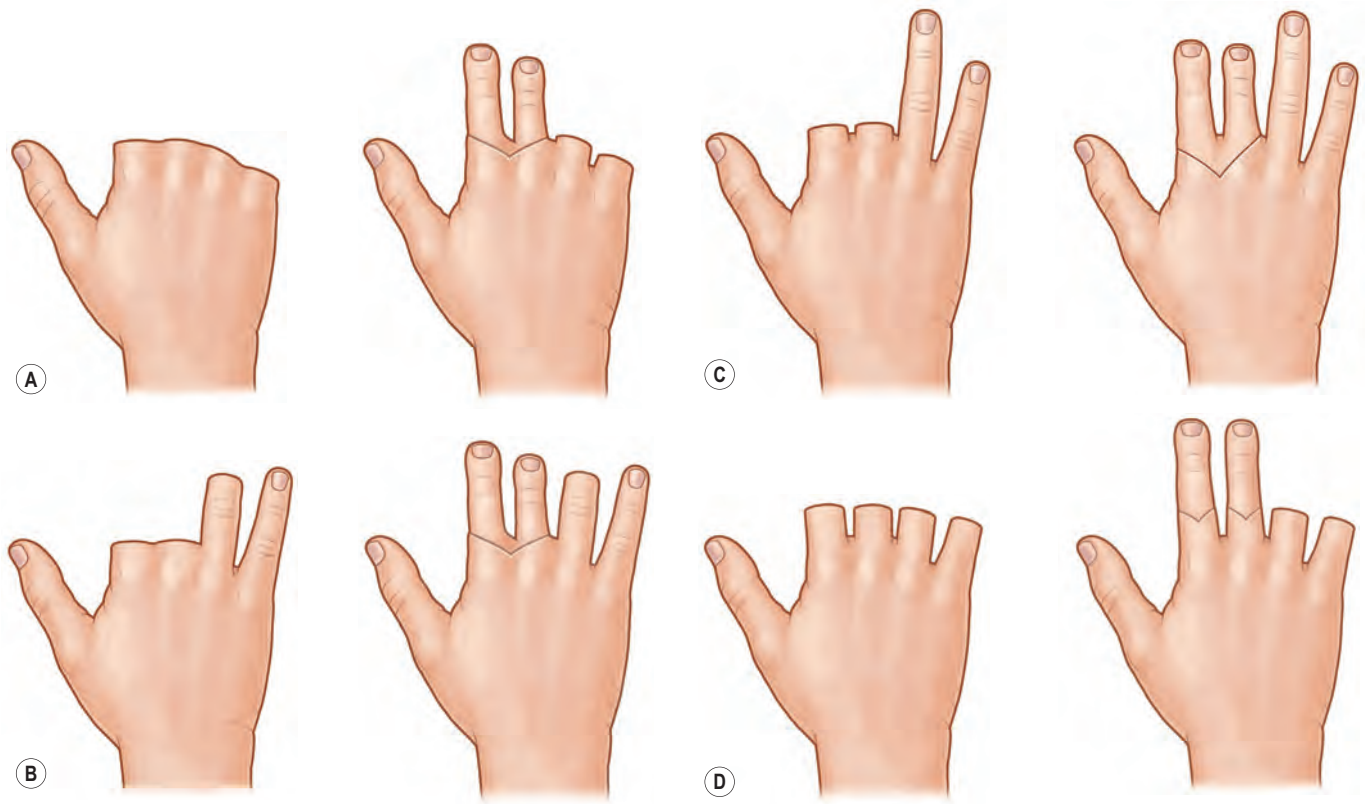

Fig. 14.3 Indications for combined second- and third-toe harvest versus bilateral toe harvest. A combined second- and third-toe transplantation is preferred for: **(A)** amputations proximal to the webspace (indicative of a level at or proximal to the metacarpophalangeal joints); or **(B)** when the remaining fingers are at the level of, or shorter than, the little finger. Using this technique when the remaining finger is longer than the little finger will produce a hand with gross unequal finger lengths and an uneven digital arcade **(C)**. **(D)** Bilateral second toes are best suited when the webspaces are preserved, indicative of amputations distal to the metacarpophalangeal joints with adequate bone for osteosynthesis.

pronation osteosynthesis or an opposition transfer can be performed to provide better pinch.[81,96]

Decision-making in bilateral metacarpal hand injuries requires a careful balance of the severity of injury (type I or II), patient's needs, and donor site morbidity. Other options should also be discussed with the patient. Type II injuries are much more difficult than type I, requiring up to but not exceeding five toes to achieve a functional level of prehension.[30] In general, the use of a great toe, usually from the left foot, is sacrificed for dominant thumb reconstruction together with a combined two-toe reconstruction from the opposite foot to achieve a tripod pinch. In the non-dominant hand, single-digit pulp-to-pulp pinch is considered adequate with the use of a lesser toe for thumb reconstruction.[30] Although the option of sacrificing both great toes or more

Fig. 14.4 The reconstructed tripod pinch of a type I metacarpal hand, showing stability of grip and good opposition with the thumb.

Fig. 14.5 Use of a prosthetic thumb for a type IIC metacarpal hand after combined second- and third-toe transplantation for middle- and ring-finger reconstruction. This is useful for determining the exact position of the future transplanted thumb and for planning additional procedures (e.g., opponensplasties).

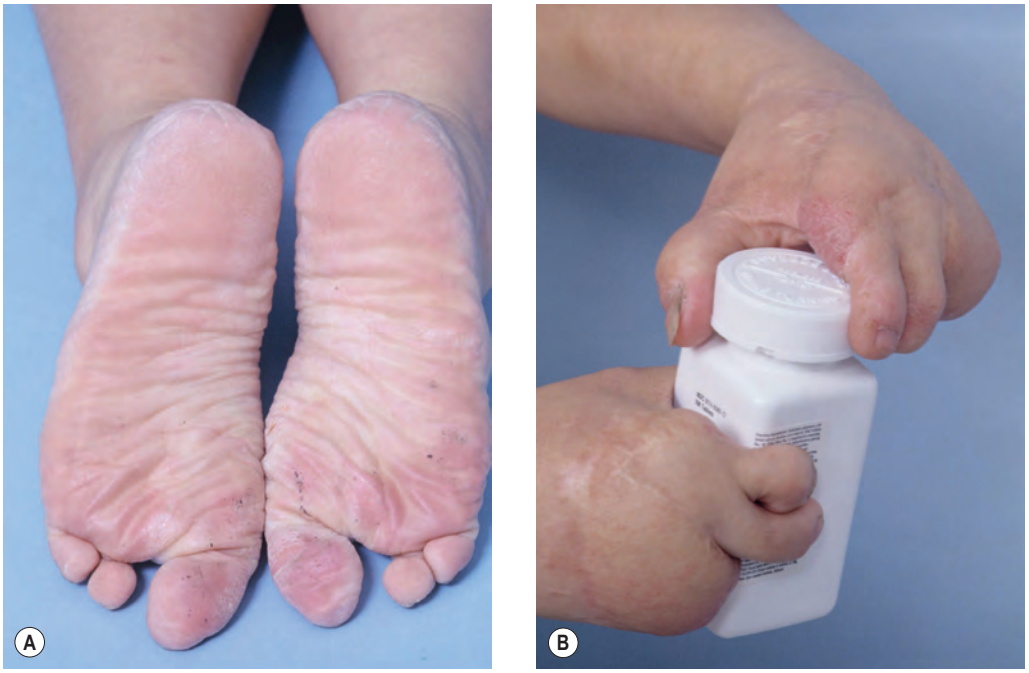

Fig. 14.6 (A,B) Appearance of bilateral metacarpal hands and donor sites after toe-to-hand transplantations. Up to a total of five toes can be harvested for the most severe defects of bilateral type II metacarpal hands requiring reconstruction of opposing digits in both hands.

lesser toes for hand reconstruction may seem attractive, we have found that the donor morbidity reaches a level that is incompatible with activities of daily living. In instances where multiple toes are needed, the patient needs to participate fully in the decision-making with regard to the foot morbidity, especially in certain populations where patients are far less tolerant of sacrificing their toes to reconstruct their hands (Fig. 14.6).[29]

Treatment/surgical technique

Despite the many configurations and combinations of toe-to-hand transplantations available, a few important principles exist for all cases which, when adhered to, allow easier dissection, reduced foot morbidity, and improved overall functional and aesthetic outcomes.

General principles in vascular dissection

The venous drainage system should be identified and selected before the arterial system. One sizeable vein located in the intermediate layer and drained by the great saphenous vein is usually enough, but should not be confused with the arterial system.

As for the arterial blood supply, we recommend the vascular pedicle dissection starts at the first webspace and proceeds in retrograde manner. This method alleviates concerns regarding vascular anatomy and allows early detection of system dominance pattern (dorsal *vs*. plantar) which shall guide the rest of surgery minimizing damage and reducing time.[97,98] In our experience, the first dorsal metatarsal artery (FDMA) is usually dominant (70%) and identified by its dorsal relation to the intermetatarsal ligament (Fig. 14.7).[65,99] Once this is confirmed, it permits early ligation of the plantar system, minimizing tedious and destructive dissection in the foot. In the 20% of cases where a first plantar metatarsal arterial (FPMA) system is dominant, as identified by its plantar relations to the deep intermetatarsal ligament (see Fig. 14.7), the FDMA is then ligated, reducing time spent on dorsal dissection, and the plantar dissection continued together with the harvest of the digital nerves. The length of the arterial pedicle harvested should be able to reach the chosen recipient artery. However, in a dominant FPMA system, dissection should be limited to the non-weight-bearing zones, with the use of vein grafts if necessary to increase pedicle length. In cases where both the FDMA and FPMA appear equally dominant (10%; see Fig. 14.7), the dorsal system is always selected due to its easier harvest and less donor morbidity. Following toe harvests, at least 20 minutes should be allowed for observation of adequate perfusion before detaching the flap.

Clinical hints and tips

- Always start the vascular pedicle dissection from the first webspace and identify the trifurcation (two branches to two adjacent toes and one communicating branch to the plantar artery) then trace the arterial pedicle in a retrograde fashion. In 70–80% of cases, the first dorsal metatarsal artery can be used as the arterial pedicle.
- To avoid "cobra-head" disfigurement, create four mobile flaps through a cruciate incision, and interpose these with the V-shaped flaps of the transplanted toe.
- The neurovascular bundles are skeletonized during the dissection to avoid difficult inset and bulky appearance at the junction of transplanted toe and amputated stump.

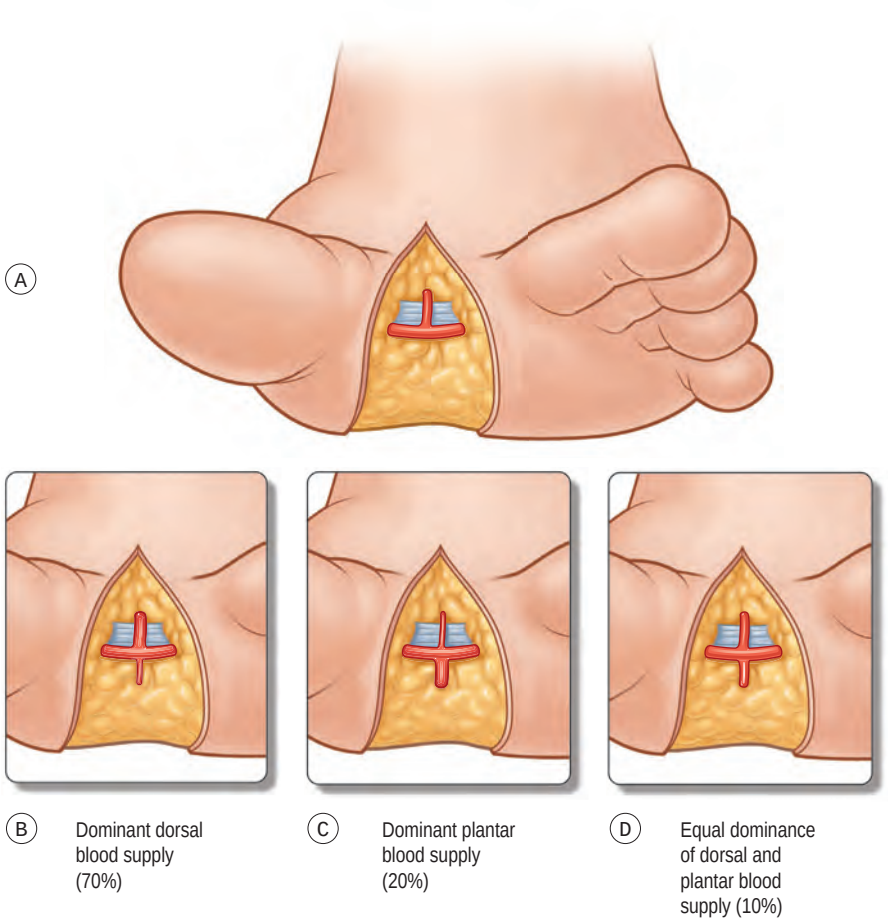

Fig. 14.7 **(A)** Retrograde dissection of the arterial pedicle begins in the first webspace and allows early confirmation of a dominant dorsal or plantar system. **(B)** In 70% of cases, a dominant first dorsal metatarsal artery is present (MAKE DORSAL VESSEL THREE TIMES LARGER THAN PLANTAR VESSEL), whereas in 20% of cases, a dominant first plantar metatarsal artery is present **(C)** (MAKE PLANTAR VESSEL THREE TIMES LARGER THAN DORSAL VESSEL). In 10% of cases, both systems are equally dominant, in which case the dorsal system is selected **(D)**.

General principles in recipient preparation

A two-team approach greatly reduces the overall operating time, surgeon fatigue, and risks of anesthesia.[55] Proper preparation of the recipient site allows a smooth transition from flap harvest to inset without any delays. Preservation of all viable lengths of bone, joints, neurovascular bundles, and tendons should have been performed at the initial operation by a surgeon who has working knowledge of toe-to-hand transplantations.[56] A cruciate incision allows the creation of four equal triangular flaps for smooth interdigitation with the V-shaped flap of the transplanted toe and prevents the ugly "cobra" appearance that features prominently at the toe–digit junction (Fig. 14.8). Following preliminary inset, excess fatty tissues are trimmed by skeletonizing the neurovascular bundles of the recipient flaps. All these maneuvers allow the creation of a finger or thumb with a more natural-looking appearance.

Clinical hints and tips

To reduce foot morbidity and avoid the use of skin grafts, pay careful attention to the placement of incisions on the foot. Webspace incisions should not cross the midline on to the territory of the contralateral toes, and all proximal incisions should converge to a V proximal to the osteotomy sites. In addition, scars should be kept away from all weight-bearing sites.

General guidelines in donor closure

Careful placement of incision lines in the donor foot minimizes weight-bearing pain and scar tenderness and permits earlier mobility. V-shaped flaps are placed proximal to the osteotomy site whereas distally, the incisions are situated midway between the webspaces to permit tension-free closure, even with combined second–third or third–fourth-toe

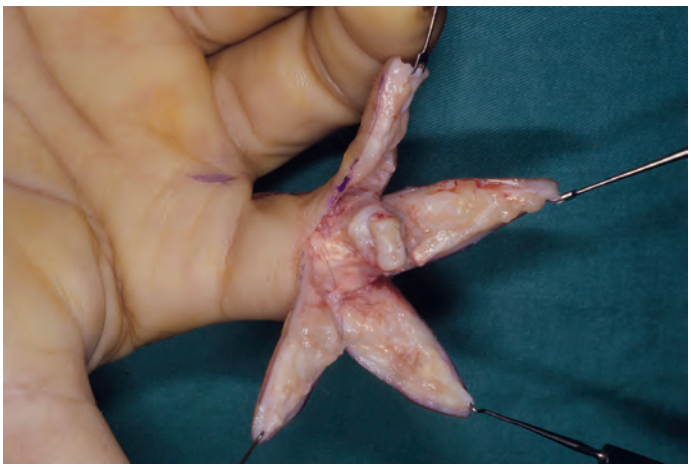

Fig. 14.8 A cruciate incision at the recipient site allows the creation of four equal triangular flaps and prevents a bulbous appearance at the subsequent toe-to-finger junction.

Fig. 14.9 A prepared recipient site with interosseous wires inserted, ready for inset of the toe flap.

transplantations. Incisions on weight-bearing areas as well as extensive foot dissection should be avoided. Skin grafts are generally discouraged due to difficulties in replacing glabrous skin, wound breakdown due to repeated pressure from weight-bearing and footwear, and also because it prevents early ambulation. When skin grafts are required, for example, after pulp flap, webspace flap, and wrap-around flap harvests, they should be carried out meticulously with strict prevention of ambulation until the grafts are healed.

General principles in flap inset

Intraosseous wires provide a stable, not rigid, method of fixation, achieving a union rate of 98.5%.[59] They are also advantageous for the following reasons: a shorter segment of recipient bone is required for osteosynthesis; and the semirigid fixation allows early postoperative correction if the transplanted toe is found to be malaligned or malrotated (Fig. 14.9).

Clinical hints and tips

- To preserve maximum bone length in the amputation stump, use parallel intraosseous wires as the preferred method of osteosynthesis, as this requires only 0.5 cm of available bone, achieves a good union rate, and allows postoperative correction of any malalignment or malrotation.
- Careful attention to tendon repairs increases range of motion and also corrects the natural tendency of the toe to claw. The extensor tendons are always reconstructed first. Preserving the extensor tendon apparatus over the proximal interphalangeal joint, wherever possible, allows the intact intrinsic system of the hand to work synergistically with the reconstructed extrinsic system. Release of the extensor digitorum longus attachment from the metacarpophalangeal joint capsule, suturing of the extensor digitorum brevis to the dorsal expansion or to the interosseous musculotendinous structure, and a tight extensor repair in full extension are different ways of overcoming the naturally flexed position of the toe.[36] In addition, a K-wire is also inserted at the end of the procedure, transfixing the distal interphalangeal joint and the proximal interphalangeal joint in full extension.
- The flexor tendon repair is carried out against the tension of the extensor repair to restore a normal digital cascade. In proximal amputations, the flexor tendon of the transplanted toe should be pulled through proximally into zone III for repair to prevent an increased risk of tendon adhesions in "no man's land" (zone II).

Clinical hints and tips

- To achieve the best functional outcome of the reconstructed tendons, preserve all extensor apparatus as far as possible to allow synergistic action of the native intrinsic system with the reconstructed extrinsic system. To correct the natural tendency of the toe to claw, perform a tight extensor tendon repair and insert a K-wire with the distal and proximal interphalangeal joints in extension for 6 weeks followed by splinting for up to a year.
- To achieve maximal stability of the interphalangeal joint following a trimmed great-toe harvest, ensure that the perijoint flap consisting of the periosteum, medial collateral ligament, and joint capsule is redraped and closed in a tight manner around the trimmed interphalangeal joint of the great toe.

Nerve repair is carried out next. The proper digital nerves are selected for end-to-end anastomosis with recipient digital nerves that have been trimmed back to reveal healthy nerve stumps. If additional dorsal recipient nerves are available, these can be sutured to any harvested branches of the superficial and deep peroneal nerves. Following nerve repair, the skin flaps are closed temporarily to allow for final skin adjustments if necessary. Care must be taken to prevent a tight closure which may eventually compress the pedicles. If in doubt, a skin graft should be used rather than try to force primary closure. A single arterial anastomosis is then performed and perfusion of the toe checked before the venous anastomosis. If it is judged to be inadequate, the entire pedicle should be assessed for any kinking, twisting, or compression with further stripping of the adventitia if necessary. If required, further shortening or a vein graft should be used to ensure healthy inflow.

Clinical hints and tips

- To ensure maximal success and reduce vascular complications, harvest the combined second- and third-toe flap with the first dorsal metatarsal artery as the dominant pedicle, and the second and third common digital artery as a backup in case of inadequate perfusion.
- To reduce donor site morbidity, close the donor site primarily in all cases. It is not necessary to reconstruct the transmetatarsal arch even when disturbed, for example, in transmetatarsal osteotomies, as this does not affect gait and walking ability in the long term.

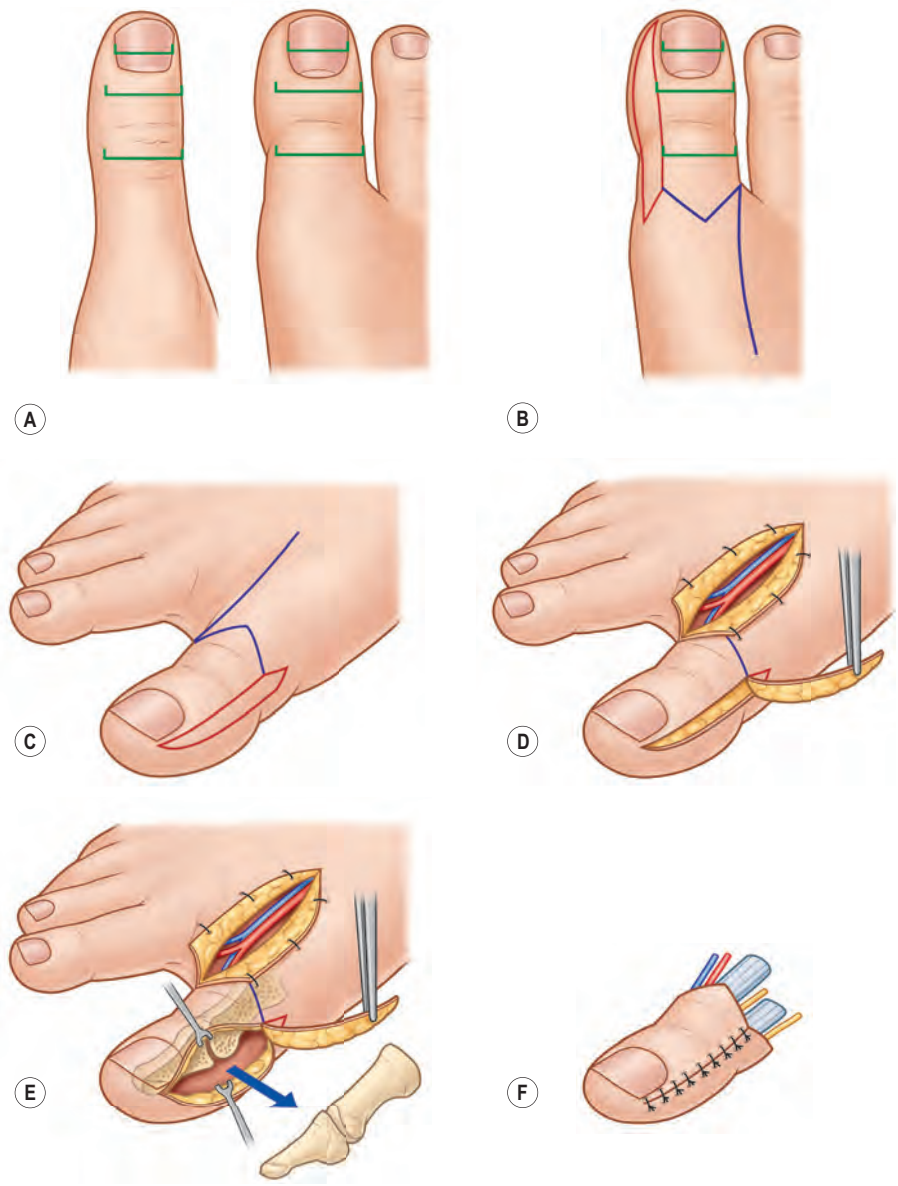

Fig. 14.10 Trimmed great-toe harvest technique. **(A)** Markings of the thumb are made at three positions on the thumb and transposed to the toe: nail eponychium, widest point (interphalangeal joint), and middle of proximal phalanx. **(B, C)** The discrepancies are marked on the medial side as an area to be excised. **(D)** The skin flap is elevated superficial to the collateral ligament and joint capsule. **(E)** The perijoint flap is created by raising the periosteum, medial collateral ligament, and joint capsule as a single flap, exposing the phalanges. The medial joint prominence and 2–4 mm of the proximal and distal phalanges are removed by an oscillating saw. **(F)** Following tight redraping of the perijoint flap, the skin is closed to create a toe of smaller circumference, ready for transfer.

In a combined second- and third-toe transplantation, two anastomoses should be prepared as a higher rate of arterial spasm, and re-exploration rates of up to 20%[100] have been found when using a single dominant artery. A second anastomosis using the second and third common plantar artery should be carried out when the perfusion to the third toe is uncertain. Once perfusion is established, the hand is then turned around, and the venous outflow checked for healthy back-bleeding. Venous anastomosis is carried out through a separate incision on the dorsum of the hand. A recipient vein of suitable caliber is selected and mobilized from the adjacent fingers if necessary. The skin incisions are then loosely closed definitively over small silastic drains placed in the dorsum of the hand and fingers, and finally the K-wire is inserted across the distal and proximal interphalangeal joints in full extension. The hand is then wrapped in a non-circumferential, non-compressive dressing with the transplanted toe largely exposed to monitor perfusion.

Specific operations

Trimmed great toe (Video 14.1 ▶)

Harvest of the trimmed great toe begins with measurements taken and compared at three locations on the normal contralateral thumb and the great toe to reconstruct a new thumb with matching proportions: the nail eponychium, the interphalangeal joint, and the middle of the proximal phalanx (Fig. 14.10). The size discrepancies are marked on the medial aspect of the great toe as an area of tissue to be excised, with an excess of 2–3 mm on each side and tapering of both the proximal and distal ends to facilitate closure.

Elevation of the trimmed great toe begins in the first webspace to identify the dominant blood supply and carry out retrograde dissection, as previously described. Following identification of the flexor and extensor tendons and also after careful preservation of the deep peroneal nerves, the

trimming of the great toe commences. The marked area of redundancy is excised with incisions down to and superficial to the medial collateral ligament of the interphalangeal joint. The next step is removal of bony excess. To facilitate access to the phalanges, a plantar-based perijoint flap composed of periosteum, joint capsule, and medial collateral ligament is raised. About 4–6 mm of the joint prominence and 2–4 mm of the phalanges are removed with an oscillating saw and the remaining bones smoothed with a burr. The perijoint flap is then redraped with the excess tissue excised and sutured in a tight manner to ensure the stability of the joint. Finally, the medial skin incisions are approximated and the overall appearance checked before carrying out the transverse osteotomy at the level of the proximal phalanx and the flap islanded, ready for inset (see Fig. 14.10).

Second toe: total and partial (Video 14.2)

Transplantation of a partial second toe is used for distal digit amputations whereas a transplantation of total second toe is used for the reconstruction of more proximal finger amputations.

For either, the skin markings encircle the base of the second toe and cross the midpoints of the first and third webspaces, finally converging as a V proximally and extending at least 5–10 mm beyond the osteotomy site (Fig. 14.11). The toe harvest commences by identifying the dominant arterial supply in a retrograde fashion and one sizeable vein, as previously described. Both the extensor digitorum longus and brevis tendons are identified and traced proximally for adequate length. Branches of the peroneal nerves are usually not harvested in preference of the plantar digital nerves. The dissection is then continued on the plantar aspect of the foot, similarly with a V extending from the base of the toe and further extension with avoidance of any weight-bearing areas. The flexor sheaths are opened and the flexor tendons pulled out and cut at a proximal level to ensure adequate length. The plantar nerves are traced proximally to the bifurcation of the common digital nerves and internal neurolyses carried out if necessary to obtain adequate length before dividing them. The removal of excess fibro-fatty tissues by skeletonization of each neurovascular component is routinely carried out, as this greatly facilitates wound closure and improves the aesthetic appearance of the transplanted toe. This is especially so for partial toe transfers, due to the relative lack of space for flap inset at the level of the middle phalanx.

The bone length required for a complete second-toe transfer is achieved by an osteotomy at the proximal phalanx, the metatarsal shaft, or via a metatarsophalangeal joint disarticulation preferably. In a partial toe transfer, the neurovascular bundles are freed distal to the osteotomy sites at the middle or proximal phalanges or the disarticulated joint. Metatarsophalangeal joint disarticulation is usually necessary to permit direct skin closure, even following partial toe transfers.

Partial second-toe transfer has further evolved into specific-structure partial transfer such as vascularized nail, pulp or joint with preservation of the second toe. The donor site of such a specialized partial second-toe flap can be covered with a full-thickness skin graft.[101]

The second-toe flap can also be modified to improve the appearance of the reconstructed new thumb. Although the second toe can be transferred to create a functionally

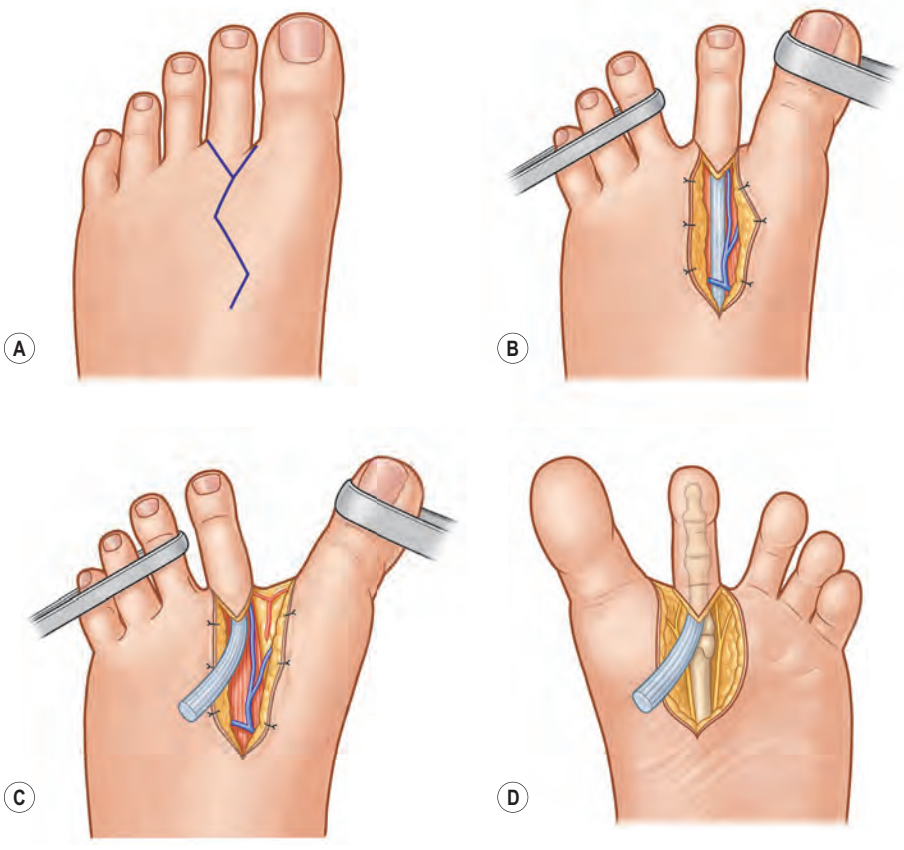

Fig. 14.11 Second-toe harvest technique. **(A,B)** A dorsal S incision is made on the dorsum of the foot to expose the donor veins, extensor mechanism, and arterial pedicle, although dissection begins in the first webspace to allow a retrograde dissection **(C).** Plantar dissection begins with a midline incision, avoiding the weight-bearing areas of the foot, to expose the digital nerves and to harvest the flexor tendon **(D).**

acceptable thumb, the appearance falls short due to narrow neck, bulbous appearance, and short nail. The lateral pulp flap from the great toe can be harvested with the second toe based on the same vascular pedicle and used to augment the volar aspect of the second toe to give more bulk and correct the narrow neck and the eponychium of the nail complex of the second toe can be excised to lengthen the nail and mimic the thumb nail.[102]

Third toe

The third toe can also be transferred to reconstruct missing digits. Indications are: (1) the second toe is not available or is not suitable for transfer because of previous injury, surgery, or deformity; (2) the second toe is on the same foot from which the great toe has been harvested for thumb reconstruction and therefore the second toe is spared for gait; and (3) the third toe provides a better size match for finger reconstruction than the second toe.[103]

For reliable harvest of the third-toe flap, the key principles used in great and second toe dissection apply. However, since the majority of the patients undergoing transplantation of the third toe have already had transplantation of either the great or the second toe or will have it, the second metatarsal pedicle is either not available or must be preserved for subsequent transfer of the great or second toe. Therefore, the third toe is preferably transferred based on the third plantar metatarsal artery, which is usually bigger in caliber than the second or third dorsal metatarsal arteries. As the pedicle of choice for the third toe is the plantar pedicle, it will be simpler and quicker to proceed directly to the dissection of the plantar vascular pedicle, and if found short, a vein graft is used for the vascular anastomosis.[103] In most cases, however, the pedicle is long enough to reach the proper digital artery at the level of the proximal phalanx in the hand.

The donor site is closed in the same way as described for the second toe.

Wrap-around flaps: great and second toes

The great-toe wrap-around flap was originally used in conjunction with a non-vascularized iliac bone graft for reconstructing thumb loss distal to the metacarpophalangeal joint,[79] although reconstructions at more proximal levels have been described.[104] The use of these flaps can be extended to the replacement of skin and nail loss in the thumb and ring avulsion finger injuries with an intact skeleton, tendon, and proximal interphalangeal joints. Reconstruction of the latter is better achieved with a second-toe wrap-around flap which provides an excellent contour and nail match and also avoids using the great toe as a donor.[35]

Harvest of the great-toe wrap-around flap follows similar principles as the trimmed great-toe technique, previously described. Preoperative markings are made with measurements taken from the contralateral thumb and transposed on to the great toe (see Fig. 14.10A). The flap utilizes the dorsal, lateral, and plantar skin, leaving behind a cuff of skin and subcutaneous tissue on the medial aspect for donor closure. Disarticulating the remaining interphalangeal joint and closing the medial skin flap over the proximal phalanx is preferred rather than using a cross-toe flap from the second toe. The second-toe wrap-around flap begins in exactly the same manner as the partial or complete second-toe flap (see above). The flap is then carefully degloved from the underlying skeleton, except for the distal phalanx, which is always included in the flap to maintain distal stability and prevent bone resorption. Careful consideration is also given to the placement of scars during flap harvest for their subsequent positioning on the "trailing" edges of the fingers. Disarticulation at the metatarsophalangeal joint in the remnant toe provides a donor defect amenable to primary closure and improved appearance.

Fig. 14.12 Pulp flap harvested from the great toe.

Neurosensory pulp flaps

The size of the defect is outlined and marked on the selected toe (Fig. 14.12). The lateral aspect of the great toe is preferred for its richer nerve supply, more abundant tissues, and therefore increased likelihood of primary closure.[65] Principles for flap harvest are similar to those previously described, but important considerations are keys to achieving success: (1) identifying and including both the branches of the deep peroneal nerve and proper digital nerve to provide the best sensory outcome; (2) dissection and inclusion of the proper digital artery by tracing its origin from the first dorsal or plantar metatarsal artery in the first webspace; (3) skeletonizing the neurovascular bundle to allow tunneling of the vessels during flap inset.

First-web neurosensory flap

This is a useful flap due to its rich sensory innervations, pliability, and size, with dimensions of 14 × 7 cm achievable[105] for resurfacing of bigger defects in one or multiple fingers, and the potential to replace glabrous skin for palm defects.[104,106,107] After outlining the defect in the first webspace, the vein is first identified, as previously described. The location of the intermetatarsal ligament is identified next as this structure points to the first dorsal or plantar metatarsal artery and the distal communicating artery that supplies this flap. Once the dominant blood supply is confirmed, retrograde dissection continues in a straightforward manner, continuing with either the dorsal or plantar approach. Branches of the proper digital arteries must be traced and included if the flap dimensions extend to the pulps of the great or second toes.

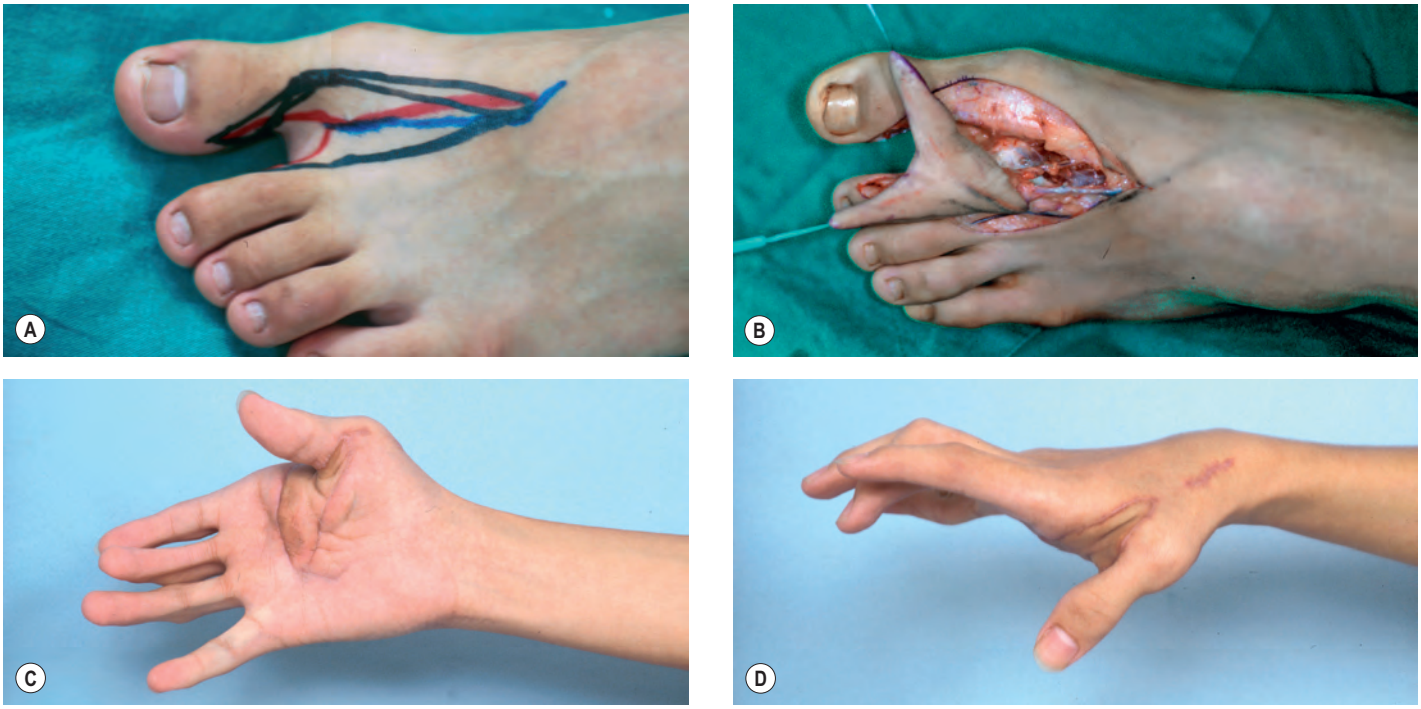

Fig. 14.13 (A–D) First-web neurosensory flap harvest from the left foot for reconstruction of the first webspace of the right hand.

Likewise, in this situation, the proper digital nerves are harvested in conjunction with the deep peroneal nerve branches to provide adequate sensation. The donor defect is readily reconstructed with a split-thickness skin graft and tie-over dressings. Careful attention to detail and strict non-weight-bearing reduce the incidence of wound-healing complications and the need for prolonged foot care (Fig. 14.13).

Combined second- and third-toe transplantation (Video 14.3)

Combined second- and third-toe transplantations carry the advantages of only needing potentially one set of microvascular anastomoses, less operative time, and confining donor morbidity to one foot.[90] Its popularity has been limited, however, by the length of digits achievable following reconstruction and probably concerns regarding the donor morbidity, especially in certain populations.[29] If carried out carefully, however, this procedure is extremely useful in replacing two adjacent finger amputations at a level proximal to the webspace, especially when the other remaining fingers are shorter than the little finger. It is especially useful in the metacarpal hand deformity to provide tripod pinch function, hook grip capability, and lateral stability.

Skin incisions in the first and third webspaces should not cross the midline to allow primary closure of the donor site, and converge to a V 1 cm proximal to the level of osteotomy. In proximal phalanx amputations with at least 5 mm of bone remaining, the toe is disarticulated from the metatarsophalangeal joint and then subsequently shortened to the required length and osteosynthesized to the finger skeleton. Through metacarpophalangeal joint amputations are reconstructed with the corresponding metatarsophalangeal joints of the toes with their joint capsules intact. Even more proximal amputations require harvest of the respective metatarsals (Fig. 14.14).

Retrograde dissection of the dominant arterial supply is performed in the first webspace, as previously described. The second and third plantar arteries should be dissected and preserved as a backup in case a second set of anastomosis is required. The common digital nerve to the second and third toe, together with their respective proper digital nerves, is also isolated and preserved for transfer during the plantar dissection. Direct closure of the donor site in a tension-free manner should be achievable without the need for a skin graft. In cases where the metatarsals have been osteotomized, the authors' present policy is to not replace the foot defect with a bone graft as previous analysis of patients has demonstrated no difference in walking and gait performance.[65]

For situations when one neighboring second toe needs to be preserved for specific reasons and the amputation level at the recipient site is distal to the webspace, a bilateral third-toe transplantation provides an alternative solution. A split combined second and third toe from the other foot can be also performed and, in this case, two sets of pedicle vessels from the dorsal or plantar system are prepared and the best selected. Separation of second and third toes can be done after the adjacent toes were taken down or before.[108]

Postoperative care

Immediate postoperative period

The immediate postoperative care is critical to ensure the success of the microsurgical procedure. Patients ideally should be kept for close monitoring of the flap in a microsurgical intensive care unit for a minimum of 5 days. If this facility is not available, they should be kept in a warm room and nursed by experienced staff trained in the routine monitoring of free

Fig. 14.14 Combined second- and third-toe harvest as a transmetatarsal transfer for reconstruction of a metacarpal hand. **(A)** Surface markings on the donor foot before harvest showing the position of the first dorsal metatarsal artery and a suitable vein. **(B)** Harvested toe with artery, veins, nerves, and tendons. **(C,D)** Reconstructed hand following inset showing primary closure of all wounds without tension.

flaps. Although both internal devices such as implantable Doppler[109] and external devices such as infrared temperature assessment and pulse oximetry may be useful modalities,[110] the most reliable method of flap monitoring is still clinical observation. At the first sign of vascular compromise, rapid action should be taken to avoid further flap deterioration.[111] Infection should also be identified and controlled early as it has been found to be the single greatest factor contributing to vascular compromise and re-exploration in toe-to-hand surgery.[112] Beside flap monitoring and infection control, all patients are carefully monitored to ensure they are warm, well-hydrated, and pain-free. The hand is kept slightly elevated above the level of the heart, but not higher. Non-constricting, non-bulky dressings should be used as this prevents clot formation which could induce vasospasm during dressing change and also prevents early mobilization. A routine intraoperative bolus of dextran is given, followed by continuous infusion over the next 5 days. In addition, a 2-week course of oral aspirin is administered to reduce the incidence of platelet aggregation.

Motor rehabilitation

Toe-to-hand transplantations require a close collaboration between surgeons, nurses, physiotherapists, occupational therapists, and prosthetists to provide the necessary postoperative rehabilitation program and maximize the functional outcome. Individual patient motivation and employment needs also have to be considered. A five-stage rehabilitation program[65] ensures that these objectives are met:

1. Protective stage (days 1 to 3): Psychological support is provided while the patient is still in the microsurgical intensive care unit through interaction with the hand therapist.
2. Early mobilization stage (day 4 to week 4): The goal is to prevent excessive swelling and joint stiffness. On day 4, controlled gentle passive range of motion for about 15° is performed on the less involved joints. In the subsequent weeks the passive movement involves all joints both proximal and distal to the osteosynthesis site and is gradually increased in range but not to interfere

with bone union or to induce stress on the repaired tendons and the neurovascular structures. A protective splint is provided between exercises.

3. Active motion stage (weeks 5 to 6): While the passive exercises are still maintained, gentle active exercises under supervision begin, and the splint is changed to a dynamic one. Once tendon healing is no longer a concern, blocking flexion and extension exercises are started. At this stage, more care can be directed towards softening the scar and improving appearance, and to avoiding adhesion by providing compression bandages, ultrasound, and scar massage.
4. Activities of daily living training stage (weeks 7 to 8): Depending on patient capabilities, different manual jobs that simulate daily manual activities are designed to increase muscle power and range of motion.
5. Pre-vocational training stage (week 8 and beyond): The goal is to further improve muscle strength, hand dexterity and coordination. Vocational activities are encouraged, and a night-time extension splint to prevent claw deformity is recommended for 1 year at least. Group sessions with other patients who have also received toe-to-hand transplants can be helpful to encourage integrating the reconstructed hand into the patient's normal life.

Sensory rehabilitation

The finger and thumb pulps are unique in that they contain a higher density of sensory nerve endings than other body areas, packed within a relatively small area of skin that is tightly adhered to the underlying bone via fibrous septa.[113] Although toe transfers allow the replacement of this specialized glabrous skin, targeted sensory rehabilitation plays an important role in producing an optimal functional result. Several studies have demonstrated the importance of sensory re-education in maximizing both subjective and objective sensory recovery following nerve repair in digits;[67,114–116] this is of even greater importance in toe-to-hand transplantations due to the fewer number of sensory endings in the toe as compared to the fingertip.[117] Two types of sensory re-education program are used in the authors' unit: early and delayed.

Early re-education focuses on improving the local adaptation to the submodalities of light touch, pinprick, and pressure with correct localization, according to Dellon.[67] Static and moving two-point discrimination tests are usually chosen to measure local sensory recovery[70,87,107,118] following early re-education, although our unit has shown that there is very little correlation between this method of assessment and sensory threshold testing using the Semmes–Weinstein monofilament kit.[119] These results suggest that subjective recovery of functional sensibility may not always reflect the actual recovery of nerve function at the microscopic level. In fact, from our earlier study, the actual number of Meissner corpuscles was found to be decreased after transplantation, even though good functional sensibility was restored,[120] stressing again the importance of delayed sensory education which emphasized the retraining of central cortical functions like concentration, memory, and relearning.

Delayed sensory re-education consists of touching objects, both blinded and non-blinded, to appreciate further the differences in texture, size, shape, and consistency from different surfaces. The significant improvement that can be seen following this re-education can probably be explained by the increased cortical reorganization caused by increased neural activity in the postcentral gyrus that compensates effectively for the decreased local neural activity.[121–123]

Outcomes, prognosis, and complications

Outcomes and prognosis

The success rates of microsurgical toe-to-hand transplantations are around 96–98%.[53,112,124–126] Therefore, the goal of this surgery should no longer be flap survival but improved aesthetic and functional outcomes. In a series of 2200 procedures carried out by the authors over 30 years (1985–2015) at Chang Gung Memorial Hospital and Medical College, a success rate of 97% was achieved (see Fig. 14.1).

Range of motion

In terms of range of motion, an average of 25° and 29° following thumb reconstruction using the great toe should be achievable at the metacarpophalangeal joint and interphalangeal joint, respectively.[125] The trimmed great-toe technique generally results in an anticipated reduction of movement at the interphalangeal joint of 18°, although this did not seem to affect pulp-to-pulp pinch prehension.[78] In toe-to-finger transplantations, an average total range of motion of 50–60° is usually achievable for the proximal and distal interphalangeal joints.[60,127] If a metatarsophalangeal joint has been transferred to reconstruct the metacarpophalangeal joint, the expected range of movement should average 50°, or 52° if a composite joint reconstruction has been carried out via a metatarsophalangeal joint disarticulation during harvest.[12,90]

Strength assessment

In general, an average of more than 75–80% approximation to the opposite thumb has been reported for both grip and pinch strength following thumb reconstruction, in many instances exceeding the strength of its counterpart.[25,125,128] Independent strength assessment in finger reconstructions is more difficult to measure and is often dependent on an intact thumb function to produce a stable tripod or pulp-to-pulp pinch. The reconstructed finger is also often shorter and may not be accurately assessed using conventional methods of assessment like the traditional dynamometer or pinch meter. These instruments may need to be specially modified to conform to the length and profile of transplanted toes. Furthermore, restoring the prehensile patterns of the hand may be a much more valid measure of outcome and has been achieved in most series, especially following reconstructions for multiple-finger amputations and the metacarpal hand deformity.[8,20,82,129,130] In addition, from the authors' series of toe transfers for isolated finger amputations, we have also found restoring the digital arcade and storage function of the hand to be useful both functionally and psychologically.[26,103]

Fig. 14.15 Donor site after combined second- and third-toe harvest in the left foot and second-toe harvest in the right foot.

Appearance and sensory outcomes

A major advantage of toe-to-hand transplantations is the replacement of tissue that bears a near-normal resemblance of what was lost. Both Chung and Wei[128] and Poppen *et al.*[125] found a much higher use of the reconstructed hand following toe-to-thumb transplantation as compared to its use before thumb reconstruction. With improved sensory recovery comes an enhanced appreciation of the reconstructed digits and also a better overall integration into the body. These improvements are largely dependent on a comprehensive sensory re-education program as described. Performing the toe-to-hand transplantation surgery within a month of the injury has also been shown to lead to better sensory results.[123] Overall, the average recovered two-point discrimination should not be expected to exceed approximately 7–8 mm.[49,76,107,120]

Donor site outcome evaluation

An evidence-based recommendation of the superiority of a specific type of toe-to-hand transfer is difficult to draw from the perspective of donor site morbidity.[131] Generally, the morbidity is well accepted after isolated second-toe transfer[34,35,89] (Fig. 14.15). On the other hand, great-toe harvest followed by combined second- and third-toe dissection appear to have more donor site morbidity, but it remains largely acceptable especially when the gain in hand function is taken into consideration.[132,133] And, in spite of increased dynamic and static loading on the first metatarsal head and heel, this seldom translates into significant complaints regarding gait or appearance[65] (see Fig. 14.15). Even after 16 years median follow-up, 92% of patients reported no or only minor complaints.[45]

The practice of using non-vascularized bone blocks to replace harvested metatarsal bones and the repair of the metatarsal ligament after toe transfer have been abandoned for a long time, as no problems when walk or take-off have been documented. However, every measure should be taken to ensure additional potential complications such as skin necrosis, hypertrophic scarring, or painful neuroma[134] are minimized. The potential donor defect should always be discussed in detail with the needs of each patient individualized with regard to lifestyle, hobbies, and concerns regarding appearance.

Complications

The most common complication in the immediate postoperative period is vascular compromise due to vasospasm followed by arterial, and less commonly, venous thrombosis. In our earlier experience, the re-exploration rate was 17.6% with an 89% salvage rate.[112] Emergency re-exploration of the anastomosis is warranted following failed bedside measures such as lowering the hand, release of sutures, topical application of warm saline and 2–4% lidocaine, and fluid optimization. In re-exploration, the hematoma is evacuated, the adventia is sharply excised with free use of warm saline and 2–4% lidocaine if there is vasospasm, and the anastomosis is revised once lumen occlusion is confirmed. Additional anastomoses using another arterial pedicle may be required in certain cases, for example, combined toe units. In some cases of intractable spasm, excision of the spasmodic segment, like that done in thrombotic vessels, and replacing it with vein graft or flow-through venous flap for tension-free closure may become necessary.

Venous compromise is usually treated in the same manner, but it is less critical and does often lead to total toe loss. Despite careful preoperative planning and early recognition of problems, around 3–5% still fail, possibly due to irreparable damage or inherent problems with the suitability of the vessels.[135,136] Once the cause of the problem is identified, a repeat toe transfer may be indicated with the use of an interim groin flap.[137] Other complications, including skin flap necrosis or wound-healing problems with resultant exposed structures, must be remedied as soon as possible to prevent desiccation of tendons or neurovascular bundles, which result in further complications from the injury. Longer-term complications may be directly related to the original injury or indirectly as a result of suboptimal reconstruction, often correctable by secondary procedures.

Secondary procedures

Despite meticulous planning and optimization of the technique, secondary procedures are still required in a percentage of cases (14–20%) to improve the functional and aesthetic outcome of the hand and foot following toe-to-hand transplantations.[40,138,139] Revision procedures for functional improvement such as tenolysis, arthrodesis, and webspace deepening usually yield good results.[40] Flexor tenolysis is one of the most common secondary procedures described for most series and may be related to the methods of bone osteosynthesis or the severity of the original injury requiring a period of immobilization.[40,140]

Revision procedures for aesthetic improvement are usually minor, and aim to increase resemblance of the toe to the finger or thumb.[36,38,141] The most common procedure is a pulp plasty carried out under local anesthesia to reduce the bulbous appearance of the toe, although other procedures including scar revision and flap thinning may be required (Fig. 14.16).

Future directions

Microsurgical toe-to-hand transfer had its principles and techniques well established by the end of 1990s. And, what can be expected from the surgery has become well-known to

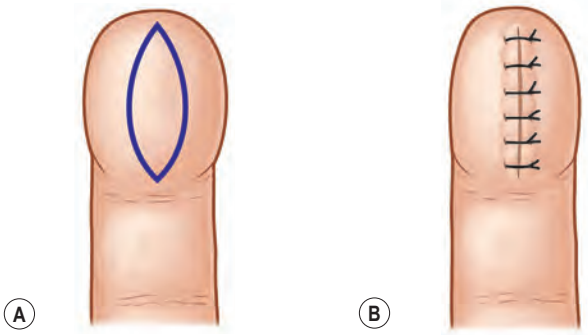

Fig. 14.16 (A,B) Pulp plasty technique.

the working reconstructive surgeon today. Nevertheless, there is still room for improvement.

Patient-reported outcomes and evidence-based studies are largely missing; the need for these publications will further determine which toe-to-hand transplantation techniques can provide the highest reward with the least morbidity. Furthermore, preoperative planning for complicated toe-to-hand reconstructions may benefit from 3D printing and computer-aided design and modeling to increase surgical precision and to enhance aesthetics and function.[142,143]

Robotic surgery could be another potential, and with the advantages of physiological tremor suppression, user-friendly ergonomics, and ultraprecise control of the instruments, ultra partial toe transfer may become feasible with reduction of surgical time and complications.[144]

56. Wei FC. Tissue preservation in hand injury: the first step to toe-to-hand transplantation. *Plast Reconstr Surg*. 1998;102:2497–2501. *This article gives useful guidelines in the initial management of amputated digits, especially if a preemptive view of future toe-to-hand transplantation is to be considered and discussed with patients. The main recommendations outlined in this editorial emphasize tissue preservation, facilitating future toe-to-hand transplantation in terms of reconstructive options, functional and aesthetic outcomes in the hand, and donor site morbidity in the foot. Although tissue conservation is the main goal at this stage of treatment, this should not be at the expense of tissue viability. If in doubt about management issues, advice should be sought from the reconstructive microsurgery unit.*
77. Wei FC, Chen HC, Chuang CC, et al. Microsurgical thumb reconstruction with toe transfer: selection of various techniques. *Plast Reconstr Surg*. 1994;93:345–351, discussion 52–57. *This review looked at the established method of thumb reconstruction using different options. Selection of technique requires balancing the patient's functional needs, appearance of the reconstructed thumb, and donor site cosmesis. Based on their experience with 103 toe-to-thumb transfers performed over the previous 9 years, this paper attempts to provide guidelines for appropriate selection among the four most commonly employed toe transfer techniques (second toe, total great toe, great toe wrap-around, trimmed great toe) so that both optimal results and patient acceptance can be achieved.*
90. Wei FC, Colony LH, Chen HC, et al. Combined second and third toe transfer. *Plast Reconstr Surg*. 1989;84:651–661. *This study reported a 4-year experience with 26 consecutive combined second- and third-toe transfers to replace missing adjacent fingers in order to delineate the indications and technical considerations and to emphasize prevention of donor site complications. The surgical technique is described in detail. Combined second- and third-toe transfer is reserved for adjacent finger amputations proximal to the digital webspace with remaining fingers no longer than the small finger. Radial amputations are replaced with contralateral combined toe units, while ipsilateral toes are more ideal for ulnar amputations. When properly applied in selected patients, this single-stage microsurgical procedure can restore prehensile function, improve the appearance of the hand with multiple digital amputations, and preserve near-normal donor foot function.*
99. Wei FC, Silverman RT, Hsu WM. Retrograde dissection of the vascular pedicle in toe harvest. *Plast Reconstr Surg*. 1995;96:1211–1214. *A retrograde approach to dissection of the vascular pedicle in toe-to-hand transfer is presented, along with a simplified view of the vascular anatomy of the first webspace. This paper described the several advantages of this approach. First, the dominant vascular supply to the toe is elucidated early in the procedure, allowing for less unnecessary dissection of an inadequate pedicle. This also eliminates the need for preoperative arteriography. Furthermore, in cases where a lengthy pedicle is not required, retrograde dissection dispenses with harvest of a proximal vessel, which will not be needed for the transfer, thus minimizing donor morbidity.*

Tissue preservation in hand injury: the first step to toe-to-hand transplantation. *Plast Reconstr Surg*. 1998;102:2497–2501. *This article gives useful guidelines in the initial management of amputated digits, especially if a preemptive view of future toe-to-hand transplantation is to be considered and discussed with patients. The main recommendations outlined in this editorial emphasize tissue preservation, facilitating future toe-to-hand transplantation in terms of reconstructive options, functional and aesthetic outcomes in the hand, and donor site morbidity in the foot. Although tissue conservation is the main goal at this stage of treatment, this should not be at the expense of tissue viability. If in doubt about management issues, advice should be sought from the reconstructive microsurgery unit.*

Microsurgical thumb reconstruction with toe transfer: selection of various techniques. *Plast Reconstr Surg*. 1994;93:345–351, discussion 52–57. *This review looked at the established method of thumb reconstruction using different options. Selection of technique requires balancing the patient's functional needs, appearance of the reconstructed thumb, and donor site cosmesis. Based on their experience with 103 toe-to-thumb transfers performed over the previous 9 years, this paper attempts to provide guidelines for appropriate selection among the four most commonly employed toe transfer techniques (second toe, total great toe, great toe wrap-around, trimmed great toe) so that both optimal results and patient acceptance can be achieved.*

Combined second and third toe transfer. *Plast Reconstr Surg*. 1989;84:651–661. *This study reported a 4-year experience with 26 consecutive combined second- and third-toe transfers to replace missing adjacent fingers in order to delineate the indications and technical considerations and to emphasize prevention of donor site complications. The surgical technique is described in detail. Combined second- and third-toe transfer is reserved for adjacent finger amputations proximal to the digital webspace with remaining fingers no longer than the small finger. Radial amputations are replaced with contralateral combined toe units, while ipsilateral toes are more ideal for ulnar amputations. When properly applied in selected patients, this single-stage microsurgical procedure can restore prehensile function, improve the appearance of the hand with multiple digital amputations, and preserve near-normal donor foot function.*

Retrograde dissection of the vascular pedicle in toe harvest. *Plast Reconstr Surg*. 1995;96:1211–1214. *A retrograde approach to dissection of the vascular pedicle in toe-to-hand transfer is presented, along with a simplified view of the vascular anatomy of the first webspace. This paper described the several advantages of this approach. First, the dominant vascular supply to the toe is elucidated early in the procedure, allowing for less unnecessary dissection of an inadequate pedicle. This also eliminates the need for preoperative arteriography. Furthermore, in cases where a lengthy pedicle is not required, retrograde dissection dispenses with harvest of a proximal vessel, which will not be needed for the transfer, thus minimizing donor morbidity.*

Benign and malignant tumors of the hand

Justin M. Sacks, Kodi K. Azari, Scott Oates, and David W. Chang

SYNOPSIS

- Benign and malignant tumors of the hand arise from distinct tissue types.
- The majority of these tumors are benign.
- Accurate assessment, diagnosis, and treatment will optimize clinical outcomes.
- Reconstructive procedures of the hand and upper extremity should be performed only after the diagnosis is confirmed and appropriate surgical margins are achieved.
- Surgical incisions must be planned carefully with definitive surgery in mind, utilizing a longitudinal incision in line with or parallel to a potential limb salvage procedure.
- Reconstructive procedures, in the setting of a neoplasm of the hand, are performed only after the final pathological diagnosis and clear resection margins are established.
- An understanding of both oncologic and reconstructive principles is required in order to achieve an optimal clinical outcome.

Introduction

- Most tumors of the hand are benign, recognized early, and treated by excision.
- Ninety-five percent of hand tumors that do not involve the skin are benign.
- Malignant tumors of the hand can be divided into two categories: primary and metastatic. Primary tumors can arise from the skin (e.g., melanoma, basal and squamous cell carcinoma), soft tissues (e.g., sarcoma), or bone (e.g., osteosarcoma). Metastatic disease originates most commonly from cancers of the breast, kidney, thyroid, lung, and colon.
- Appropriate evaluation, diagnosis, and treatment for tumors of the hand are required for optimal patient care. A careful history and physical examination will rapidly focus the investigation of a suspicious mass found in the hand.
- Magnetic resonance imaging (MRI) has become the "gold standard" to evaluate soft-tissue masses for malignancy. Computed tomography (CT) is preferred for osseous lesions.
- Incisional or excisional biopsy is required for definitive diagnosis in many cases.

Clinical tips

Most hand tumors:
- arise from any cell type
- are benign
- are treated with a favorable prognosis

When in doubt:
- excisional biopsy
- plan incisions carefully
- definitive surgery in mind

Basic science/disease process

Tumors of the hand can arise from the skin, adipose tissue, synovium, tendons, cartilage, bones, muscles, fibrous tissue, nerves, and blood vessels. The majority of hand tumors are benign, most are recognized early, and the prognosis is typically good.[1,2] Malignant tumors also occur in the hand and can be divided into two categories: primary and metastatic. In addition, premalignant lesions such as actinic keratoses and atypical nevi can occur on the hands.

In this chapter, benign and malignant tumors are classified and discussed by their tissues of origin. Understanding the origin of hand lesions will assist in accurate diagnosis and appropriate therapeutic interventions.[3]

The management of hand tumors requires the hand surgeon to function as both oncologic surgeon and reconstructive surgeon. A complete understanding of both oncologic and reconstructive principles is therefore required to achieve an optimal outcome. The role of the oncologic surgeon is to eradicate the tumor completely, which can compromise both aesthetics and function. In contrast, the role of the reconstructive surgeon is to optimize hand function. Balancing these sometimes competing goals can be challenging.[4]

An effective strategy to evaluate, diagnose, and treat tumors of the hand and associated upper extremity is required for optimal patient care. A careful analysis of the history and physical examination will rapidly focus the investigation of a newly evident hand lesion. The use of radiography (X-rays), CT, and MRI will strengthen the apparent diagnosis.[5] However, incisional or excisional biopsy will, in most instances, be the final determinant of diagnosis.

Diagnosis/patient presentation

Patient history

A thorough history and physical examination remain the foundation of proper initial diagnosis. Questions concerning the history of the tumor are solicited. These include duration, changes in size or color, associated pain, and occurrence of ulceration. Pain can signify a malignancy or a mass that has encroached on neurologic structures. The sensitivity of the mass to cold or heat needs to be clarified, as the former typifies a subungual glomus tumor.[6]

Inquiring about risk factors for tumors of the hand will strengthen eventual diagnostic conclusions. The patient should be questioned about a history of cutaneous malignancies, extensive sun exposure or sunburns as a child, chemical and ionizing radiation exposure, and trauma or infections. The patient should also be questioned about rheumatologic conditions, such as gout, psoriasis, and rheumatoid arthritis.

The age of the patient needs to be considered when evaluating a mass in the hand. Certain masses are specific to certain age groups. For instance, bone cysts are typically seen in adolescents and young adults, whereas metastatic tumors in the hand are rare under the age of 50 years.[7]

Questions about previous biopsies or excisions will complete a thorough historical evaluation of the patient with a hand tumor. Pathology reports for previous biopsies or excisions will need to be obtained and reviewed. Prior operative reports will help clarify the diagnosis and optimize future surgical interventions in instances in which the current pathology is unknown.

Clinical tips

History

Past medical history:
- rheumatoid arthritis – rheumatoid nodule
- gout – tophus

Pain: suggestive of malignancy

Cold sensitivity: subungual lesion – glomus tumor

Pain relieved by NSAIDs: osteoid osteoma

Infections

Trauma

Physical examination

The physical examination of the hand involves a complete examination of the skin, tendons, muscles, ligaments, bones, and neurovascular structures. An evaluation of the regional lymph nodes for adenopathy is the cornerstone for assessing the malignant potential of a hand mass. For example, adenopathy can be observed in epithelioid or clear cell sarcomas.[8,9]

An inspection of the lesion begins in the examination room. An adequate light source is essential to visualize the lesion's characteristics. Color and texture changes are noted, and an examination for ulcerations, erythema, and edema is performed. Transillumination of the mass can be helpful in distinguishing between solid and cystic etiologies. The lesion is palpated, and the mass size is appreciated along with its shape and contour. The mobility of the mass is assessed to determine whether it is fixed to underlying anatomic structures. Having the patient flex and extend the fingers and wrist will further delineate whether the lesion is associated with tendons or deeper structures within the joints. A complete vascular examination with palpation of pulses is required. If pulses are not palpable, Doppler ultrasonography can be used to define the vascular status of the hand and upper extremity. Allen's test is mandatory. Neurologic testing of fine and gross motor and sensory function is also performed.

When benign lesions are to be followed clinically, photographic documentation is an essential tool to judge the rate of growth over time. Photographs are also recommended for patients with multiple and subtle lesions.

Laboratory studies

Laboratory studies are helpful in determining the etiology of some hand tumors. A hematology profile can determine an infectious etiology. Serum calcium, phosphorus, and alkaline phosphatase levels are often increased in patients with metastatic tumors, and alkaline phosphatase is also increased in patients with osteosarcoma. An erythrocyte sedimentation rate assesses for inflammation; the rate is often increased in Ewing's sarcoma, lymphoma, and myeloma. An extremely elevated prostate-specific antigen level is specific for metastatic prostate cancer. In male patients older than 50 years with evidence of blastic hand lesions on X-rays, a serum prostate-specific antigen test should be performed. Although these laboratory findings are not specific for hand tumors, they can help focus the search for a diagnosis.

Clinical tips

Laboratory tests
- Increased ESR: Ewing's sarcoma, lymphoma, myeloma
- Increased Ca^{++}: metastatic tumors
- Increased alkaline phosphatase: osteosarcoma
- Males, age >50, and blastic bone lesions: check PSA

Imaging

Multiple radiologic modalities are available for imaging benign and malignant hand lesions and masses. Radiographs are not essential for most skin lesions. However, radiographs are required for very large skin lesions and for those apparently

fixed to underlying anatomic structures based upon physical examination.

The plain X-ray is one of the most important studies for evaluating lesions and masses of the hand. X-rays are easily obtained and can evaluate a mass from multiple angles. The size of the mass can be inferred from X-rays. In the hand, a mass >3 cm in diameter should be considered potentially malignant. The architecture of the mass as it relates to the cortex of the associated bone can be determined rapidly by X-ray. Sharp cortical margins indicate a benign process, while a "moth-eaten" or destroyed cortex indicates a malignant process. Erosions and periosteal elevation on X-rays can signify a potential malignancy or an infectious process. Soft-tissue calcifications may signify a malignancy (Fig. 15.1). Rounded calcifications with central lucencies can portend a vascular etiology.

Ultrasonography can be helpful in assessing soft-tissue masses. This technique is non-invasive and inexpensive. Ultrasonography can determine if a tumor is solid or cystic and differentiate between a discrete mass and diffuse edema. In many instances, ultrasonography can be used to guide needle biopsy.

Scintigraphy or bone scanning is beneficial in screening for skeletal masses. This technique is sensitive in isolating abnormalities, but the findings are not very specific for malignancy. For example, there is intense uptake with osteoid osteoma, a benign bone tumor. Bone scans are very helpful when searching for sources of metastasis in the workup of hand and upper extremity primary malignancies.

Fig. 15.1 In this proximal phalanx lesion of the thumb a destroyed cortex potentially indicates a malignant process.

CT is extremely useful for the assessment of bones and cortical destruction. CT scans have markedly greater bony resolution than standard radiographs. If bone involvement by the mass is equivocal on X-rays, CT is the next appropriate radiographic modality. CT also distinguishes calcification patterns from ossification and is superior in assessing periosteal versus endosteal reactions.

MRI is superior to CT for the evaluation of soft-tissue masses. MRI is better able to assess the intra- and extraosseous extent of soft-tissue masses. It has become the gold standard to evaluate soft-tissue masses for malignancy.[10] The MRI study should include T1-weighted, fat-suppressed T2-weighted, and short tau inversion recovery images. The contrast agent gadolinium can further enhance the visualization of soft-tissue tumors. An MRI study obtained with various views can clearly delineate the extent of soft-tissue involvement prior to operative intervention. A drawback of MRI is that it cannot reliably distinguish between benign and malignant processes. In addition, for MRI of hand masses, a dedicated hand coil is required.

The next logical progression in the workup of a skin, soft-tissue, or bony lesion is a biopsy. The accuracy of pathologic assessment is dependent on the type of specimen obtained. A frozen-section analysis can be performed to assess the adequacy of the tissue sample. However, the accuracy of frozen-section diagnosis is only 80%, whereas permanent-section diagnosis is accurate 96% of the time. The accuracy of core needle biopsy is intermediate between the two, at 83–93%.[2]

A biopsy can be closed or open. In a closed biopsy, a needle or trephine is used to obtain samples. Closed biopsy is useful for metastatic workup. However, tissue samples from closed biopsy are often inadequate for initial diagnosis.[11]

Open biopsies can take many forms: the type of open biopsy performed is determined by the patient's history, physical findings, and imaging findings. For all open biopsies, longitudinal incisions should be in line with or parallel to incisions that would be used in a later limb salvage procedure if the tumor proves to be malignant. If a tourniquet is used, the upper extremity must not be exsanguinated because doing so may cause spread of malignant cells into the lymphatics. Proper hemostasis should be maintained, and adjacent anatomic compartments should not be violated unless a radical excision is required. An important tenet is to biopsy all infections and culture all masses.[3,12] Chronic infections can masquerade as malignancies, and masses can result from subclinical infections.

In an incisional biopsy, only a piece of the lesion is removed. A longitudinal incision is made; if soft-tissue masses invade adjacent compartments, muscle fibers are split longitudinally. A piece of the lesion is then excised for pathological diagnosis.

An excisional biopsy removes the entire lesion and is potentially a single-stage cure for a benign lesion. Excisional biopsy is limited to lesions ≤1 cm.

Enneking developed a method for musculoskeletal tumor dissection based on the histologic grade, location, and extent of the mass. An intralesional dissection is through the plane of the tumor, whereas a marginal dissection is through the tumor "reactive zone". A wide dissection involves removal of the mass plus a margin of normal tissue but remains within a single compartment.[12] A wide dissection is performed when there is a suspicion of malignancy. A radical dissection involves extracompartmental resection.

Clinical tips

Imaging studies

X-ray

- Size
  - Size >6 cm: malignant

Patient selection

All patients with a lesion or a mass of the hand must be appropriately evaluated. A history and physical examination are critical to determining what further workup is needed. Once the process needed to investigate the lesion or mass is determined, it is then the physician's responsibility to determine the appropriate diagnosis and plan the treatment.

Treatment/surgical treatment by tissue of origin

Skin tumors

Neoplasms of the skin can be benign, premalignant, or malignant. In addition, there are masses such as sebaceous cysts and cutaneous horns that can masquerade as tumors but are not true neoplasms and thus are considered pseudotumors.[13] For the majority of benign neoplasms or tumors, an excisional biopsy will completely eradicate the mass. For malignant skin neoplasms, such as melanoma, complete excision with clear margins does not always correlate with complete eradication of the skin tumor because of the potential for metastatic spread.[1]

Clinical box

Incisional biopsy

- Longitudinal incision
- Tourniquet, do not exsanguinate
- Avoid violating adjacent compartments
- Split muscle fibers longitudinally
- Frozen section to assess adequacy of sample
- Cultures
- "Biopsy all infections. Culture all masses."

Cutaneous horn

A cutaneous horn is an exophytic lesion that originates from the skin and is composed of keratotic material (Fig. 15.2).[13] Cutaneous horns are located on sun-exposed areas of the body such as the dorsum of the hands and forearms. These unsightly lesions can interfere with function. They can occur

Fig. 15.2 Cutaneous horn. The lesion typically presents on the palmar surface of the hand. This lesion represents the typical keratin horn.

in association with a variety of tumors, including epidermal inclusion cysts, epidermal nevi, fibromas, and pyogenic granulomas. In addition, cutaneous horns can be associated with both premalignant and malignant neoplasms such as actinic keratoses and squamous cell carcinomas. In fact, 10% of cutaneous horns are found in association with squamous cell carcinoma.

Cutaneous horns are treated by excisional biopsy with 1–2-mm margins. Incisional biopsy is not recommended for this lesion because of the potential for sampling errors.[2]

Epidermal inclusion cyst

Epidermal inclusion cysts are the third most common hand tumors (Fig. 15.3). These masses, which originate from an

Fig. 15.3 Epidermal inclusion cyst. These masses, which originate from an invagination of epithelium, can follow trauma, injection, or an incision. The epithelium is internalized, resulting in subcutaneous keratin deposition.

invagination of epithelium, can follow a trauma, injection, or incision.[2,14] The epithelium is internalized, resulting in subcutaneous keratin deposition. Epithelial cysts are typically painless and most commonly occur in the digits.

Treatment of an epidermal inclusion cyst involves a complete marginal excision of the cyst and its wall. The risk of recurrence of this lesion following complete excisional biopsy is extremely low.

Sebaceous cyst

A sebaceous cyst is another lesion originating from the skin and is similar in appearance to an epidermal inclusion cyst (Fig. 15.4). Sebaceous cysts arise from an obstructed apocrine gland, which produces sebum as opposed to keratin.[2] When they occur in the hand, sebaceous cysts are found on the dorsal aspect. Palmar skin does not contain sebaceous glands, so sebaceous cysts do not appear there. Treatment is similar to that of an inclusion cyst, and the risk of recurrence is low.

Verruca vulgaris

The human papillomavirus causes verruca vulgaris or common warts (Fig. 15.5). Types 1–4, 7, and 10 have been implicated in the etiology of skin lesions involving keratinized epithelium. Verruca vulgaris presents as a rough raised surface anywhere on the hand and is 20 times more common than the verruca plana or flat wart, which is found commonly on the dorsum of the hand. Verrucae vulgaris are often found at sites of trauma in the periungual region (such as from habitual nail biting). The typical course of these benign neoplasms is self-limited, with spontaneous resolution in 1–2 years. However, there have been reports of malignant transformation of verrucae vulgaris, most commonly when they occur on the mucosa.[15]

Treatment is instituted if the lesions become cosmetically unacceptable or if they interfere with hand function. The first-line therapy is topical agents such as salicylic acid, which results in cure rates of 70–80%. Cryotherapy is considered the second-line therapy for lesions unresponsive to topical agents and offers cure rates of 60–80%. Third-line treatments include immunomodulatory agents, lasers such as carbon dioxide and pulsed dye, and photodynamic therapy. It is critical to be highly suspicious of lesions that do not respond to therapy, as they may be malignant. Excision is therefore recommended for treatment-refractory verrucae or to rule out malignancy.

Fig. 15.4 Sebaceous cyst. These pseudotumors arise from an obstructed apocrine gland, which produces sebum as opposed to keratin.

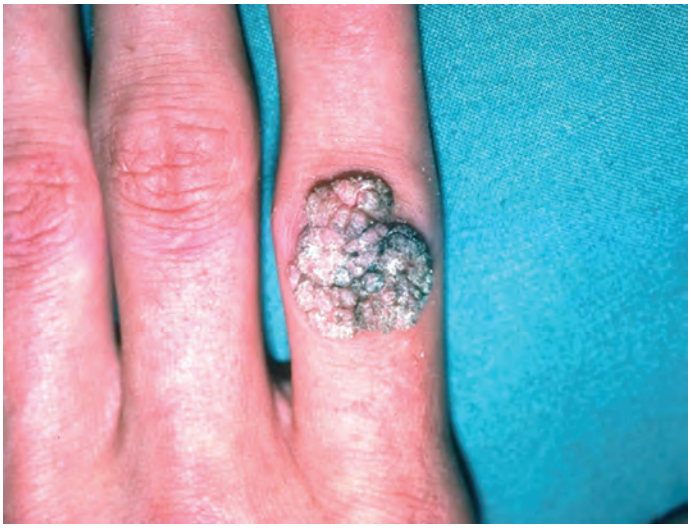

Fig. 15.5 Verruca vulgaris. This lesion presents as a rough raised surface commonly on the dorsum of the hand.

Nevi

A melanocytic nevus or benign pigmented nevus is a benign proliferation of melanocytes (Fig. 15.6). Nevi can be either acquired or congenital. The acquired form typically begins to appear 6 months after birth, and acquired nevi increase in both number and size throughout childhood and adolescence. Congenital nevi require surveillance because of the potential for malignant transformation. Nevi are classified by size as small (<1.5 cm), medium (1.5 cm to <20 cm), and large or giant (>20 cm). The lifetime risk for malignant transformation of giant congenital nevi is 10%.[16]

Common acquired nevi are defined by their anatomic location within the epidermis and dermis. Junctional nevi are found at the dermal–epidermal junction. These lesions transform into compound nevi when their growth extends into the dermis. Nevi found completely within the dermis are termed intradermal nevi. Acral nevi are typically found on the palmar or plantar surfaces. Longitudinal melanonychia refers to streaking of the nail secondary to melanin deposits in the nail plate; these lesions can result from acral nevi involving the nail matrix.

Nevi of the hand and upper extremity should be evaluated for any clinically suspicious changes. These include asymmetry, border irregularities, color changes, diameter >6 mm, or elevation of the lesion. A useful mnemonic for these changes is "ABCDE". When there is any doubt about diagnosis, excisional biopsy is recommended.[17]

Keratoacanthoma

Keratoacanthoma is thought to be derived from the epithelium of hair follicles (Fig. 15.7). This skin lesion closely resembles

Fig. 15.6 Nevus. A benign proliferation of melanocytes, either acquired or congenital.

squamous cell carcinoma. However, keratoacanthoma growth is more rapid and central necrosis is more dominant. These lesions are typically found on hair-bearing regions. A keratoacanthoma begins as a small red papule and progresses to a large ulcerated mass. This mass is "volcano"-shaped, with a large central crater. The natural course of the lesion involves regression after a latent phase of 6 months to several years.[18]

Excisional biopsy is necessary to rule out a malignant neoplasm, most commonly squamous cell carcinoma. Treatment can include curettage if a benign nature is considered likely. Because the natural history of these lesions is to involute, classically they have been treated conservatively. However, poor cosmetic outcomes can result from this approach.

Muir–Torre syndrome is an autosomal-dominant disorder associated with multiple keratoacanthomas. This clinical entity is also associated with visceral malignancy, and the workup of patients with multiple keratoacanthomas should include colonoscopy and CT.[19,20]

Fig. 15.7 Keratoacanthoma. In appearance, this skin lesion closely resembles squamous cell carcinoma. The lesion begins as a red papule progressing to a large ulcerated mass.

Dermatofibroma

A dermatofibroma is a fibrous tumor involving the dermis (Fig. 15.8). This neoplasm contains fibroblasts, collagen, and histiocytes. The clinical presentation is that of a firm, solitary mass of varying color. Dermatofibromas usually form in young adulthood and are found more typically in females. Excisional biopsy is performed to rule out a malignant lesion such as a sarcoma, squamous cell carcinoma, or melanoma.[21]

The malignant form of this lesion is a dermatofibrosarcoma protuberans, which is occasionally found in the hand.[22] While the metastatic potential is low, there is a potential for recurrence after excision. A wide excision with 3-cm margins is recommended and should include underlying fascia and muscle. The likelihood of local control associated with this procedure exceeds 90%, with the probability of regional or distant metastases being less than or equal to 5%. Adjuvant radiotherapy is indicated in the event that a patient has unresectable macroscopic disease.[23]

Fig. 15.8 A dermatofibroma is a fibrous tumor involving the dermis. These lesions form in young adulthood and are found more typically in females.

Fig. 15.9 Seborrheic keratosis. A benign neoplasm originating from keratinocytes, common in middle-aged and older patients and distributed widely over the body.

Seborrheic keratosis

A seborrheic keratosis is a benign neoplasm that originates from keratinocytes (Fig. 15.9). Seborrheic keratoses are very common, typically present in middle-aged and older patients, and can be distributed widely over the body. Initially, they appear as a hyperpigmented lesion but later coalesce into a characteristic waxy, "stuck-on" appearance. The clinical conundrum with these lesions is that, although they are benign in nature, they may mimic melanoma. These lesions require a biopsy to rule out a malignancy. If a malignancy is not suspected, these lesions can be treated with cryotherapy, curettage, or excision.

Actinic keratosis

Actinic keratoses are premalignant lesions and in fact are the most common precancerous skin condition (Fig. 15.10). An actinic keratosis presents as a rough, scaly, erythematous plaque found in an area of chronic sun exposure. The lesion is commonly tender to palpation. Histologically, this lesion shows dysplastic keratinocytes confined to the lower third of the epidermis. Actinic keratoses are the direct result of chronic sun exposure and are more common in fair-skinned persons. The potential for malignant conversion to squamous cell carcinoma ranges from 0.25% to 1.00% per year. Regression can be spontaneous if sun exposure after diagnosis is limited.

Fig. 15.10 Actinic keratosis. A premalignant skin lesion found on the upper extremity. It presents as a rough, scaly, and erythematous plaque found in areas of chronic sun exposure.

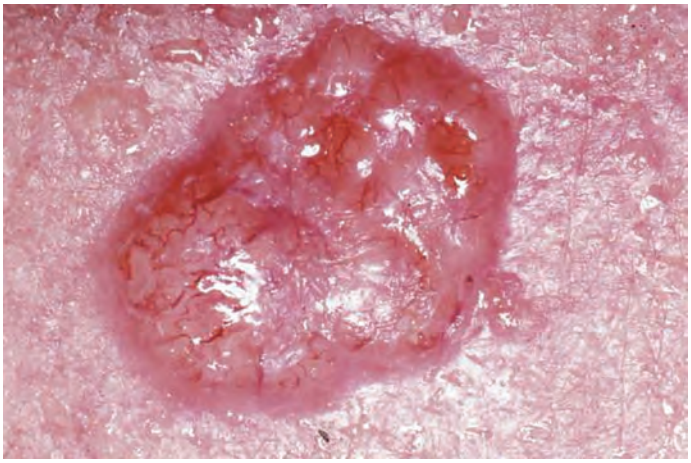

Fig. 15.11 Basal cell carcinoma. These lesions are malignant neoplasms of the basal epithelium forming insidiously but rarely metastasizing.

Treatment ranges from continued clinical observation to ablation. Cryotherapy can be used for isolated lesions. For more dispersed lesions, topical 5-fluorouracil, dermabrasion, and cutaneous peels such as trichloroacetic acid peel can be used. Newer reports have shown positive benefits using photodynamic therapy with porphyrin derivatives acting as a photosensitizer. Cure rates with this new modality have been reported as similar to those with topical 5-fluorouracil.[24]

Basal cell carcinoma

Basal cell carcinoma is the second most common skin malignancy on the hand and is the most common form of skin cancer (Fig. 15.11). Basal cell carcinomas are malignant neoplasms of the basal epithelium. Five major types of basal cell carcinoma exist: fibroepithelioma, morpheaform, nodulo-ulcerative, pigmented, and superficial. The nodulo-ulcerative is the most common form, and the morpheaform variant is the most aggressive form of the tumor. The lesions form insidiously and rarely metastasize.[1,2,25]

Basal cell carcinomas present in sun-damaged areas. The middle to older age group is commonly afflicted. Clinically, the lesion is observed as ulcerated skin with pearly elevated edges. Treatment consists of excisional biopsy with 2-mm margins. The key is surgical resection until only normal tissue remains. Regular follow-up is indicated to identify recurrences and new lesions. Since there is a low likelihood of metastasis, no further workup is required.

Squamous cell carcinoma

Squamous cell carcinoma is the most common malignant tumor in the hand (Fig. 15.12).[26] The tumor typically presents in late middle age or later. Usually, squamous cell carcinoma is found on the dorsum of the hand secondary to chronic sun exposure. Squamous cell carcinomas are pink or skin-colored and can present as firm hyperkeratotic lesions. Since there is a potential for malignant spread, it is critical to evaluate lymph node status by physical examination.

Etiologies of squamous cell carcinoma, in addition to sun exposure, include a history of therapeutic radiation, chronic

Fig. 15.12 Squamous cell carcinoma. The most common malignant tumor in the hand, typically found on the dorsum of the hand secondary to chronic sun exposure. It is critical to evaluate lymph node status upon physical exam.

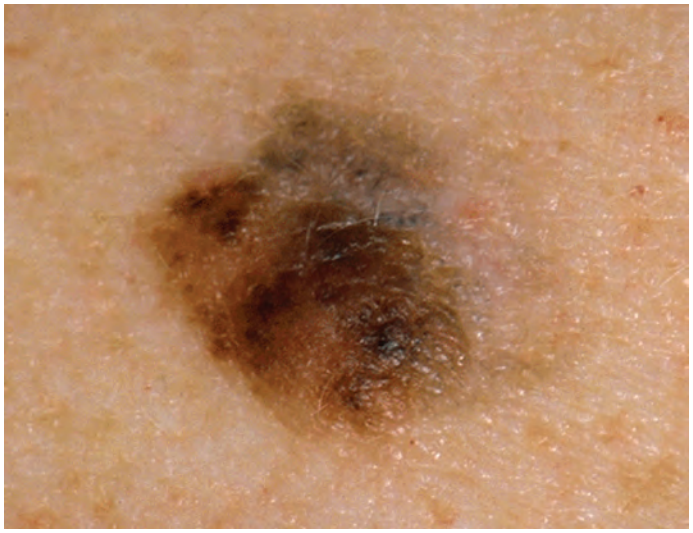

Fig. 15.13 Melanoma. A highly malignant tumor of melanocytes, melanoma may arise from atypical moles. One-half of these tumors develop *de novo* and are unrelated to pre-existing nevus.

inflammation, chronic sinus sites secondary to osteomyelitis, and immunosuppression. A Marjolin's ulcer is a squamous cell carcinoma present in a chronic burn ulcer. It is important to beware of non-responsive subungual lesions mimicking fungal infections. It is essential to biopsy all chronic infections to rule out malignancy.

Treatment of squamous cell carcinomas ranges from electrodesiccation and curettage for low-risk tumors to excisional biopsy for high-risk lesions. Excision with 5-mm margins of normal tissue results in complete clearance of 95% of tumors.[27] Other studies have shown that wide local excision with 4-mm margins has a clearance rate of 96% and that 6-mm margins clear 99% of tumors. Metastasis is found within the first 5 years in 5% of patients with squamous cell carcinoma. This is in contrast to basal cell carcinoma, which typically does not metastasize. Long-term follow-up after treatment of these lesions is therefore critical to assess for recurrence or metastatic spread.

A recent study of patients with squamous cell carcinoma of the fingertips using Mohs technique was performed in 43 cases. Microinvasive disease was diagnosed in 5 cases, *in situ* disease in 7 cases, and invasive disease in 45 patients. Recurrences were observed in 2 patients (3.5%). No tumor recurrences were observed in 4 to 5 years of follow-up. Mohs surgery provides the highest cure rate for the treatment of nail squamous cell carcinoma.[28]

Melanoma

Melanoma is a highly malignant tumor of melanocytes (Fig. 15.13). Although melanomas represent only 5% of all skin cancers, they are responsible for 75% of the deaths from skin cancer.[2,29] Based on these percentages, the prompt, accurate diagnosis and treatment of these tumors are critical for the well-being of all patients who present with a suspicious skin lesion on the upper extremity. The typical presentation of melanoma is a pigmented mass with appearance changes (ABCDE; see above). Melanomas may arise from atypical moles, but half of these tumors develop *de novo* and are unrelated to a pre-existing nevus (Fig. 15.14).[1] Acral lentiginous melanoma is a variant that occurs on the palmar, plantar, and nail plate surfaces.[30,31]

Diagnosis is established by incisional or excisional biopsy. Determination of the depth of invasion is a critical component of pathologic analysis. The Breslow system, which is most commonly used, reports the depth of invasion in millimeters and correlates with rates of lymphatic spread and distant metastasis. The Clark system reports invasion based on anatomic levels.

Treatment of melanoma *in situ* is excision with a 0.5-cm tissue margin. For invasive lesions <1.0 mm thick, a 1-cm

Fig. 15.14 Subungual melanoma. These lesions must be differentiated from hematoma and onychomycosis. Evaluation of lymph node basins must be determined clinically and pathologically in lesions of intermediate thickness.

margin is used. For lesions that are 1–4 mm thick, a 2-cm margin is used; and for lesions >4 mm thick, a 2–4-cm margin is used. The risk of metastasis is only 2% for thin (<1 mm) lesions but higher for lesions that are 1–4 mm thick (addressed below). It is important to examine clinically the lymph nodes that drain melanomas.

Lymphatic metastases from melanoma are believed to occur in an orderly, anatomic progression. The first node to which a melanoma metastasizes is considered the sentinel lymph node (SLN) and can be predicted by the lymphatic drainage pattern of the skin area where the tumor is located. By performing a biopsy of the SLN in patients with intermediate-thickness melanomas, the potential for metastasis to other nodes can be predicted. The SLN is identified at the time of tumor resection by lymphoscintigraphy and the use of dye.[32] Technetium-99m is given the morning of the operation, with surgery being performed 4 hours later after Lymphazurin blue is injected intradermally around the lesion. Next, the "hot" lymph node is searched for using a radioactive sensor and by visualizing the path of the blue dye. This lymph node, the SLN, is then sent for frozen-section pathologic assessment. If the SLN is positive, a full dissection of the draining lymph node basin(s) is performed. Consideration should then be given to adjuvant chemotherapy. No further treatment is given if the SLN is negative.

For thick melanomas (>4 mm), the risk of nodal metastasis is high (60–80%). Any clinically identified positive nodes are resected along with the primary lesion. If the clinical node examination is negative, SLN biopsy is not routinely indicated because this group will probably not benefit from loco-regional disease control.

Subungual melanomas may masquerade as a subungual hematoma or onychomycosis. Typically, treatment of subungual melanoma is an amputation at the distal interphalangeal joint.[30]

Synovial lesions

Ganglion cysts

Ganglion cysts are the most common soft-tissue tumors of the hand and upper extremity (Fig. 15.15). Ganglion cysts are mucin-filled structures associated with joint capsules, tendons, or tendon sheaths. The etiology of these cystic structures is presumed to be secondary to synovial herniation and trauma but remains unclear.[33]

Fig. 15.15 Ganglion cysts. The cyst is a mucinous-filled structure associated with joint capsules, tendons, and tendon sheaths. The etiology of these cystic structures is presumed to be secondary to synovial herniation and trauma.

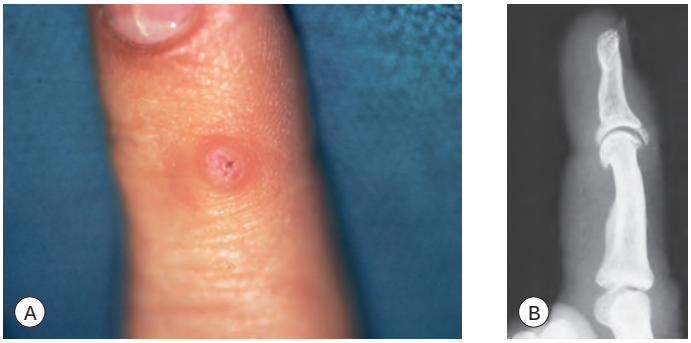

Fig. 15.16 Mucous cyst. **(A)** Ganglions found on the dorsal proximal interphalangeal joint associated with osteoarthritis are termed mucous cysts. **(B)** Excision of the cyst along with excision of osteophytes must be performed to treat this clinical entity completely.

In the hand, ganglion cysts typically occur in the dorsal carpal region (60–70%) and originate from the scapholunate interosseous ligament. The volar carpal region is the next most commonly involved region, with 20% of ganglion cysts originating from the scapho-trapezio-trapezoid ligament. Ganglion cysts are also found on the volar retinaculum (10–20%). Ganglion cysts found on the dorsal proximal interphalangeal joint associated with osteoarthritis are termed mucous cysts (Fig. 15.16). These are treated by excision of the cyst along with associated osteophytes. If atypical presentations occur or if clinical examination does not clarify a potential ganglion cyst, then ultrasonography or MRI can be helpful in determining a diagnosis.

A key point in the treatment of ganglion cysts is to clarify their benign nature for the patient. Patients often seek reassurance when confronted with this lesion. The natural course of volar retinaculum ganglion lesions is spontaneous resolution in almost two-thirds of patients. Aspiration of these masses results in complete resolution in the same proportion of patients. Aspiration of volar and dorsal ganglions in other locations with fenestration techniques has improved results. However, recurrence is still observed.[33]

The definitive management of ganglion cysts is surgical excision with a cuff of retinaculum. For larger ganglions in the volar and dorsal regions of the hand, removal of the ganglion with its stalk and a portion of the cuff of the joint capsule is required. The capsule is not repaired so as not to limit motion. Arthroscopic removal of ganglion cysts in the dorsal region of the wrist is currently being performed. Success rates have been favorable, although long-term follow-up data are currently lacking.

Giant cell tumor (pigmented villonodular synovitis)

Giant cell tumors are the second most common soft-tissue masses in the hand (Fig. 15.17). A giant cell tumor is a benign tumor containing multinucleated giant cells and xanthoma cells. Giant cell tumors are found in synovial fluid-producing sites such as joints, capsular ligaments, and tendon sheaths.[34,35] They are slow-growing and can have a mass effect on adjacent structures, at times indenting cortical bone. They are firm,

Fig. 15.17 Giant cell tumor (pigmented villonodular synovitis). A benign tumor containing multinucleated giant cells and xanthoma cells found in synovial fluid-producing sites such as joints, capsular ligaments, and tendon sheaths.

nodular, and non-tender. Most commonly, they are found over the volar aspect of the hand.

The treatment for this tumor is careful, complete excision. When dissecting these tumors out of the hand, the surgeon must beware of nerve displacement. The main problem with these masses is the potential for recurrence; the recurrence rate has been reported to be 5–50%. A malignant form of this tumor has been described but is extremely rare.

Nerve tumors

Schwannoma/neurilemoma

Schwannomas, the most common benign nerve tumors of the hand, arise from Schwann cells (Fig. 15.18). The presentation of schwannoma is one of a slow-growing, well-circumscribed, eccentric, and essentially painless mass.[36] However, there may be a neurologic deficit or pain if the lesion is in the distribution of motor or sensory nerves. Schwannomas are mobile transversely, not longitudinally. They are typically found on the volar surface of the hand and forearm in the fourth to sixth decades of life.

The treatment for schwannoma is to "shell it out" from surrounding intact nerve fascicles, under magnification. The risk of a postoperative neurologic deficit is 4%. There are very rare reports of malignant transformation.

Neurofibroma

Neurofibromas are benign, slow-growing tumors arising within nerve fascicles (Fig. 15.19).

Fig. 15.18 Schwannoma/neurilemmoma. This soft-tissue mass arises from Schwann cells and is typically found on the volar surface of the hand and forearm.

The lesions appear histologically as diffuse growths of Schwann cells, fibrous tissue, and axons. When groups of these lesions are encountered, von Recklinghausen's disease or neurofibromatosis should be considered as a diagnosis.

The treatment for neurofibromas is excision; however, this is likely to require segmental nerve resection and nerve grafting based on the anatomy of the tumor in that normal nerve fascicles are incorporated into the tumor.

Fig. 15.19 Neurofibroma, a benign slow-growing tumor arising within nerve fascicles. When encountered in groups, von Recklinghausen's disease or neurofibromatosis should be considered as a diagnosis.

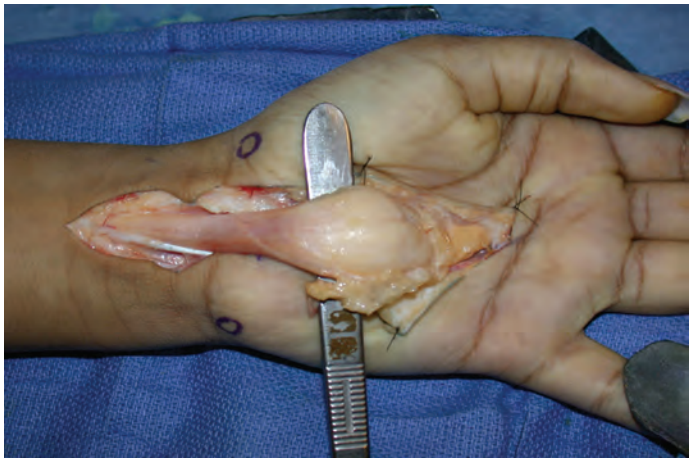

Fig. 15.20 Lipofibromatous hamartoma. This mass is a fibrofatty infiltration of the nerves, most commonly found in the median nerve. In a child who presents with carpal tunnel syndrome, this should be considered part of the differential diagnosis.

Malignant transformation of neurofibroma is possible, and rapid enlargement may indicate malignant transformation.[2] In patients with neurofibromatosis, malignant degeneration into plexiform neurofibromas can occur. A pseudoarthrosis, which is a rare condition frequently associated with neurofibromatosis, can occur in the upper extremity. This appears as "sucked candy" on radiographs.

Lipofibromatous hamartoma

Lipofibromatous hamartoma represents a fibrofatty infiltration of the nerves (Fig. 15.20). This tumor is most commonly found in the median nerve. In a child who presents with carpal tunnel syndrome, lipofibromatous hamartoma should be considered part of the differential diagnosis.[37] Exploration of the mass reveals fusiform swelling of the nerve without invasion into perineural tissue.

Interfascicular resection is not possible and in fact is contraindicated for the treatment of this lesion. Instead, simple decompression is recommended. Gradual deterioration of nerve function can occur; only then should resection and nerve grafting be considered.

Fat tumor: lipoma

A lipoma is a benign tumor composed of adipose tissue (Fig. 15.21). Lipomas can be located subcutaneously or intramuscularly. If present in the carpal tunnel or Guyon's canal, lipoma can lead to nerve compression. Lipomas typically have a longstanding history with very slow growth. Physical examination and history will invariably lead to the diagnosis. If imaging is warranted, X-rays will reveal lucent soft-tissue shadows, and MRI will show a signal intensity consistent with adipose tissue.

The treatment of lipoma is simple excisional biopsy consisting of a marginal resection. The well-defined margins of the tumor make excision not technically challenging. The primary indication for excision is size increase and mass effect (nerve compression).

The malignant form of this mass, liposarcoma, has rarely been reported in the hand. However, liposarcoma can be confused with a lipoma if encountered.

Fibrous tissue lesions

Benign lesions

The majority of the lesions of fibrous tissue found in the hand are benign. These include simple scars, hypertrophic scars, and keloid tissue. Hypertrophic scars are confined within the original wound margins, whereas keloids grow beyond these margins. Both exhibit increased cellularity and vascularity. Other benign fibrous tumors found in the hand include juvenile aponeurotic fibroma, desmoid tumors, fibrous histiocytoma, and Dupuytren's disease. The last of these constitutes fibrosis of the palmar fascia that leads to subsequent contractures of the fingers involving the metacarpophalangeal, proximal interphalangeal, and distal interphalangeal joints.

Sarcomas

Malignant fibrous histiocytoma is the most common soft-tissue sarcoma in adults (Fig. 15.22).[37,38] It develops in the sixth to eighth decades of life. This tumor presents as a painless enlarging mass that is most common in the forearm. Treatment is wide excision or amputation. Neoadjuvant therapy can be administered to reduce tumor bulk and avoid amputation of the limb. A metastatic workup is required, with the most common site of metastasis being the lungs.

Synovial sarcoma is among the more common sarcomas in the hand and wrist. This malignant soft-tissue tumor occurs near tendons and joints and may invade bone. Its most common presentation in the upper extremity is that of a firm, indolent, painless mass on the dorsum of the hand.[8] It typically presents in young adults to middle-aged patients. Synovial sarcoma is a very aggressive tumor. Treatment is wide or radical surgical excision. Nodal status must be evaluated because of the high rates (50%) of metastasis from this mass. Adjuvant radiotherapy or chemotherapy is recommended.

Epithelioid sarcoma is the most common malignant soft-tissue tumor of the upper extremity (Fig. 15.23). It most commonly appears on the hand and forearm in adolescents and young adults as a firm, slow-growing mass.[8] Epithelioid

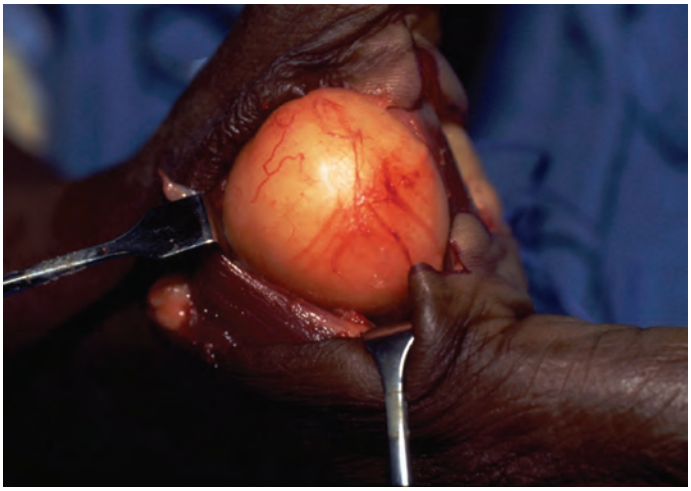

Fig. 15.21 Lipoma. This lesion is a benign tumor composed of adipose tissue. Commonly they are located subcutaneously or intramuscularly in the upper extremity.

sarcoma can affect the digits and palm with proximal spread along tendon sheaths. It can be misdiagnosed as a wart or an ulcer. Treatment of epithelioid sarcoma is wide or radical excision. Nodal status needs to be evaluated as metastasis is typically to regional lymph nodes.

Chemotherapy and limb salvage surgery with reconstruction has become the standard treatment for sarcomas of the extremities, including the hand. Local flaps are often inadequate for repairing extensive defects resulting from tumor resection. Such defects may require free tissue transfer. The use of free flaps in reconstructing oncologic defects has enabled reconstructive surgeons to effect a paradigm shift in limb salvage. Complex free flap reconstructions are now routinely being used to preserve limbs that, due to locally advanced disease, would have been previously amputated. This has redefined the surgical management of sarcomas of the extremities. This shift toward limb preservation has prompted surgeons to re-evaluate the indications for amputation and thus improved patients' quality of life. In addition, tremendous advances in the multidisciplinary management of sarcoma have been made. Neoadjuvant chemotherapy and radiotherapy are now used to reduce tumor size to enable neurovascular-sparing resections that preserve limb function.

Vascular lesions

Hemangioma

Hemangiomas are benign capillary malformations. They can present as superficial, cutaneous lesions; as deep, cavernous

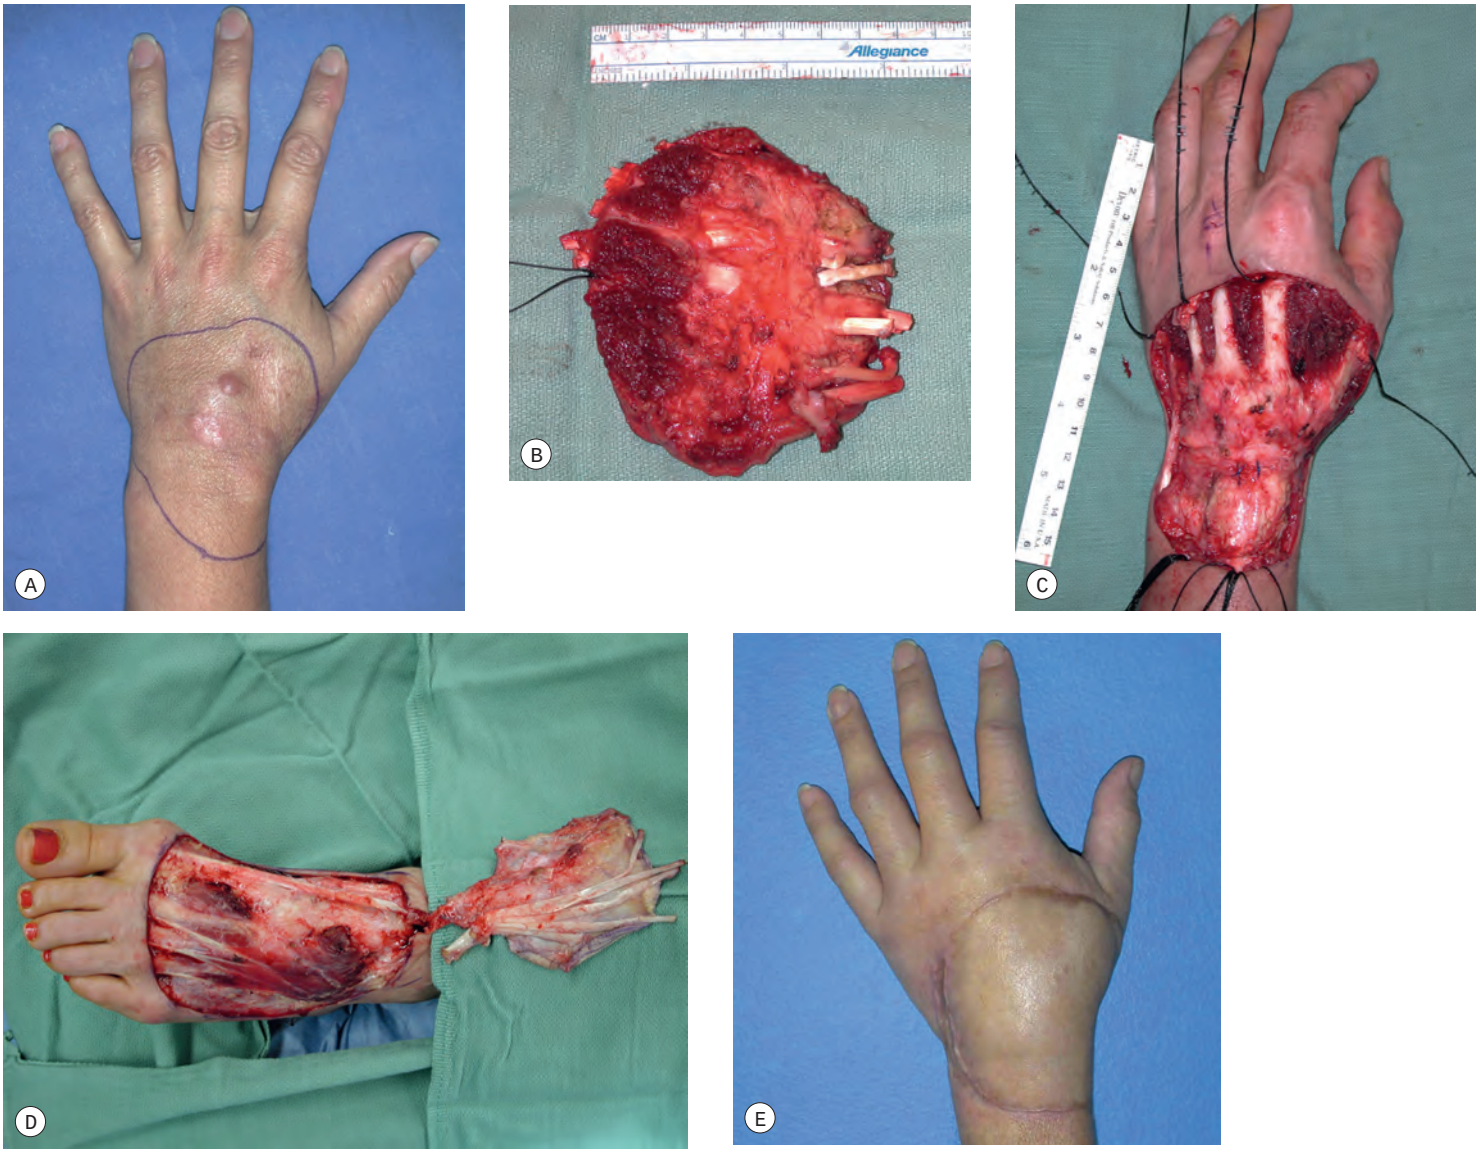

Fig. 15.22 Malignant fibrous histiocytoma. This sarcoma presents as a painless enlarging mass commonly found on the upper extremity. Treatment for this tumor is wide excision with mandatory metastatic evaluation. **(A)** Dorsal hand lesion. **(B)** Specimen revealing composite resection involving extensor tendons. **(C)** Wide local excision with proximal and distal extensor tendons tagged for reconstruction. **(D)** Dorsalis pedis flap elevation, including dorsal foot extensors. **(E)** Postoperative flap.

The most common malignant soft-tissue tumor of the upper extremity. **(A)** Recurrent epithelioid sarcoma following wide local excision. **(B)** Composite resection involving both distal radius and ulna. **(C)** Bone allograft with internal fixation. Soft-tissue coverage supplied by a reverse radial forearm flap. **(D)** Intraoperative flap inset. **(E)** Postoperative result.

lesions; or as a mixture of the two forms (Fig. 15.24). Hemangiomas typically are not present at birth but appear in the first month of life. They are characterized by a rapid growth phase during the first year. The rate of involution is 50% by 5 years of age and 70% by 7 years of age.[39]

Treatment is typically observation, as most will involute. However, laser therapy, systemic steroids, intralesional steroids, and interferon have all been shown to have beneficial effects. When hemangiomas become symptomatic in adults, they require a marginal resection. Even after resection, these lesions can recur.

Fig. 15.24 Hemangiomas present as: (1) superficial in the cutaneous form; (2) deep, which represents cavernous lesions; or (3) a mixture of both. Not present at birth, they are characterized by a rapid growth phase during the first year. Expected involution is 50% by 5 years of age and 70% by 7 years of age.

Infantile hemangiomas can be associated with Kasabach–Merritt syndrome (Fig. 15.25). This aggressive hemangioendothelioma leads to a consumptive coagulopathy secondary to platelet trapping. High-dose steroids and vincristine have been used to treat this syndrome.[40]

Maffucci's syndrome is a condition characterized by multiple hemangiomas and enchondromas.[41] The digits in patients with this condition are short and angulated. There is a risk of malignant transformation of the enchondromas and hemangiomas into chondrosarcomas and angiosarcomas.

Vascular malformations

Vascular malformations are typically present at birth, in contrast to hemangiomas, and represent malformed vascular channels. Malformations are described by their location as capillary, venous, lymphatic, or mixed venous–lymphatic malformations (Fig. 15.26). These are considered "low-flow" tumors. Treatment can be observation, laser therapy, sclerosing agents, or excision.[42]

"High-flow" vascular malformations have arterial or arteriovenous components. These masses represent a "time bomb" with the potential for rapid expansion. Treatment of these tumors involves preoperative embolization followed by excision.

Fig. 15.25 Kasabach–Merritt syndrome. This aggressive hemangioendothelioma leads to a consumptive coagulopathy secondary to platelet trapping.

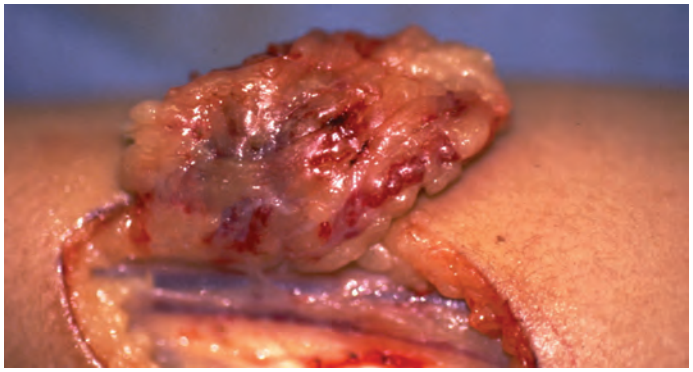

Fig. 15.26 Vascular malformations are typically present at birth, in contrast to hemangiomas, and represent malformed vascular channels. Treatment can be observation, laser therapy, sclerosing agents, or excision.

Other vascular malformations seen in the hand are aneurysms and pseudoaneurysms (Fig. 15.27). The former can originate from the radial, ulnar, or digital artery. Aneurysms involve all three layers of the vessel wall – the intima, the media and adventitia. In contrast, pseudoaneurysms represent a defect in the arterial wall contained by fibrous tissue.

Glomus tumor

A glomus tumor is a benign tumor of the neuromyoarterial apparatus, which is responsible for controlling circulation to

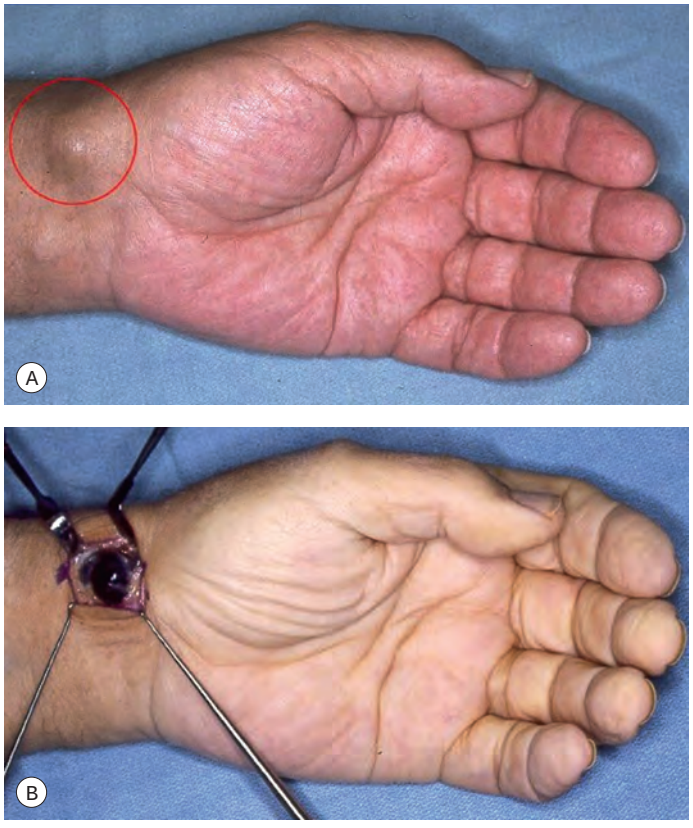

Fig. 15.27 Pseudoaneurysm. This represents a defect in the arterial wall contained by fibrous tissue as opposed to an aneurysm, which involves all three vessel wall layers (intima, media, and adventitia). **(A)** Radial artery pseudoaneurysm. **(B)** Radial artery pseudoaneurysm exposed.

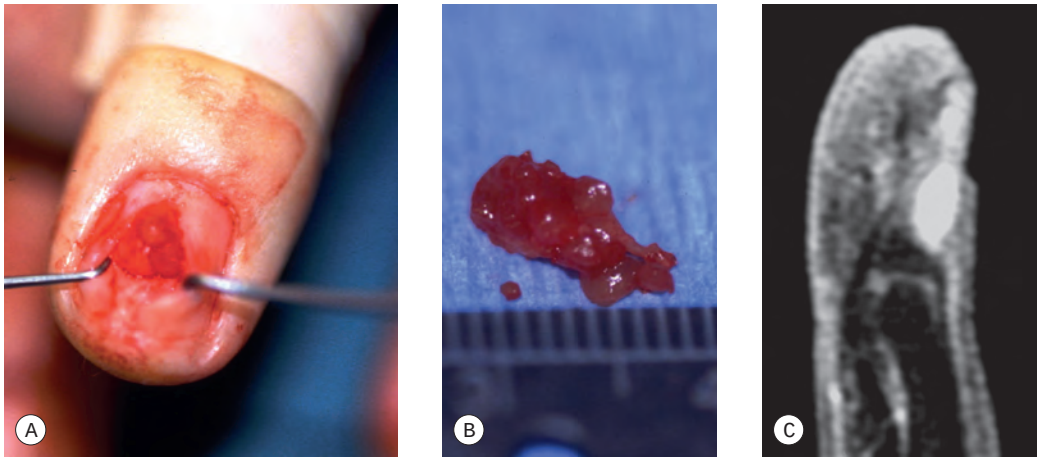

Fig. 15.28 Glomus tumor. A benign tumor of the neuromyoarterial apparatus responsible for controlling skin circulation presenting in a subungual location. **(A)** Glomus tumor *in situ*. **(B)** Glomus tumor excised. **(C)** Magnetic resonance imaging scan of glomus tumor distal phalanx.

the skin. Glomus tumors frequently present subungually (Fig. 15.28). The classic triad of symptoms is cold hypersensitivity, intermittent severe pain, and point tenderness.[6,43]

Diagnostic workup for a suspected glomus tumor should include radiography and MRI. Radiographs reveal a "scalloped" osteolytic defect. MRI will commonly reveal a high-signal-intensity lesion. Excisional biopsy is curative.

Pyogenic granuloma

Pyogenic granuloma is a rapidly progressing vascular lesion (Fig. 15.29). Pyogenic granulomas of the hands are commonly found on the fingers. The lesion begins as a solitary "red" nodule and progresses to a chronically inflamed vascular lesion. The exact etiology is unknown.[42] Current beliefs are that the lesion begins with trauma followed by a subsequent subclinical infection. Treatment modalities range from excision with 1-mm margins, to curettage, to topical silver nitrate; however, all are associated with some incidence of recurrence.

Muscle lesions

Myositis ossificans

In myositis ossificans, benign ossification occurs in muscles and other soft tissues (Fig. 15.30). The etiology can be traumatic. In the upper extremity, the deltoid and brachialis muscles are involved most frequently. Over time, the volume of heterotopic bone will diminish.

Leiomyoma

Leiomyoma is a benign, smooth-muscle neoplasm (Fig. 15.31). Leiomyomas are rare in the hand. Treatment is excisional biopsy. If a lesion is clinically suspicious, biopsy is necessary to differentiate leiomyoma from leiomyosarcoma.[21]

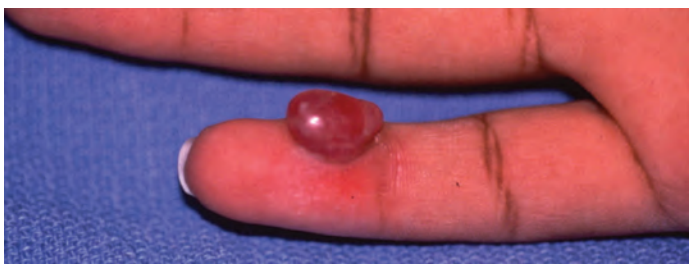

Fig. 15.29 Pyogenic granuloma. Rapidly progressing benign vascular lesion commonly found in the finger. Etiology is unknown.

Rhabdomyosarcoma

Rhabdomyosarcoma is a malignant tumor of muscle stem cells. Presentation is typically before 15 years of age. In the hand, rhabdomyosarcoma presents as a slowly developing, deep, painless mass. Rhabdomyosarcomas have been observed in the thenar eminence and between the metacarpals.

The treatment for rhabdomyosarcoma is wide resection or amputation. Regional lymph node dissection is usually necessary. Adjuvant radiotherapy and chemotherapy are recommended.[38]

Cartilage and bone tumors

Enchondroma

Enchondroma is the most common primary tumor in the bones of the hand. Essentially, it is a benign cartilage lesion within the bone. The tumor most commonly presents in the fourth decade of life. Typically, it arises in a proximal phalanx or metacarpal. The common clinical presentation is pain and edema secondary to pathologic fracture. The diagnosis is strengthened by radiographic patterns showing a radiolucent lesion with cortical thinning and "popcorn" calcification (Fig. 15.32).[44,45]

Treatment can begin with observation. However, solitary lesions have a potential for malignant transformation to chondrosarcoma (<5% risk).[45] A healing fracture resembles a chondrosarcoma, so it is important to follow up these lesions radiographically. If a pathologic fracture occurs, it is recommended that the fracture be treated first, followed by curettage of the tumor. A bone graft or allograft is placed into the bone cavity.

Ollier's disease is a non-hereditary condition characterized by multiple enchondromas.[45] The tumors occur mainly unilaterally. Pain is uncommon unless there is a fracture. There is a 30–50% risk of malignant transformation, so it is critical to follow patients with Ollier's disease closely.

Osteoid osteoma

Osteoid osteoma represents a benign bone-forming lesion typically affecting the distal radius, carpus, and phalanges

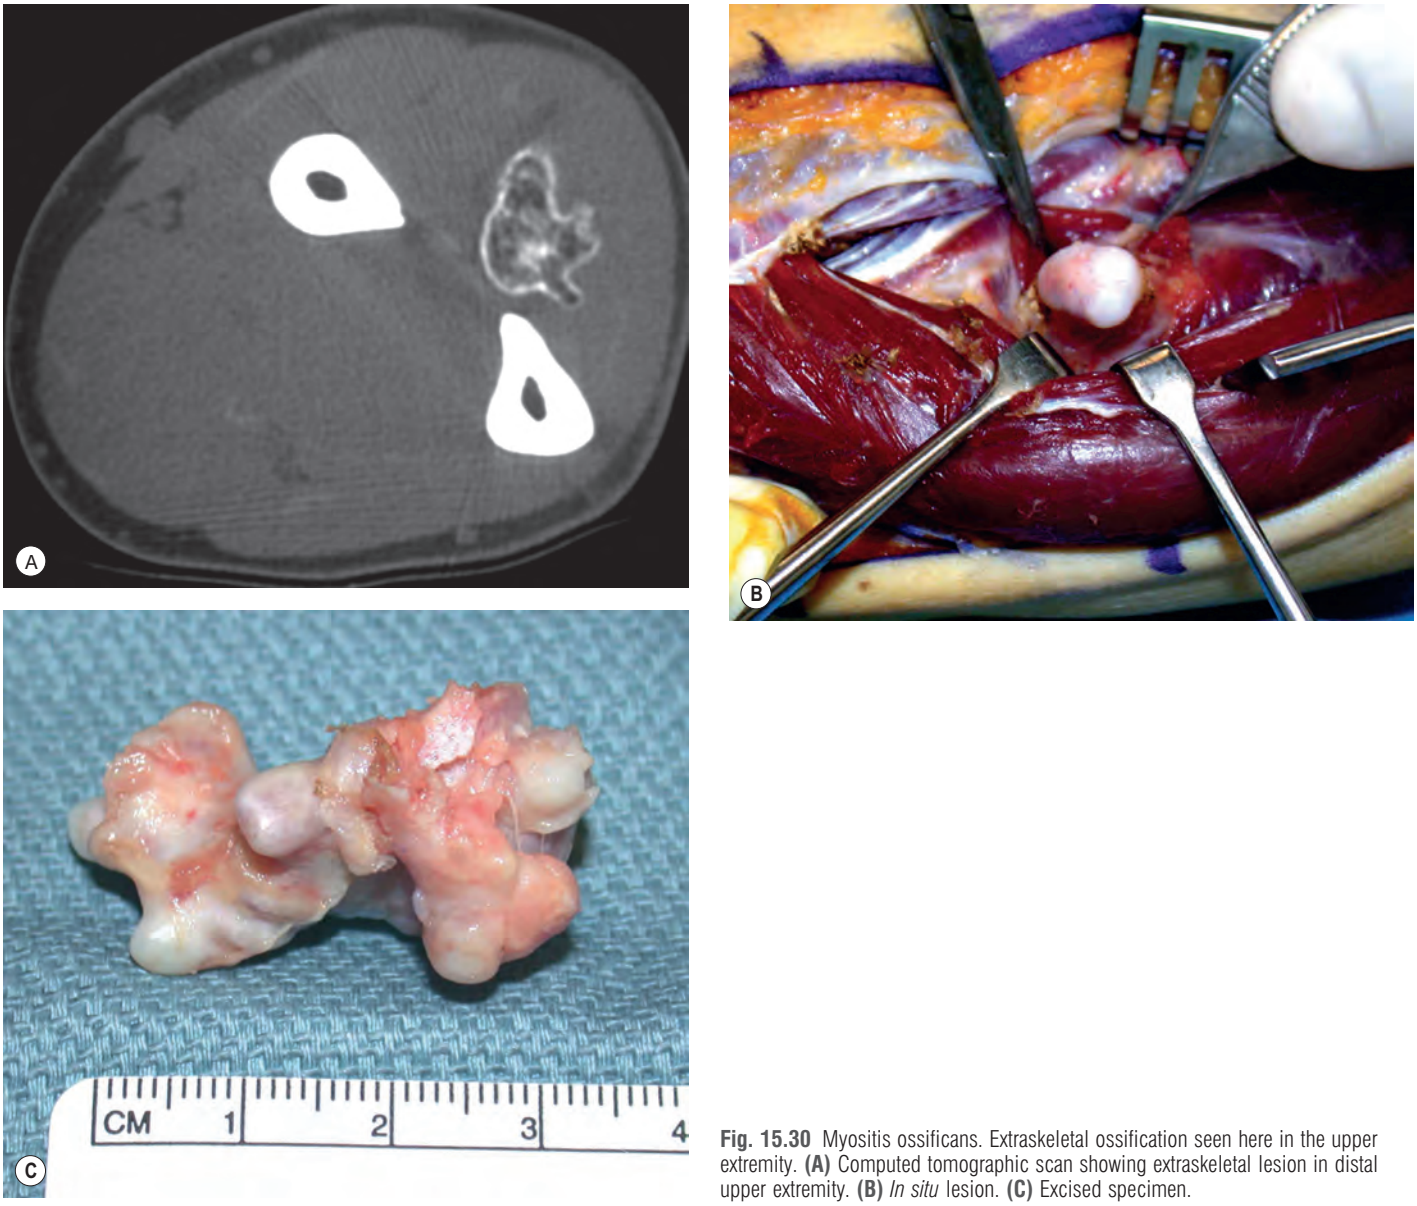

Fig. 15.30 Myositis ossificans. Extraskeletal ossification seen here in the upper extremity. **(A)** Computed tomographic scan showing extraskeletal lesion in distal upper extremity. **(B)** *In situ* lesion. **(C)** Excised specimen.

(Fig. 15.33). These bone tumors rarely form in the hand (<1%). They present during the first two decades of life, and patients may complain of persistent pain relieved only by nonsteroidal anti-inflammatory agents. Radiographs reveal sclerosis around a central lucency.[46,47] Treatment can be either curettage or resection. There is a potential for recurrence if a lesion is incompletely removed.

Osteochondroma

Osteochondroma represents the most common benign bone tumor (Fig. 15.34). It develops during adolescence and enlarges during puberty. Osteochondroma is a benign bone prominence with a cartilage cap. Osteochondroma can present in the hand as multiple enchondromas or as an asymptomatic hard lump, which can cause a growth deformity (e.g., short deformed ulna or radius displacement). Osteochondroma can also cause a mechanical block to flexion from the angular growth disturbance.[44]

The treatment of this lesion is observation initially, with excision if there is pain or deformity. Bone grafting is performed for the correction of angular deformity. There is a 10–25% chance of malignant degeneration when multiple osteochondromas are present.

Solitary unicameral bone cyst

Solitary unicameral bone cysts are rare in the hand and usually present in the forearm**.** The cyst usually becomes clinically evident because of a pathologic fracture causing pain and edema. Radiographs show radiolucency in the affected metaphysis with a thin cortical wall (Fig. 15.35). Treatment is curettage and bone graft.

Aneurysmal bone cyst

Aneurysmal bone cyst is a benign vascular tumor of bone, rare in the hand and usually found in the forearm (Fig. 15.36).

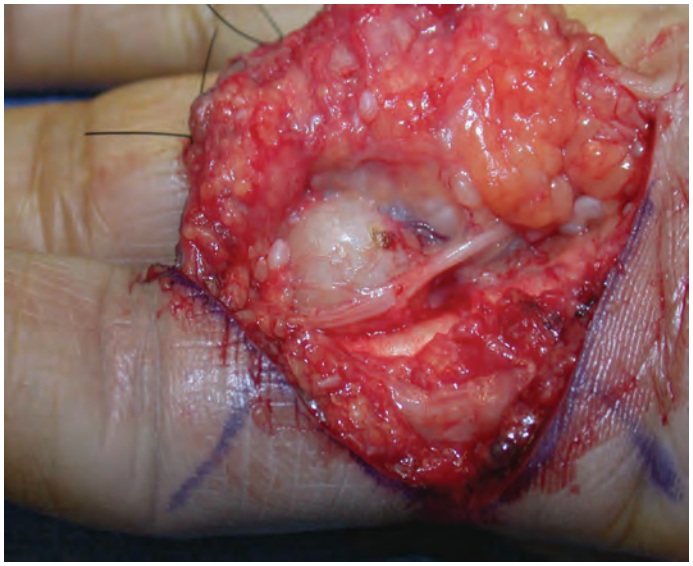

Fig. 15.31 Leiomyoma. A benign smooth-muscle neoplasm seen here on the velar aspect of the hand in close proximity to neurovascular structures.

Growth is rapid and can be locally invasive. Radiographs reveal a large radiolucency with a "blown-out" cortex. Treatment of this mass is curettage and bone or strut grafting. Amputation has been used for destructive distal phalanx lesions. There is a high recurrence rate (60%) following curettage. Ray section will treat recurrences.[48]

Giant cell tumor of bone

Giant cell tumor of the bone is a distinct entity from a giant cell tumor of the tendon (Fig. 15.37). The tumor may present with joint pain and swelling. Pathological fracture is commonly seen as the presenting diagnosis in up to 10% of the affected population.[49] The neoplasm is multicentric, with a potential for metastatic spread, most often to the lungs (<2% of cases). The tumor appears in the distal radius up to 10% of the time, with other sites more commonly the proximal tibia and distal femur.[49] Metastatic workup is appropriate for this tumor secondary to the potential for metastatic spread.

Surgical treatment can include extended curettage, wide excision, or amputation.[50,51] Recurrence rates for extended curettage are significant.[52] However, when extended curettage

Fig. 15.32 Enchondroma. A benign cartilage lesion within the bone presenting here in the proximal phalanx.

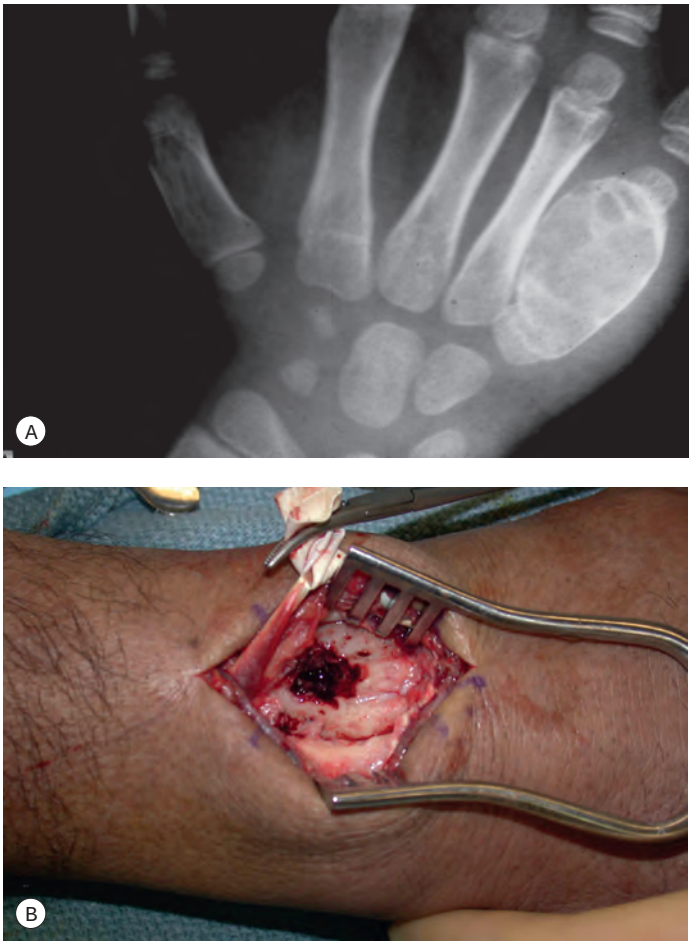

Fig. 15.35 (A,B) Solitary unicameral bone cyst: a benign cyst of the bone usually presenting in the forearm. This lesion, seen here in the small-finger metacarpal, shows radiolucency in the metaphysis with a thin cortical wall.

Fig. 15.36 Aneurysmal bone cyst. A benign vascular tumor of bone seen here in the metacarpal bone. Radiographs reveal a large radiolucency with a "blown-out" cortex.

Fig. 15.37 Giant cell tumor of bone. A multicentric neoplasm with a potential for metastatic spread. Treatment of this mass is wide excision or amputation.

is performed the cavity can be packed with either cancellous bone graft or methylmethacrylate cement.[52] In cases of wide local excision reconstruction where the bone is made unstable, such as the distal radius, reconstruction is required typically with an autograft or allograft.

Reconstruction of the distal radius is performed to optimize the function of the wrist, specifically the radiocarpal joint. Surgical reconstruction can be performed with either an arthroplasty or arthrodesis involving the use of non-vascularized (tibia, fibula, iliac crest, or distal part of ulna) or vascularized (fibula and distal portion of the ulna) bones.[53–56] Reconstruction with vascularized and non-vascularized fibular grafting has been shown to give the patient improved function over arthrodesis.[53,57] However, distal radius resection managed with a radiocarpal arthrodesis through use of an intercalary bone graft stabilized with a long plate also has shown proven functional benefits.[58]

Healing complications related to the use of a bone allograft or autograft may involve malunion and nonunion of bone. In addition the graft can fracture, necessitating further surgical intervention.[54] In reference to distal radius reconstruction potential subluxation of the carpus, and degenerative osteoarthritis can lead to limited wrist movement and pain. Donor site complications related to autograft harvest involving the

fibula, such as ankle instability, pain, footdrop, and paresthesia, might develop.[59]

Osteosarcoma

Osteosarcoma is the most common primary malignant bone-forming tumor. Presentation is a firm, rapidly enlarging, painful mass. Although rarely found in the hand, osteosarcoma can occur in the metacarpals and proximal phalanges.

Treatment starts with incisional biopsy. Local and systemic staging is then performed. This is followed by wide excision, or possibly finger or ray amputation for osteosarcoma in the hand. Neoadjuvant chemotherapy and postoperative adjuvant chemotherapy are recommended for high-grade lesions of the hand.[60–62]

Chondrosarcoma

Chondrosarcoma is a malignant cartilaginous tumor and the most common primary malignant tumor of the hand, although this site is rare. This mass presents typically in patients >40 years old. In the metacarpals and proximal phalanges, chondrosarcoma is firm, insidious, and painful. Radiographically, the presence of lytic lesions with cortical destruction and soft-tissue destruction differentiates chondrosarcoma from enchondroma.[44,63]

Treatment for hand tumors is incisional biopsy to establish the diagnosis and then wide excision or ray amputation. Local and systemic staging is critical.

Staging and treatment of musculoskeletal sarcomas

A sarcoma, as previously discussed, is described as a malignant neoplasm arising from transformed connective tissue cells originating from embryonic mesoderm.[64] These cells can include adipose tissue, bone, cartilage, muscle, and bone. Commonly they can present as an asymptomatic mass originating in an extremity. However, this neoplasm can occur anywhere in the body such as the trunk, retroperitoneum, or the head and neck.[64]

Enneking *et al.* developed a classification system for the staging of musculoskeletal tumors.[65] This three-stage classification system is based on grade (G), site (T), and metastasis (M), using histological, radiologic, and clinical criteria. Grade 0 refers to benign lesions, G1 to low-grade, and G2 to high-grade lesions. Low or G1 lesions have a low risk of metastases (<25%). They are well differentiated, and have fewer mitoses and moderate cellular atypia. G2 lesions, high-grade lesions, are characterized by an increased rate of metastasis.[3] T0 represents a benign intracapsular and intracompartmental lesion, whereas T1 is an intracapsular and T2 an intracompartmental lesion. M0 represents no regional or distant metastasis and M1 represents regional and distant metastasis. Stage I represents a low-grade lesion without metastasis, stage II represents a high-grade lesion without metastasis, and stage III represents a metastatic lesion regardless of tumor grade (Table 15.1). The Enneking classification correlates the tumor stage with the recommended excision margins depending on whether it is a benign or malignant mass. Based on the stage, the appropriate surgical margin is chosen to obtain appropriate local control.

Four types of surgical margin are typically described when removing tumors of the hand. An intralesional resection is through the plane of the tumor, leaving gross or macroscopic tumor behind. A marginal resection is performed through the tumor pseudocapsule or "reactive zone", potentially leaving "satellite" or "skip" lesions. A wide resection plane involves removal of the mass with normal tissue but remains within the relative tissue compartment. This resection can potentially leave "skip" lesions. Finally, a radical resection of tumor involves removing the entire intracompartment and extracompartment of involved and uninvolved tissue. An example of this would be a soft-tissue sarcoma of the hand requiring a radiocarpal disarticulation.

Table 15.1 Enneking's classification system of musculoskeletal sarcomas

Stage	Grade	Site	Metastases
IA	G1	T1	M0
IB	G2	T2	M0
IIA	G1	T1	M0
IIB	G2	T2	M0
IIIA	G1–G2	T1	M1
IIIB	G1–G2	T2	M1

Grade: G1, low; G2, high.
Site: T1, intracompartmental; T2, extracompartmental.
Metastases: M0, no regional or distant metastases; M1, regional or distant metastases.

Oncological treatment for upper extremity sarcoma emphasizes limb salvage as an alternative to amputation and is determined mainly by the stage of the disease.[3] Treatment options for musculoskeletal sarcomas include chemotherapy, radiation therapy, and surgery. Since neither radiation nor chemotherapy alone or in combination has been shown to attain long-term local control of disease, surgical ablation is a critical step in the management of these neoplasms.[64,66,67] A multidisciplinary team involving the medical and surgical oncologist along with an integrated hand surgeon adept at reconstructive surgery best handles the overall treatment of a sarcoma of the upper extremity.

Metastases

In the hand, metastases from tumors at other sites are rare. However, the most common sources of metastatic spread to the hand are primary breast, kidney, thyroid, lung, and colon cancers. The distal phalanges are the most common site of metastasis in the hand (Fig. 15.38).[7] The symptoms and signs reported are pain, edema, and erythema. Radiography can reveal destructive lytic lesions. The diagnosis is confirmed by incisional biopsy.

Treatment of metastatic lesions in the hand begins by identifying the primary tumor. Once a primary tumor is identified, a systematic workup is undertaken that takes into consideration other metastatic lesions in the body. Treatment of hand lesions may include local radiotherapy for tumors that are radiosensitive, such as metastases from breast, prostate, and thyroid cancers. A digit or ray amputation can be performed to reduce the tumor load or effect a cure. However, metastasis to the hand is an ominous sign. Life expectancy in these patients is usually <6 months.[1,7]

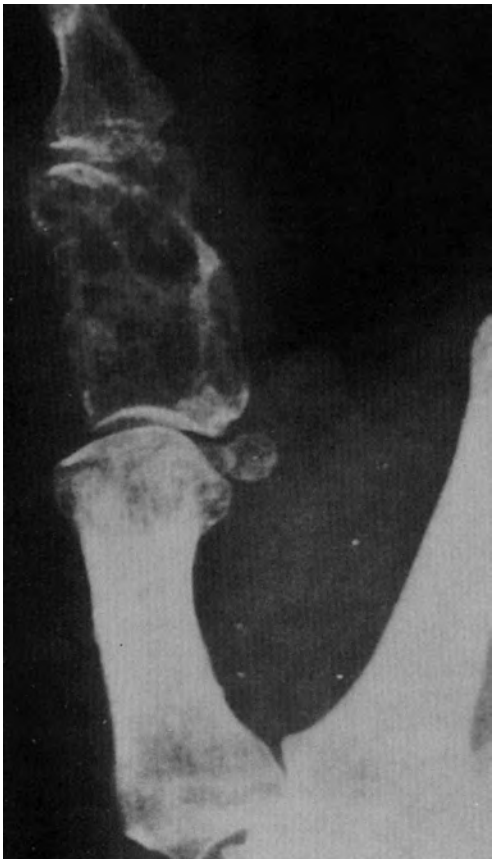

Fig. 15.38 Metastasis. Sources of metastatic spread to the upper extremity most commonly are from primary breast, kidney, thyroid, lung, or colon cancer. The distal phalanx, as seen here, is the most common site.

Postoperative care

For most lesions of the hand, simple excision and closure will suffice for treatment. In these instances, a sterile bulky dressing with or without a splint will be required. For larger soft-tissue resections with concomitant reconstruction, appropriate volar or dorsal splinting is required. The patient is instructed to elevate the extremity for the first several days to alleviate postoperative swelling. If bone reconstruction is performed, appropriate postoperative radiographs must be obtained during the first week to determine if there is displacement of fixated structures.

The success of upper extremity reconstruction is quantified by limb function, sensation, cosmesis, and stable wound coverage. Appropriate postoperative splinting and aggressive rehabilitation to maximize long-term upper extremity function are critical to complete postoperative care.[68] The role of the upper extremity reconstructive surgeon is critical as the team-leader to obtain optimal clinical outcomes.

Outcomes, prognosis, and complications

Tumors of the hand are typically recognized early. They may originate from any cell type, and most are benign. Malignancy is uncommon but must be ruled out. A careful history and physical examination followed by an appropriate diagnostic workup will typically lead the hand surgeon to the correct diagnosis. When the tumor type remains in question, excisional biopsy will very often lead to both diagnosis and cure. The critical element when dealing with tumors of the hand is to follow a careful surgical plan that preserves function as much as possible while simultaneously removing the neoplastic process completely.[69]

Future directions

The majority of tumors of the hand and upper extremity are benign. Variations in care, that cannot be accounted for by differences in pathophysiology or other objective evidence may represent opportunities for process improvement. Future research will define the role of patient algorithms and decision aids for managing suspected benign tumors of the upper extremity.[69]

Malignant tumors of the hand and wrist. *J Am Acad Orthop Surg*. 2006;14:680–692. *Malignant tumors in the hand and wrist compose a wide variety of lesions involving skin, soft tissues, and bone. Squamous cell carcinomas are described as the most common, followed by basal cell carcinomas and malignant melanomas. Other soft-tissue malignancies are defined as less common and can present diagnostic problems. These lesions often remain clinically indolent for some time prior to diagnosis. Delay in diagnosis of these tumors can have morbid and fatal consequences. Bone malignancies involve both primary lesions, with chondrosarcomas being the most common, and metastatic lesions. Treatment of malignant tumors in the hand and wrist requires special considerations because of the critical function role in the upper extremity. It is critical for upper extremity surgeons to be familiar with the wide clinical array of these tumors, the appropriate evaluation necessary to arrive at a precise diagnosis, and the treatment plan that will achieve the most favorable outcomes, oftentimes requiring a multidisciplinary approach.*
2. Chakrabarti I, Watson JD, Dorrance H. Skin tumours of the hand. A 10-year review. *J Hand Surg [Br]*. 1993;18:484–486. *This was a retrospective study performed over 10 years. The incidence, histological type, and clinical progression of skin tumors of the hand that were referred to a regional plastic surgery unit were evaluated. Eighty-five patients were studied with 98 malignant or premalignant lesions identified. The majority of skin lesions were squamous cell carcinoma. Recurrence after excision was seen in lesions greater than 1.5 cm in diameter. The overall incidence of squamous cell carcinoma of the hand was seen to be five cases per million per year. Other skin lesions and tumors were noted to be rare.*

Infections of the hand

Amy M. Moore and Ryan P. Calfee

SYNOPSIS

- Hand infections are common with diverse etiologies. It is important to have a high index of suspicion to diagnose and treat hand infections expeditiously in order to prevent morbidity and maximize outcomes.
- A thorough understanding of hand anatomy and the pathophysiology of hand infections is necessary to adequately provide treatment and improved functional outcomes.
- The treatment of hand infections includes the combination of early diagnosis, empiric broad-spectrum antibiotics – later tailored to culture data, and operative intervention.
- Patients should be followed closely as hand infections can rapidly progress or spread to deeper tissues. If no clinical response is noted within 24–48 hours of initial intervention, the treatment plan should be reassessed.
- A multidisciplinary team including physicians from the emergency department, radiology, infectious diseases and hand surgery as well as hand therapists are important for global care of the patient with a hand infection.

Introduction

Hand infections encompass a diverse array of diagnoses from paronychia involving the fingertip to necrotizing fasciitis of the hand and forearm. The etiology of infections is equally diverse; however, most are the result of direct inoculation of bacteria from penetrating trauma and lacerations. If not identified and treated expeditiously, these infections can result in significant morbidity.

The purpose of this chapter is to review the basic principles, evaluation, and management of patients presenting with infections based on anatomic location (fingertip, finger, hand, wrist, joints and bone). We will also briefly discuss infection mimickers such as gout and pyoderma gangrenosum. A multidisciplinary team, including specialists from infectious disease, radiology, emergency medicine, primary care and hand surgery, is necessary to effectively diagnose and manage infections of the hand.

Basic science/disease process

Skin and soft-tissue infections account for 1.7% of all emergency department visits in the United States.[6] Further, hand infections remain one of the few surgical emergencies for hand surgeons and account for up to 35% of patients admitted to hand surgery services.[7] The fingertip is the most common site for hand infections followed by the subcutaneous tissue of the dorsum and palm, tendon, joint and bone.[8–10] The most frequent cause of major hand infections is a neglected wound with either a delayed presentation and/or appropriate initial treatment.[9]

Numerous factors influence the development and severity of hand infections. The body is capable of preventing an infection with contamination of less than 10^5 bacterial organisms per gram of tissue.[11] Higher concentrations of bacteria overwhelm phagocytic cells (polymorphonuclear cells and macrophages) and acute phase antibacterial proteins (lysozyme, C-reactive protein, interferon and complement) to produce infection.[12] Factors that impact the severity of infection include the anatomic location, virulence of the organism, viability and vascularity of the surrounding soft tissue, timing of intervention, and health status of the patient.

Immunocompromised patients are more vulnerable to, and suffer increased morbidity from infection. Malnutrition, immunosuppression, immunodeficiency, alcohol or intravenous drug abuse, autoimmune disorders, systemic steroid use and diabetes impair the immune response and increase risk of infection.[13–15] These compromised hosts also have increased polymicrobial infections and opportunistic infections.[8,9] Patients with weakened immunity may have

Historical perspective

The treatment for hand infections dates back to the Golden Age of Greece and there have been many contributions to our understanding of and ability to treat infections over time. Hippocrates, a Greek physician, is often referred to as the "true father of hand surgery". He was born in 460 BC and authored works that described the treatment of wound infections in addition to the treatment of fractures, joints and dislocations.[1] His treatment principles were practiced and popularized in Greece and continue to hold true today. For example, in the treatment of infections, Hippocrates is quoted as saying that the dressing should be kept loose "so as not to intercept the pus but allow it to flow away freely".[2]

Although not clearly delineated in the literature with regards to hand surgery, a few important steps in the evolution of medicine and surgery have certainly impacted our current understanding and treatment of hand infections. In 1846, the first surgical procedure was performed using sulfur ether inhalational anesthesia at Massachusetts General Hospital. The development of "painless" surgery could then be used for the treatment of hand infections with surgical drainage. Contributing to the understanding of the basis of infection and its treatment in the mid-1800s, Louis Pasteur used heat to remove undesirable microorganisms, which was later termed "pasteurization". This concept was recognized and utilized in the surgical arenas thereafter.[1]

A momentous leap in the treatment of hand infections occurred when the relationship between hand anatomy and infection was established. In 1905, Allen Kanavel published his work on fascial and synovial spaces of the hand. Kanavel used injection studies to define the fascial spaces of the hand and described their patterns of communication.[3] Based on his findings, he identified the appropriate location of surgical incisions which are still utilized today. A few years later, Kanavel also characterized infections as to their findings on exam. For example, he described the classic signs of flexor tenosynovitis, now referred to as Kanavel's cardinal signs, as well as advocated for thorough surgical debridement and drainage of established infections.[4]

Finally, the introduction of antibiotics revolutionized the treatment of all infections. In 1929, Alexander Fleming identified a contaminant on a culture plate that inhibited growth of *Staphylococcus*. Years later this substance was purified and produced as the drug penicillin. Penicillin use became widespread in the 1940s and its positive impact on clinical results were evident.[5] Although penicillin resistance was found early, alternative antibiotics have continued to be discovered and their importance in our current treatment algorithm for hand infections has not wavered.

attenuated clinical signs and symptoms which can lead to delayed recognition of infection and increased severity at presentation. Thus, it is important to have a high index of suspicion for infection when evaluating an immunocompromised patient with "hand pain".

Causative organisms

Staphylococcus and *Streptococcus* species are the most common organisms to cause hand infection. *S. aureus* is particularly virulent, producing leukocidin, a neutrophil toxin. *S. aureus* has been reported to cause up to 80% of hand infections.[7,16,17] Although Gram-positive organisms are most common, Gram-negative, fungal, mycobacterial organisms and viruses are also culprits especially in polymicrobial infections. Methicillin-resistant *S. aureus* (MRSA) infections, both nosocomial and community acquired, have increased in prevalence over the past few decades. In the United States, community-acquired MRSA is now responsible for the majority of hand infections.[8,18,19] Risk factors for community-acquired MRSA include crowded living conditions such as day care, the homeless, inmates, athletes with shared clothing or sporting equipment, and military personnel. Empiric antibiotic coverage for presumptive MRSA infection is recommended based on the local prevalence of MRSA.[19]

Although *S. aureus* is the most common culprit of hand infections, it is helpful to consider the etiology of the infection and associate it with the possible offending microbial organism. Human bites, or "fight bites", are notorious sources of hand infections. Although *S. aureus* and alpha-hemolytic *Streptococcus* are usually isolated from these wounds, *Eikenella corrodens* is also found. *Neisseria gonorrhea*, a Gram-negative diplococcus, should be considered in the young, sexually active patient with a hand infection without a clear nidus of infection. Domestic animal bites are usually polymicrobial, but are often associated with *Pasteurella multocida*. Fungal or mycobacterial organisms should be suspected in the presence of chronic, indolent infections. Atypical mycobacteria such as *Mycobacterium marinum* is associated with injuries from fishing, fish tanks and swimming pools. *Sporothrix schenckii* and *Enterobacter agglomerans* infections occur following contamination with soil or plant material such as rose thorns.[12,20]

Appropriate antibiotic coverage should be chosen based on the severity of infection and the exposure history. Ideally, they would be initiated after Gram stain and cultures are obtained. In cases of severe infections, a multidisciplinary approach including an infection specialist is recommended to adequately treat the patient and optimize outcomes. Current antibiotic recommendations for common organisms are listed in Table 16.1.

Diagnosis/patient presentation

Clinical tips

Global treatment of the patient with a hand infection

- Early recognition and intervention improve outcomes.
- Identify risk factors: Immunocompromised? Diabetes? Steroid use?
- Obtain baseline lab work, X-rays, and blood cultures.
- Obtain wound cultures and start empiric antibiotics. Cover for MRSA if local prevalence is high.
- Once an area of fluctuance and/or abscess is identified, surgical intervention with incision, drainage, irrigation and debridement should be performed.
- Plan for multiple washouts (every 24–48 hours) until infection is controlled.
- Immobilize the extremity for tissue rest and elevation.
- Once tolerable, begin aggressive hand therapy to maximize return of function.

Pain, erythema, edema, fluctuance and tenderness are prominent features of an existing hand infection. Systemic signs are often rare. Early recognition and intervention can greatly improve outcomes.

When evaluating a patient with a possible hand infection, it is important to perform a thorough medical history to identify risk factors. Handedness, occupation, immunization history (e.g. tetanus), smoking, drug or alcohol abuse history and previous surgeries or trauma are important details to obtain. Prior personal or family history of MRSA infections is suggestive of another MRSA infection. On physical exam, it is important to assess the entire extremity for lymphangitic spread, indicating clinically advanced infection. A head to toe examination should also be performed to identify other sources or concomitant sites of infection.

Routine laboratory studies such as the white blood cell count (WBC) and the erythrocyte sedimentation rate (ESR) are often normal in the evaluation of a hand infection. When elevations do occur, they are usually associated with more severe cases.[21] Measurement of the acute-phase reactant C-reactive protein (CRP) can be helpful when monitoring treatment response, especially in patients with osteomyelitis. The CRP level can elevate in response to a variety of stressors or clinical conditions such as surgery or trauma. Thus it is sensitive, but nonspecific. In cases requiring long-term parenteral antibiotics, i.e. osteomyelitis, flexor tenosynovitis, or necrotizing fasciitis, blood cultures should be obtained. These should be negative prior to any long-term indwelling line being placed.

Radiographic imaging is important in the assessment of hand infections. Plain radiographs should be taken with any presenting hand infection to rule out the presence of a foreign body or subcutaneous emphysema. They will also allow for assessment of the underlying bone and joints, providing either diagnostic information or a baseline for which to compare in the future as radiographic evidence of osteomyelitis occurs 2–3 weeks after the onset of infection.[22] Ultrasound (US) and magnetic resonance imaging (MRI) are also useful tools for the diagnosis and treatment of musculoskeletal infections. US can diagnose early suppurative flexor tenosynovitis, localize foreign bodies and/or focal fluid collections. MRI is useful for early detection of osteomyelitis and can be used for evaluation of cellulitis, abscess formation and necrotizing fasciitis.[22] For the diagnosis of osteomyelitis in the presence of hardware, a tagged ^{99}mTc-labeled white blood cell radionuclide scan with bone marrow imaging can be performed. This study avoids the confounder of artifact or scatter seen on CT or MRI.[23]

Table 16.1 Antibiotic recommendations for common organisms.

Organism	Antibiotic	Additional information
Methicillin-sensitive *Staphylococcus aureus*	Cephalexin, amoxicillin clavulanate (orally)	
Methicillin-resistant *Staphylococcus aureus*	Trimethoprim/sulfamethoxazole (orally), linezolid (orally or IV) If sulfa allergy, clindamycin or doxycycline Vancomycin (IV), daptomycin (IV) Quinupristin/dalfopristin (IV) Tigecycline (IV) Ceftaroline (IV)	Linezolid: expensive, avoid in endocarditis or meningitis, weekly complete blood cell monitoring Dapto: weekly creatinine phosphokinase monitoring
Vancomycin-resistant enterococci	Daptomycin, linezolid (orally or IV), tigecycline (IV), quinupristin/dalfopristin (IV)	
Gram negative	Piperacillin/tazobactam Ceftriaxone Ertapenem Quinolones/ciprofloxacin	
Pseudomonas	Piperacillin/tazobactam Cefepime Meropenem	
Anaerobic infections	Ampicillin/sulbactam, Piperacillin/tazobactam, ertapenem, meropenem Metronidazole Clindamycin Tigecycline	
Vibrio vulnificus	Ceftriaxone and doxycycline Imipenem and doxycycline	
Nocardia	Trimethoprim/sulfamethoxazole If sulfa allergy: imipenem, ceftriaxone, amikacin	6 months of treatment in immune-suppressed patients
Sporothrix schenckii	Itraconazole Fluconazole and voriconazole	
Mycobacterium marinum	Clarithromycin/azithromycin Trimethoprim/sulfamethoxazole minocycline Ethambutol	
Aeromonas hydrophilia	Ciprofloxacin Imipenem Trimethoprim/sulfamethoxazole	
Cutaneous anthrax	Ciprofloxacin Doxycycline	Treatment for 60 days to treat any remaining spores
Tularemia	Gentamicin and doxycycline	

(Reproduced with permission from Osterman M, Draeger R, Stern P. Acute hand infections. *J Hand Surg*. 2014;39:1628–35.)

Early or superficial infections, including cellulitis may respond to nonsurgical intervention. Antibiotics, immobilization and elevation should be initiated. Patients should be followed closely as the infection can rapidly progress or spread to deeper tissues necessitating operative management. Further, if no clinical response is noted following nonoperative treatment, deeper involvement should be suspected. Once an area of fluctuance and/or abscess is identified, surgical intervention with incision, drainage, irrigation and debridement should be performed. Ideally, cultures would be obtained prior to the administration of antibiotics. Fluid should be sent for Gram stain, aerobic and anaerobic cultures, and sensitivities. Fungal stains, fungal cultures and mycobacterial cultures should be sent if suspicion is high or if the patient is immunocompromised.

In the following section we review the basic principles, evaluation, and management of specific upper extremity infections according to anatomic location. A comprehensive understanding of hand anatomy including the intricate synovial connections and spaces are essential for adequate treatment and improved surgical outcomes.

Fingertip

Paronychia

Paronychia accounts for 30% of all hand infections making it the single most common infection in the hand. This infection is most commonly caused by *Staphylococcus aureus* followed by *Streptococcus* and *Pseudomonas*.[24] Paronychias originate

Fig. 16.1 Acute paronychia involving the paronychium with inflammation extending towards the eponychial fold.

from either the proximal nail fold or the paronychium (skin fold on either lateral side of the nail plate). The infection typically begins unilaterally or just proximal to the nail. Untreated, the paronychia can expand around the nail, which is termed the "runaround" infection. The infection may also spread deep between the nail plate and the nail bed. Acute bacterial infection follows disruption of the barrier between the nail plate and the surrounding nail folds such as may occur with manicures, hangnails, or nail biting.

Early paronychia presents with pain, redness, and swelling (Fig. 16.1). As the infection progresses, gross purulence may collect around, or deep to, the nail plate. Extension toward the palmar fingertip may result in a felon. Before developing an associated abscess, the developing paronychia is treated with oral antibiotics and warm soapy soaks.[25]

After developing an abscess, drainage is required. Small abscesses with thin skin coverings can be unroofed and cultured. However, in many of the cases referred for hand specialty care, formal surgical decompression is required. This decompression is performed with a digital block and a small elastic digit tourniquet. The authors recommend first elevating the involved proximal or lateral nail fold from the nail plate. If purulence has accumulated deep to the nail plate, then at least part of the nail is removed. Skin incisions are made parallel to the lateral nail folds if required. Paronychia involving the proximal nail fold may be incised transversely over the most superficial portion of the abscess or decompressed with incisions extending proximally from the corners of the nail fold (Fig. 16.2). In cases in which skin incisions are required, we leave a thin plastic drain or cotton gauze wick to allow passive egress of fluid. Patients are allowed to remove the drain/wick and dressing 1–2 days after surgery and continue soapy water soaks twice a day until all wounds are sealed and dry.

Chronic paronychia is a distinct entity most commonly found in patients with prolonged exposure of the fingertips to a wet environment. By definition, a paronychia is chronic after being present for at least 6 weeks. *Candida albicans* is the primary pathogen responsible for chronic paronychia. Patients with chronic paronychia present with thickened, indurated, and erythematous tissue proximal to the nail plate (Fig. 16.3). Nail plates may become thickened and discolored. The eponychial fold may retract. The pain associated with chronic paronychia is less impressive than that reported during acute paronychia infection. Chronic paronychia may involve multiple fingertips.

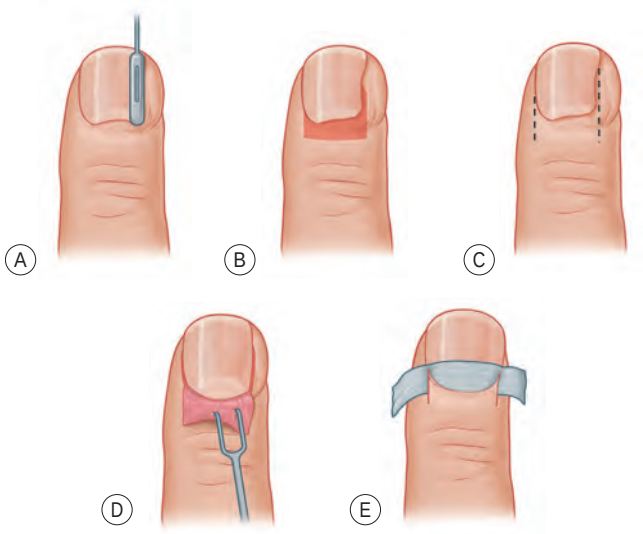

Fig. 16.2 Incisions for drainage of paronychia. **(A)** The nail plate and eponychial fold are elevated with a Freer elevator. **(B)** A skin incision is placed parallel to the lateral nail fold to drain the paronychia. **(C)** If proximal extension is needed, the incision can be carried from the corner of the nail fold and extended laterally at an angle. **(D)** A second skin incision can be performed to adequate drain the paronychia. **(E)** Wicking the incision site with gauze is recommended to prevent premature closure and re-collection of pus.

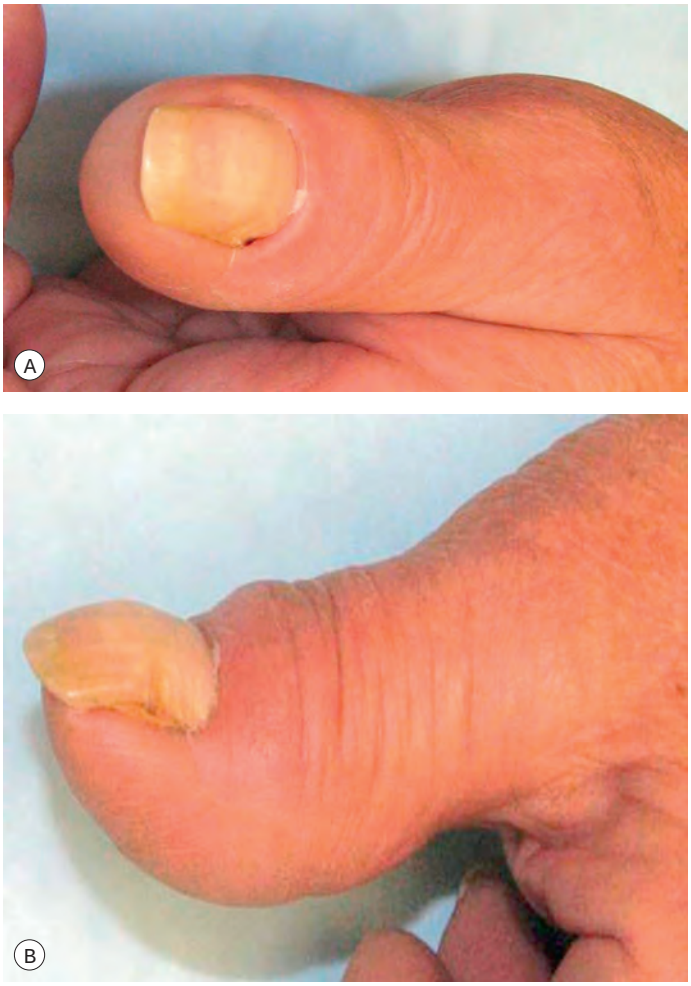

Fig. 16.3 Chronic paronychia involving thumb. **(A)** Dorsal view showing thickened, indurated and erythematous tissue proximal to the nail plate. The nail plate is also thickened and discolored. **(B)** Lateral view demonstrates retraction of the eponychial fold.

Treatment for chronic paronychia is frequently surgical but a trial of topical antifungal cream (2% ketoconazole or 2% miconazole) or oral antifungal medication (itraconazole or fluconazole) may be attempted. In the authors' experience, this may take months to obtain results and these medications are prescribed by a dermatologist. Eponychial marsupialization is the surgical treatment for chronic paronychia (Fig. 16.4). Performed with a digital block and tourniquet at the base of the finger, a 3–5 mm wide crescent-shaped portion of skin is removed starting 1 mm proximal to the eponychial fold. Although marsupialization has been described to various depths, the authors have removed the entire dermal layer but left the roof of the germinal matrix intact. Removing the deformed nail plate has reduced recurrence of chronic paronychia.[26] The wounds are left open for healing via secondary intention. Soft gauze dressings are changed once or twice a day until the wounds have healed. In our experience, marsupialization has been effective but changing the patient's occupational or leisure activities to minimize prolonged exposure of the fingertips to liquids is important to prevent recurrence.

Paronychia must be differentiated from herpetic whitlow at the time of presentation. Herpetic whitlow is a viral infection caused by herpes simplex type 1 (60% of cases) or 2 (40% of cases). It is caused from a viral inoculation of the host via infected body fluids. The virus invades the dermis and subcutaneous tissue and symptoms begin 2–14 days after exposure. Symptoms of this infection include a painful, burning or tingling sensation of the affected digit followed by erythema, edema and the development of 1–3 mm grouped vesicles over the next 7–10 days (Fig. 16.5). The infection is usually self-limiting with resolution within 3 weeks. Herpetic whitlow is characterized by a primary infection followed by a latent period in which the virus enters the cutaneous nerve endings and migrates to the peripheral ganglia. Recurrences can be induced with physiologic or psychological stress, fever, and sun exposure. Unroofing the vesicles may allow for a definitive diagnosis, usually with culture and Tzanck smear, but deeper debridement risks secondary bacterial infection or more disseminated herpetic infection.[17,27]

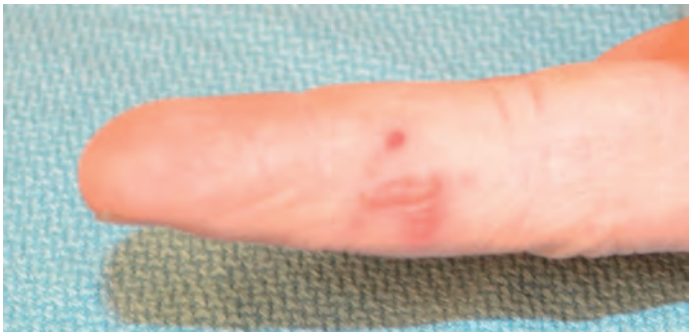

Fig. 16.5 Herpetic whitlow. Clinical signs include 1–3 mm grouped vesicles present along the digital neurovascular bundles.

Felon

A felon is an infection in the subcutaneous pulp space of the fingertip. *Staphylococcus aureus* remains the most common causative organism. Felon infections have been demonstrated to be increasingly secondary to community acquired MRSA.[18]

A felon behaves like a deep space infection forming an abscess because it is confined within the matrix of vertical fibrous septa in the pulp space. Felons most commonly follow penetrating trauma to the fingertip. Patients present with painful swollen fingertips that are exquisitely tender over the pulp space (Fig. 16.6). The swelling and pain should be confined to the pulp space distal to the distal interphalangeal flexion crease. When not treated, the felon may progress to cause tissue necrosis in the pulp space or seed infection into the distal phalanx (osteomyelitis) or the flexor tendon sheath (tenosynovitis).[17]

With the exception of the rare pulp space infection presenting prior to abscess formation, felons require surgical decompression. Similar to paronychia, various surgical approaches are described (Fig. 16.7). A longitudinal incision in the pulp space is an approach that minimizes risk to the digital neurovascular structures. Alternatively, a midaxial incision may be used (typically radial side of small and thumb, ulnar side of index, long, and ring fingers to minimize the chance of painful pinch or resting the hand on a painful scar). Regardless of the skin incision, blunt dissection with a tenotomy scissor or hemostat is required to disrupt the fascial bands in the pulp space to ensure complete decompression. Nonviable tissue is debrided and the wound is irrigated. A small plastic drain or cotton gauze wick is left in the wound and dressing changes with soapy water soaks and drain/wick removal commence the following day.

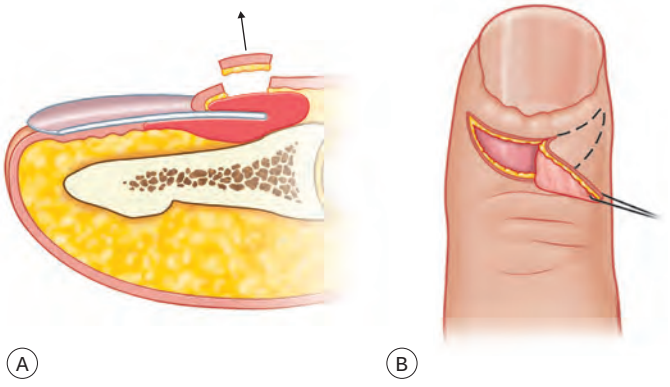

Fig. 16.4 Eponychial marsupialization for chronic paronychia. **(A,B)** A 3 mm wide crescent-shaped excision of skin is performed to the depth of the germinal matrix. The germinal matrix is maintained and unharmed.

Finger

Pyogenic flexor tenosynovitis

Clinical tips

Pyogenic flexor tenosynovitis

- Kanavel's signs on exam include:
  - fusiform digit
  - flexed resting posture of digit
  - tenderness over the flexor tendon sheath
  - pain with passive extension of the digit.
- Pyogenic flexor tenosynovitis warrants urgent surgical intervention.

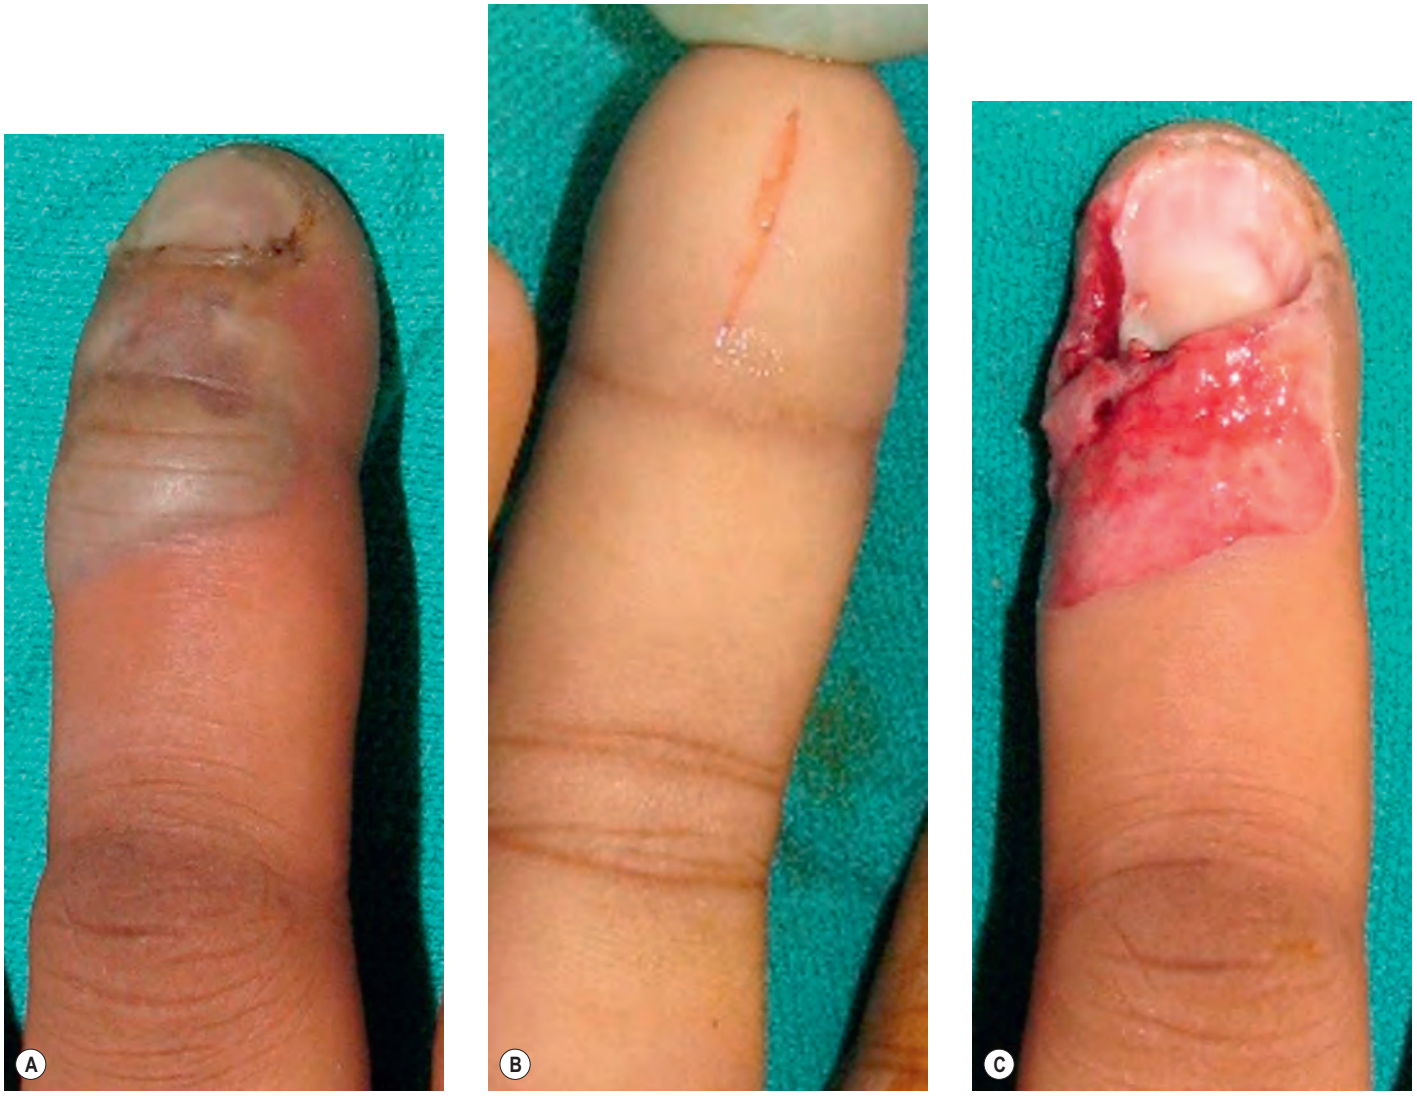

Fig. 16.6 Severe paronychia with felon. **(A)** Dorsal view of purulent paronychia with felon. **(B)** Volar view of midline incision. **(C)** Dorsal view of debrided finger with nail plate removed.

- Open the tendon sheath proximally over A1 pulley and expose sheath distally either through midaxial or volar zigzag incision.
- Use 5 French pediatric feeding tube to irrigate tendon sheath copiously from proximal to distal.
- Plan for multiple washouts (every 24–48 hours) until infection is controlled.

The flexor tendon sheath is a double-walled structure with a visceral and parietal layer. The visceral layer is closely adhered to the tendon forming the epitenon. The outer parietal layer is in contact with the pulley system. A closed system is created between these two mesothelium-lined layers. This synovial sheath envelops the flexor tendons from the level of the insertion of the flexor digitorum profundus at the distal interphalangeal joint to the metacarpal neck proximal to the A1 pulley (Fig. 16.8). The flexor tendon sheaths of the thumb and small finger communicate with the radial and ulnar bursae, respectively, and extend into the carpal tunnel and space of Parona.[28] In up to 80% of individuals the radial and ulnar bursae communicate. The nutrient supply to the flexor tendons is from direct vascular inflow via the vincula in addition to diffusion from the synovial fluid.

Pyogenic flexor tenosynovitis occurs when bacteria is inoculated into the synovial sheath – most commonly from penetrating trauma. Bacterial proliferation in the sheath leads to increased pressure and disruption of the vascular supply and the critical gliding mechanism. If not treated expeditiously, this can lead to tendon necrosis and rupture.[29] Due to the synovial connections as described above, infection can travel quickly throughout the hand and proximally into the forearm. In patients with communicating radial and ulnar bursae, a horseshoe abscess can occur.

In 1914, Allen Kanavel described the physical findings of patients with pyogenic flexor tenosynovitis. Kanavel's

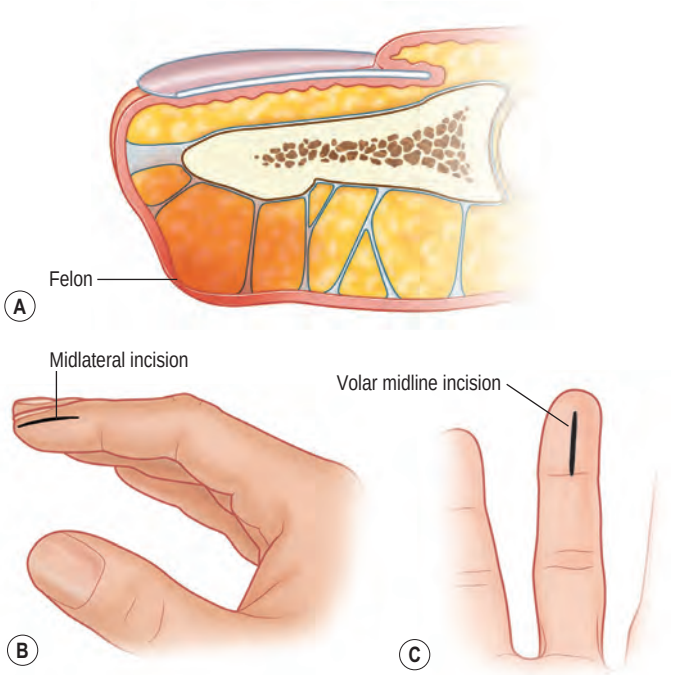

Fig. 16.7 Incisions for felon drainage. **(A)** Cross section of the distal fingertip, showing inflammation and collection of fluid within the septa. **(B)** A unilateral midlateral incision allows access to the septations of the distal pulp. Care needs to be taken to avoid the neurovascular bundles. **(C)** A single volar incision can be used. This approach has less risk to the digital neurovascular bundles. To avoid scar contracture, the incision should not pass the flexion crease.

cardinal signs include (1) tenderness over the course of the tendon sheath, (2) a flexed posture of the finger, and (3) excruciating pain on passive extension of the finger. Later a fourth sign, fusiform swelling of the finger, was added.[1,3,4] Disproportionate pain on passive extension is the most sensitive and reproducible clinical sign. However, not all signs are present if the patient presents with a very early infection or if the patient is immunocompromised. Palpation over the flexor tendon sheath is helpful to differentiate pyogenic flexor tenosynovitis from other diagnoses such as gout, herpetic whitlow or septic arthritis.

The treatment of pyogenic flexor tenosynovitis includes both surgical and medical management. As most patients present after 24–48 hours after inoculation, surgical incision and irrigation of the flexor sheath is usually warranted. Parenteral antibiotic therapy should also be initiated. As direct inoculation is the most common source of infection, skin flora, i.e., *S. aureus* and *Streptococcus* species, should be covered and antibiotics should later be tailored to culture data. If nonoperative treatment is chosen in the case of early tenosynovitis, then close observation is necessary.

Many surgical drainage approaches have been described varying from extensive open dissection of the sheath to limited exposure and catheter irrigation (Fig. 16.9).[4,30] The goal of treatment is to adequately irrigate and drain the synovial space while protecting the critical structures of the sheath, i.e., the pulley system. We recommend a proximal incision made proximal to the A1 pulley. Distally the tendon sheath is exposed either through a midaxial or volar zigzag incision. A 14-gauge angiocatheter or a 5 French pediatric feeding tube is placed in the proximal incision for irrigation. Irrigation should always proceed from proximal to distal to avoid proximal seeding of the infection. Wounds are left opened, usually wicked for the first 24 hours. If there is lack of clinical response within 24–48 hours using a limited exposure then more extensive debridement should be pursued (Fig. 16.10).

After surgical drainage, close observation is required and multiple trips to the operating room may be needed for adequate debridement and irrigation. Patients should remain on parenteral antibiotics as determined with consultation from infectious disease specialists. Active and aggressive hand therapy should begin as soon as tolerated to improve range of motion of the finger. The most common complication after flexor tenosynovitis is loss of active motion. Risk factors associated with poor outcomes include delayed presentation, age greater than 43 years, diabetes mellitus, peripheral vascular disease, renal failure, subcutaneous purulence, digital ischemia and polymicrobial infections.[15]

Hand

Deep space infections

In 1905, Allen Kanavel published his work on the fascial and synovial spaces of the hand. Kanavel used injection studies to define the fascial spaces of the hand and described their patterns of communication.[1,3,4] Based on his findings, he identified the appropriate location of surgical incisions which are still used today. These potential subfascial or deep spaces include the subaponeurotic, thenar, midpalmar, hypothenar, interdigital webspace, and Parona's spaces (Fig. 16.11). Knowledge of the relevant anatomy associated with these spaces is critical for adequate management of infections associated with them.

Deep space infections of the hands are caused by direct penetrating trauma, contiguous spread from other areas of the hand, and more rarely, from hematogenous spread. *S. aureus* and *Streptococcus* species are most commonly implicated as the infectious organism. Antibiotic therapy in addition to incision, irrigation and debridement are the mainstay of management for deep space infections.[31] There are multiple accepted approaches to the deep spaces of the hand (see Fig. 16.9).

The subaponeurotic space is found on the dorsum of the hand in the space bound by the extensor tendons dorsally and the metacarpals with interosseous muscles volarly. Patients present with significant edema and erythema on the dorsum of the hand with difficulty and pain with passive and active finger extension. Subcutaneous infections are difficult to distinguish from subaponeurotic space infections but surgical intervention is advocated for both. Longitudinal incisions avoiding exposure and desiccation of the extensor tendons is preferred.

The thenar space is located volar to the fascia of the adductor pollicis muscle and dorsal or deep to the index flexor tendons. The radial extension is to the adductor pollicis insertion on the proximal phalanx of the thumb. The midpalmar septum of the third metacarpal is the ulnar extension of the space. On presentation, the thumb is often held in palmar abduction and is exquisitely tender to palpation. Often in more severe cases, the infection extends into the first webspace and dorsoradial aspect of the hand. This extensive infection has been described as a *dumbbell* or *pantaloon* infection.[32]

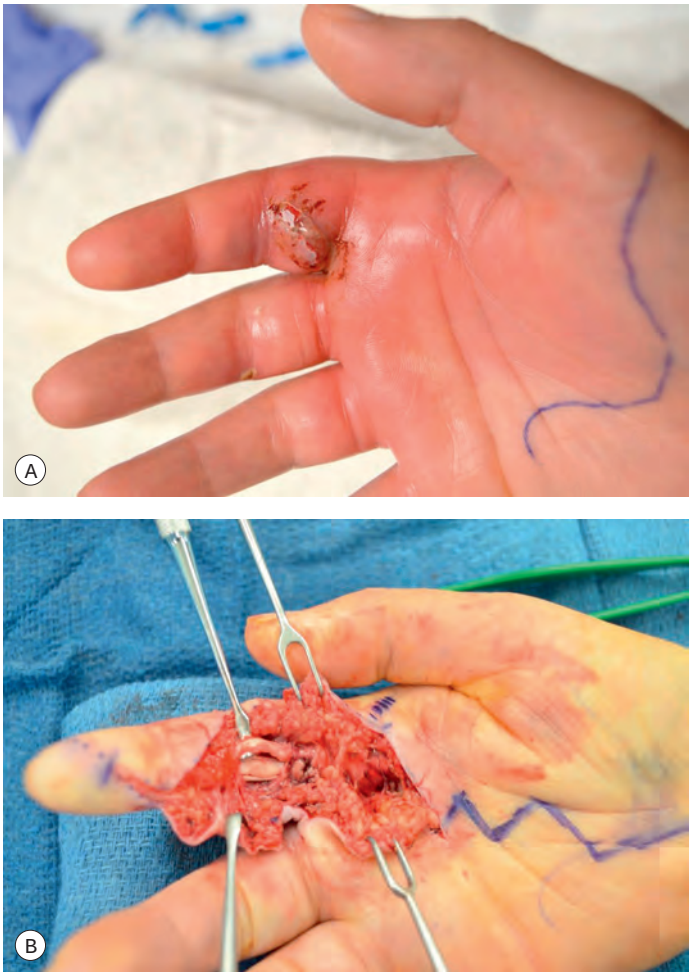

Fig. 16.10 Pyogenic flexor tenosynovitis. **(A)** Clinical photo of index finger pyogenic flexor tenosynovitis caused by a dog bite. **(B)** The patient required an open debridement and multiple washouts to obtain control of the infection and remove nonviable soft tissue.

Incision and drainage can be performed from either a dorsal or volar, or more commonly, a combined approach, but should avoid running parallel to the first webspace to avoid a first webspace contracture.

The midpalmar space is located deep to the flexor tendons of the long, ring and small fingers and superficial to the long and ring finger metacarpals and interosseous muscles. It extends radial to the septum of the long finger metacarpal and ulnar to the hypothenar musculature. On presentation, volar hand edema is notable and there is loss of the palmar concavity. Patients have pain with passive motion of the long and ring fingers. Multiple incision options exist, but regardless of the choice, a large exposure is preferable to obtain access to this space while carefully protecting the critical neurovascular structures of the palm.

The hypothenar space infection is extremely rare. This space is bound radially by the hypothenar septum originating from the palmar fascia and is deep to the hypothenar musculature but superficial to the small finger metacarpal. On presentation, there is soft-tissue swelling of the hypothenar eminence. A longitudinal incision is made over the hypothenar musculature extending through the hypothenar fascia.

The second, third and fourth interdigital web spaces are located beneath the palmar fascia and dorsally by the dorsal hand fascia. An infection of this space is termed a *collar button* abscess because it spreads volarly and dorsally but is narrowed at the intermetacarpal extension. On presentation, the fingers of the affected webspace are held in abduction (Fig. 16.12). Volar and dorsal incisions are advocated for adequate drainage of this space. Direct incision through the webspace should not be performed to avoid adduction contracture.

The space of Parona is located proximally deep to the flexor tendons and superficial to the pronator quadratus muscle. This space is contiguous with the radial and ulnar bursae and infections to this space are often extensions from infections of the hand. Patients present with significant forearm edema, tenderness and pain with finger flexion. Depending on the severity of the infection, acute carpal tunnel syndrome can also be seen.[16] A longitudinal incision on the ulnar aspect of the forearm is recommended with extension distally across

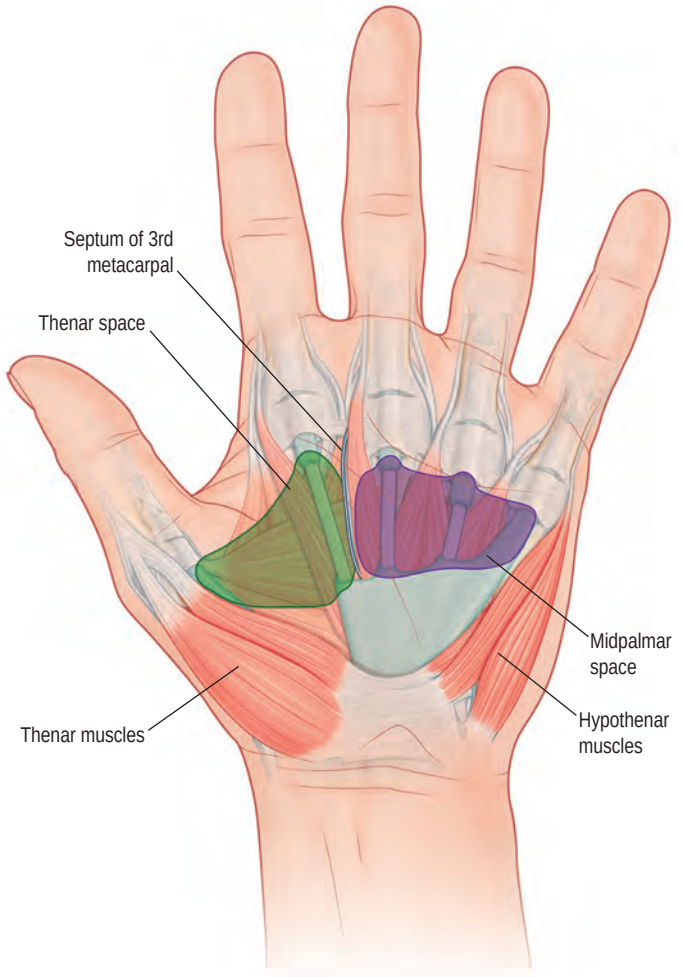

Fig. 16.11 Deep spaces of the hand.

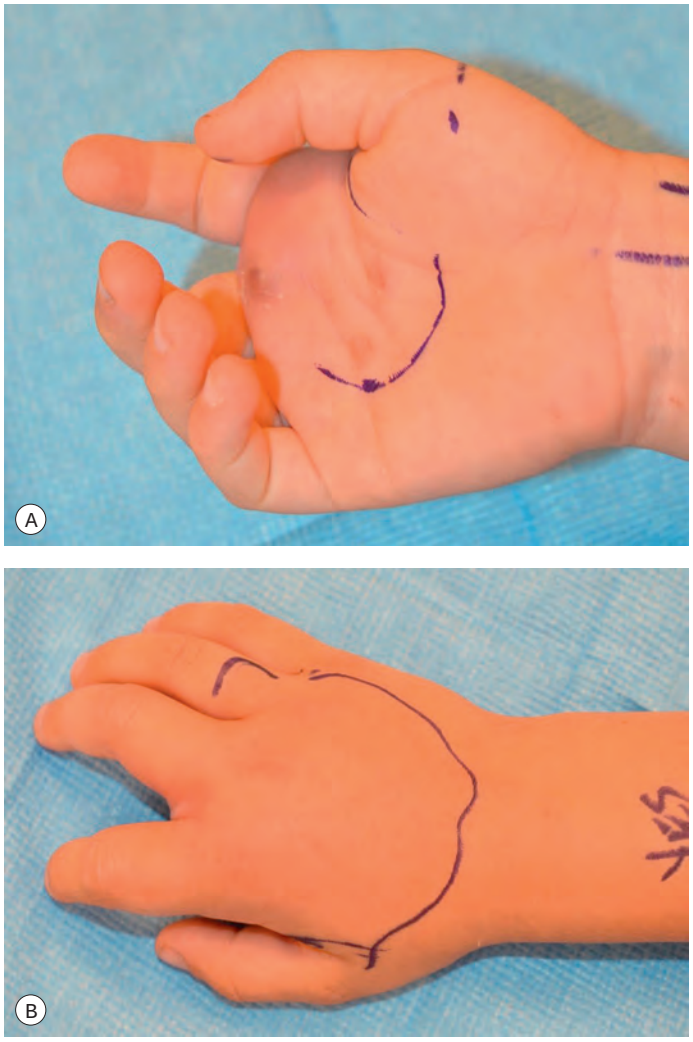

Fig. 16.12 Collar button abscess. **(A)** Volar view of hand with second interdigital webspace infection. **(B)** Dorsal view showing the index and long fingers held in abduction. Volar and dorsal incisions are recommended for adequate drainage of this space.

the wrist crease. This includes release of the transverse carpal ligament. The median nerve and flexor tendons are protected.

In general, incisions should be planned to allow for adequate irrigation and debridement of nonviable tissue while also protecting important neurovascular structures. The wounds created from surgical drainage and irrigation should most often be left open and packed with moist to dry dressings. If critical structures are exposed, tacking sutures can be placed while still allowing adequate packing of the affected spaces. Alternatively the wounds can be loosely closed over a silastic drain. The hand should be splinted, elevated and closely monitored for clinical improvement. One should have a low threshold for return to the operating room if there is lack of clinical improvement over the following 24–48 hours. Parenteral antibiotic therapy is begun after cultures are obtained and is later tailored to culture results. Early motion with the assistance of a hand therapist should be emphasized to avoid postoperative complications of tendon adhesions and joint stiffness.

Wrist/forearm

Necrotizing fasciitis

Clinical tips

Necrotizing fasciitis

- Necrotizing fasciitis is a surgical emergency.
- Most common risk factors include:
  - history of drug abuse
  - immunosuppression
  - diabetes.
- Group A β-hemolytic streptococcus is the most common organism.
- The characteristic findings include pathologic "dishwater" fluid or pus along the fascial planes. In involved areas, the subcutaneous tissues easily separate off the underlying fascia.
- All necrotic tissue and fibrinous material should be radically debrided.
- Plan for multiple washouts and debridements (every 24–48 hours) until infection is controlled.

Necrotizing fasciitis is a rare infection that requires emergent surgery. This infection spreads rapidly and threatens both life and limb. Despite the severity of the infection, it often begins after rather minor skin trauma. In a review of 317 affected limbs, demographic risk factors for necrotizing fasciitis included intravenous drug abuse, smoking and trauma, with diabetes being the most common medical comorbidity.[33] Immunosuppression, liver disease, and peripheral vascular disease have also been associated with this infection. Necrotizing fasciitis is often polymicrobial although group A β-hemolytic streptococcus is the most common organism identified in isolation.[34]

The characteristic presentation for necrotizing fasciitis includes the painful limb with rapidly progressive erythema or bullae (Fig. 16.13). Across two series, the most common examination findings at the time of presentation were warmth (97%), erythema (95–100%), edema (82%) and disproportionate pain (98–100%).[34,35] Patients are frequently hemodynamically unstable with elevated white blood cell counts, coagulopathy, and shock. When the infection is spreading up a limb along the fascial planes, the clinical situation can rapidly deteriorate in hours. Radiographs and CT or MRI may demonstrate gas within the soft tissues but the sensitivity and specificity of imaging for necrotizing fasciitis is variable. If surgical debridement will be delayed, pursuing advanced imaging in acute cases of necrotizing fasciitis is not recommended. The formal diagnosis of necrotizing fasciitis is dependent on microscopic examination of biopsied fascia.[36]

Aggressive, emergent surgical debridement is required to treat necrotizing fasciitis. The infection typically extends wider than anticipated. The characteristic findings during surgery include pathologic "dishwater" pus along the fascial planes. In involved areas, the subcutaneous tissues easily separate off the underlying fascia. All necrotic tissue and fibrinous material is radically debrided. The skin and muscle

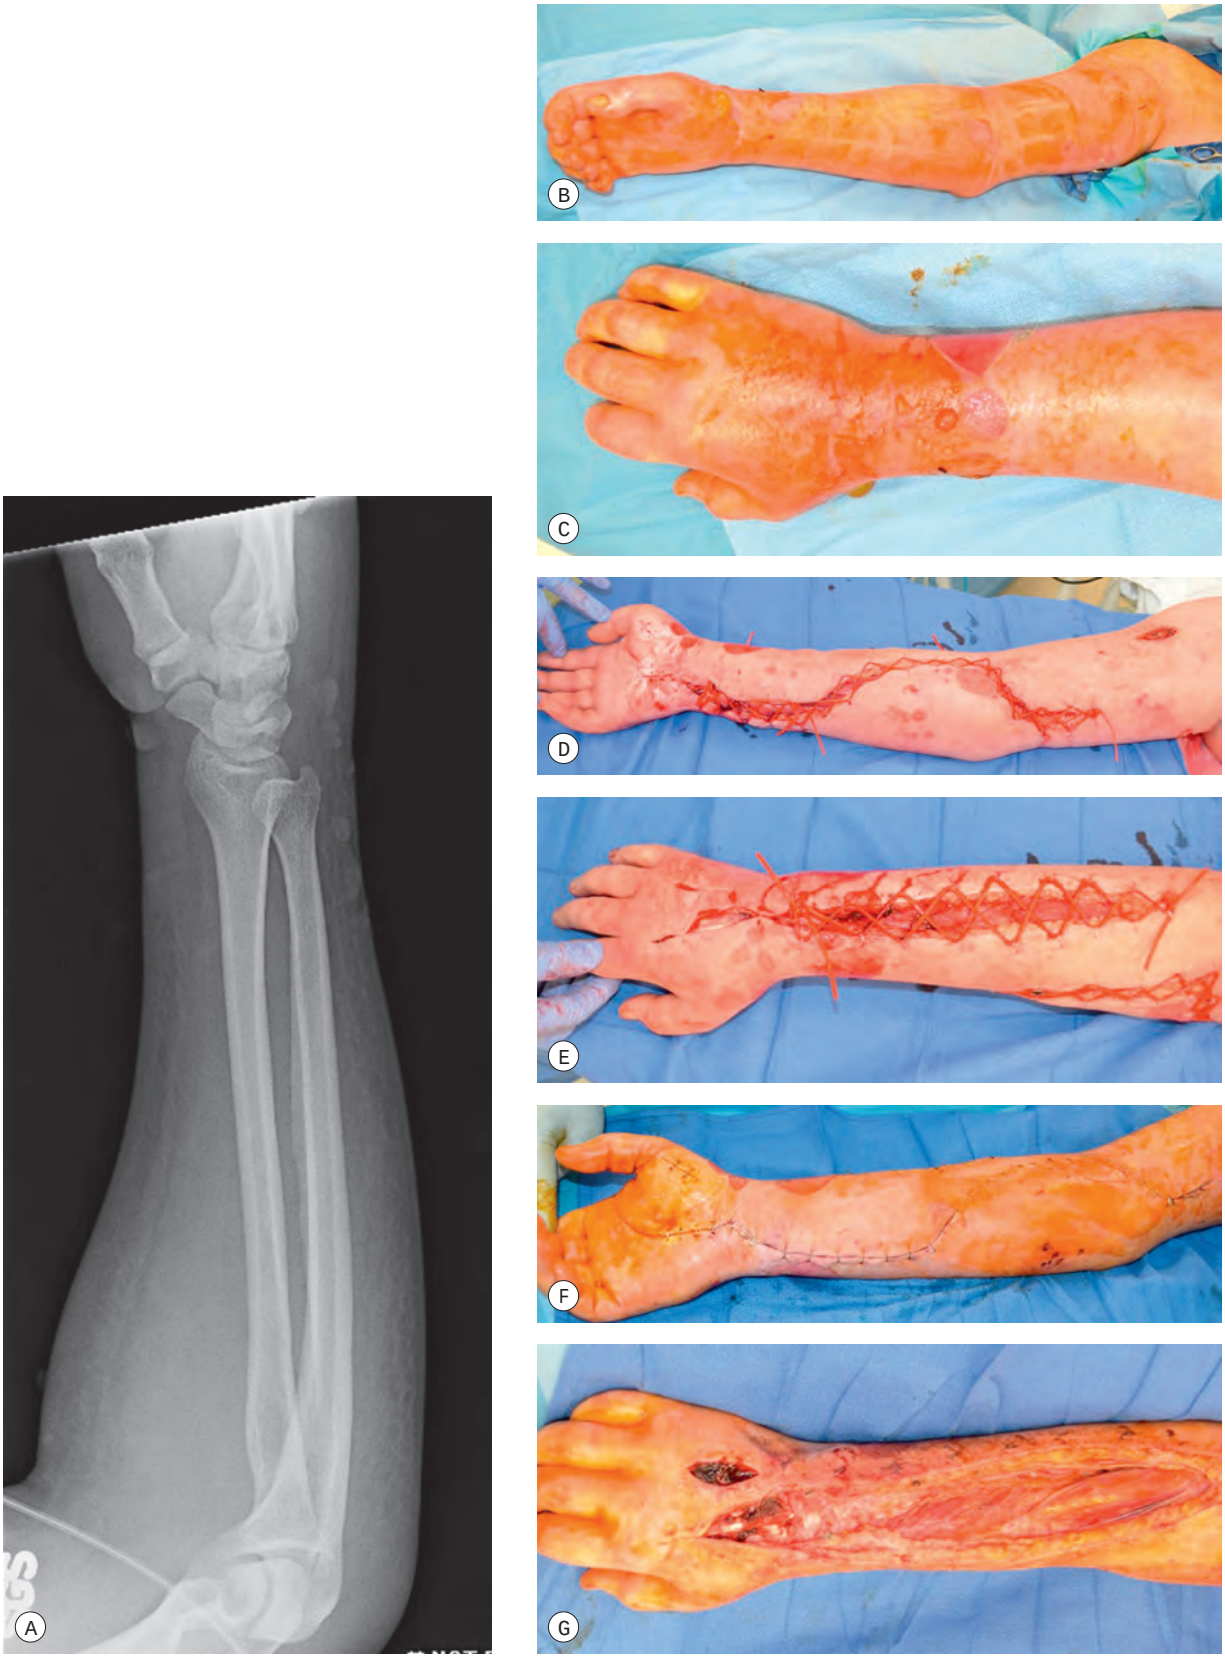

Fig. 16.13 Necrotizing fasciitis in a neutropenic patient with leukemia. **(A)** Subcutaneous emphysema present on forearm films. **(B,C)** Volar and dorsal views of upper extremity showing classic signs of progressive erythema and bullae are present. **(D–G)** Multiple washouts were performed to gain control of infection.

are not directly involved with this infection. Although antibiotics are not the primary treatment for this aggressive infection, empiric drugs are started immediately as all attempts are made to stabilize the patient. Empiric treatment includes a cephalosporin for Gram-positive coverage, gentamicin for Gram-negative effect, and penicillin for potential anaerobic involvement. Depending on the local prevalence, MRSA coverage may be advantageous. Antibiotic delivery is subsequently tailored according to culture results after the initial debridement.

In the best cases, surgical debridement preserves both the patient's life and limb. Planned, staged debridements of affected limbs are expected with an average of 3–4 debridements per patient.[33,34,37] Debridements are repeated every 24–48 hours based on the patient's clinical condition.

Joints

Septic arthritis

Septic arthritis requires prompt diagnosis and treatment to prevent articular destruction. Any joint from the fingers to the wrist can be affected. Septic arthritis most commonly results from penetrating injury, hematogenous spread, or from extension of infection from surrounding tissue. "Fight bite" injuries over the proximal interphalangeal (PIP) and metacarpophalangeal (MCP) joints are the most common penetrating injury and in a series of 159 injured hands, joint penetration was confirmed in 96% of cases and intra-articular purulence encountered in all cases explored >24 hours after injury (Fig. 16.14).[38] Distal interphalangeal (DIP) joints are at risk for septic arthritis following rupture of mucous cysts (Fig. 16.15). *S. aureus* and *Streptococcus* are the most common pathogens producing septic arthritis. Infrequent but notable causes of mono-articular septic arthritis include *Neisseria gonorrhoeae* in the young adult and *Haemophilus influenzae* in children.

Septic arthritis is characterized by swelling and pain with near complete loss of joint motion (active and passive) secondary to pain. Any periarticular penetrating trauma complicated by subsequently increasing pain and lack of motion should be evaluated for a septic arthritis. Fluctuance is difficult to appreciate in the small joints of the fingers and wrist. Although C-reactive protein levels and erythrocyte sedimentation rate may be elevated, these markers are not specific to infection and do not differentiate between septic arthritis and systemic inflammatory arthropathy. Joint aspiration is useful as both a diagnostic and potentially therapeutic measure as the differential diagnosis routinely includes gout or pseudogout. The patient history is important and should include any history of inflammatory crystalline arthropathy (although the hand can be the first manifestation) and to note whether or not any recent systemic illness occurred.

Once diagnosed, septic arthritis requires drainage of the inflammatory fluid to preserve articular surfaces. Operative approach to the DIP, PIP, and MCP joints is standard dorsal incisions. For the DIP joint, a dorsal H or Y type incision affords excellent exposure while avoiding the nail bed tissue. The capsule of the DIP joint is excised from either side of the terminal tendon. The PIP joint is approached between one lateral band and the center slip of the extensor mechanism.

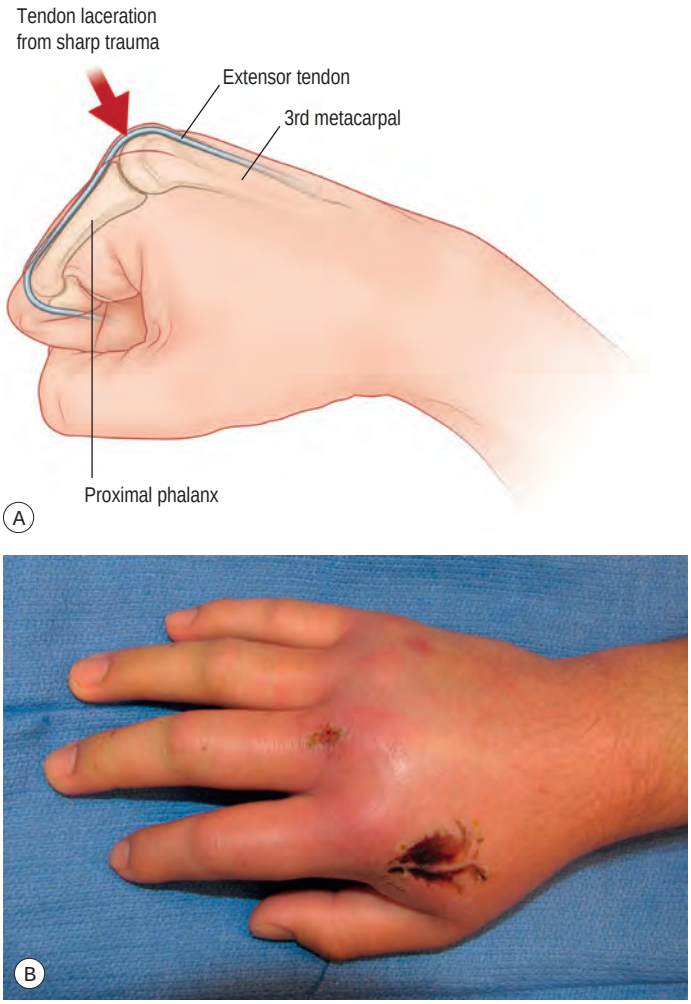

Fig. 16.14 Septic arthritis caused by "fight bite". **(A)** During clenched fist injury, the tendon and joint are usually penetrated. **(B)** A typical appearance of septic arthritis due to a "fight bite". A laceration is present over the metacarpal phalangeal joint and there is edema with surrounding erythema.

The MCP joint is approached either through the extensor hood (midline or adjacent to the extensor tendon) or by developing the interval deep to each sagittal band which allows complete capsulectomy without any compromise of the extensor apparatus. The surgical approach to any of these joints incorporates any open wounds or draining sinuses. For the septic wrist, debridement can be completed arthroscopically or open.[39] In our practices, we use a dorsal gentle S-shaped incision with elevation of the extensor compartments after opening the third extensor compartment. Either a longitudinal or ligament-sparing capsulotomy is performed and the radiocarpal, midcarpal, and distal radio-ulnar joints are debrided. Care is taken to preserve the dorsal radio-ulnar ligament and triangular fibrocartilage complex (TFCC).

After capsulectomy, the joints are irrigated and loose synovial tissue is debrided. No attempt is made to close the capsule and skin wounds are loosely approximated leaving room for small elastic drains. When gross purulence is encountered, it is our practice to routinely return to the operating room for a second debridement 48 hours later. Cultures are taken during

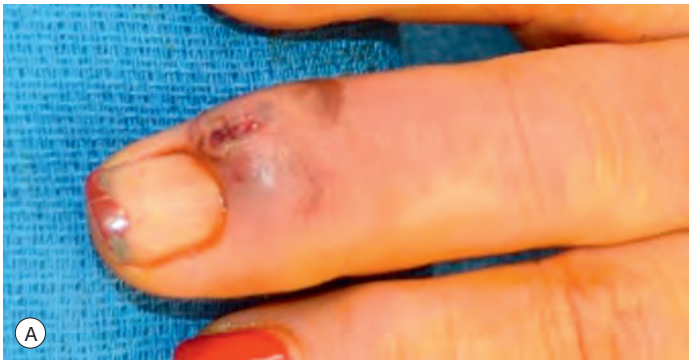

Fig. 16.15 Septic arthritis of distal interphalangeal (DIP) joint. **(A)** Dorsal and **(B)** lateral view of infected mucous cyst after attempted drainage by the patient. **(C)** X-rays demonstrate classic dorsal osteophyte of DIP joint with narrowing.

the initial debridement and an infectious disease specialist is consulted as parenteral antibiotics are typically recommended for several weeks.

If patients have a medical contraindication to surgery, serial aspiration with irrigation is performed. In that case, the involved joint is aspirated and then flushed with saline with inflow and re-aspiration until the fluid leaving the joint is clear.

Bone

Osteomyelitis

Osteomyelitis is defined as a microbial invasion of the bone. It accounts for 6% of hand infections and 70% of osteomyelitis cases involve a single bone, most often the distal phalanx.[40] A bone infection can lead to substantial morbidity and even

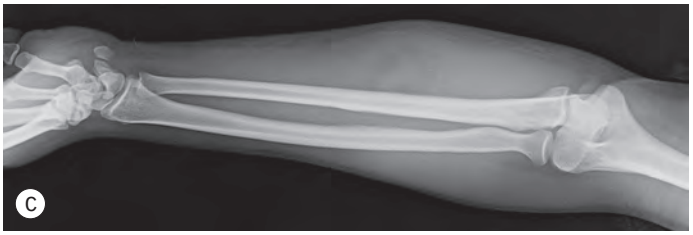

Fig. 16.16 **(A)** Chronic ulcerative wound in an IV drug abuser. **(B,C)** Forearm X-rays demonstrate underlying periosteal reaction of the ulna consistent with osteomyelitis.

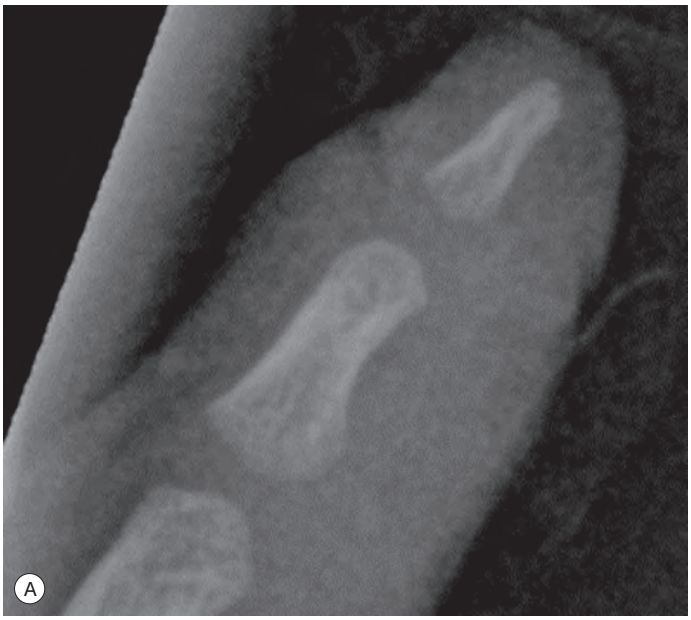
amputation, thus its identification and adequate treatment are imperative.

There are numerous etiologies for osteomyelitis, but the most common mechanisms are penetrating wounds, open fractures, contiguous spread from an adjacent infection and hematogenous seeding from a distant infection.[12,16] *S. aureus* and *Streptococcus* species are the usual offending organisms. A bone biopsy is the most accurate method for isolating the causative organism and allowing for narrowed antibiotic use.

In the development of osteomyelitis, there is a reproducible sequence of events. Initially causative organisms from etiologies given above will cause microthrombi within intraosseous vessels and periosteal elevation. This is followed by osteolysis. If the infection is allowed to progress, a sequestrum, or bone abscess, is formed. In effort to contain the infection, a sclerotic margin is formed around the infection called an involucrum. This *sequestrum involucrum* indicates chronic infection and prevents blood flow to the infection and limits antibiotic penetration.[12] Thus, in these circumstances open debridement is required.

Patients with osteomyelitis present with pain, erythema and edema. Often patients have been previously treated for superficial infections without resolution (Fig. 16.16). Systemic symptoms are rarely found at presentation. ESR and WBC are usually normal, but CRP levels can be elevated. Radiographic findings are usually absent early in the disease process, thus a high index of suspicion is needed to accurately diagnose osteomyelitis. After 2–3 weeks of infection, changes on plain radiographs can be seen (Fig. 16.17). These include osteolysis, osteopenia, osteosclerosis, periosteal reaction and metaphyseal rarefaction.[12,41] The presence of a sequestrum or involucrum indicates advanced disease. Radionuclide WBC scans or MRI can be used to detect early disease prior to changes on plain radiographs.

The treatment of osteomyelitis involves early detection, surgical debridement of infected tissue, stabilization of bone (when necessary) and antibiotic therapy guided by bone biopsy and sensitivities. Parenteral therapy is the preferred method of antibiotic delivery for bone infections. However, a multidisciplinary approach including an infectious disease consultation is recommended. Early detection of osteomyelitis with the absence of osteonecrosis can sometimes be treated without surgical debridement and close follow-up.[12] Surgical techniques that can be employed to eradicate infection include creation of a cortical window and bone curettage. In severe



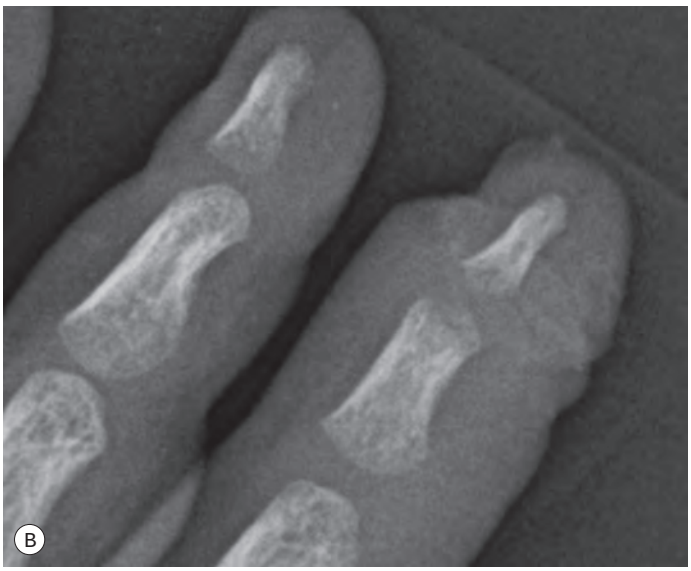


Fig. 16.17 **(A)** Initial X-ray of 2-year-old child with nail-bed injury. **(B)** X-ray 2 weeks after injury when patient presented with increased pain, erythema and edema of finger. There is cortical destruction of the middle phalanx consistent with osteomyelitis.

cases, bone resection and/or amputation may need to be performed. If a sequestrum is present, complete surgical debridement of the devitalized tissue is required to prevent recurrent infections.

Mimics of infection

Gout

Gout is a crystalline arthropathy that is typically a leading diagnosis in the differential when approaching acute infections. Patients with gout have abnormal uric acid metabolism and experience gout flares when uric acid crystals come out of solution in cool peripheral joints. Affected joints acutely become erythematous, painful, and swollen. These joints are similar to septic joints in that they are painful to move but typically exhibit more sensitivity to even light touch and the patients do not routinely have any antecedent infection or trauma that would produce a septic joint. Gout is the leading presumed diagnosis in an older patient with a spontaneous erythematous and painful DIP joint when the inflammation clearly is centered over the joint as opposed to being contiguous with the paronychium. The definitive diagnosis is established by identification of negatively birefringent crystals in joint fluid under polarized microscopy. Secondary bacterial infection can occur in the setting of gout so joint fluid is also sent for Gram stain and culture. Gout is treated with either non-steroidal anti-inflammatories (NSAIDs) or oral steroids. Relatively rapid improvement is expected within a few days. In chronic uncontrolled gout, painful tophi may develop and are surgically debulked if symptomatic. With recurrent gout attacks, patients should be counseled on dietary modifications and consideration is given to chronic suppressive medical treatment coupled with gout-specific medication for attacks.

Pseudogout

Pseudogout is a second crystalline arthropathy similar to gout. It also affects peripheral joints and presents with the same acute onset of warm, erythematous, painful joints. Pseudogout attacks result from crystallization of calcium pyrophosphate. This crystal is positively birefringent under polarized microscopy. Unlike gout, dietary modifications are not preventative. On radiographs, pseudogout characteristically produces calcified soft tissues such as the TFCC. Treatment consists of immobilization for comfort and either NSAIDs or steroid medication.

Pyogenic granuloma

Pyogenic granulomas are a benign process although the outward appearance is typically quite concerning for patients. This characteristically exophytic mass appears like a mass of granulation tissue that is friable and easily bleeds (Fig. 16.18). There is no surrounding erythema. These masses often follow a penetrating injury. Topical silver nitrate is the initial treatment. This can be repeated several times if needed. If the mass does not involute, surgical excision is expected to be curative. Under tourniquet control, a 1-mm border of skin is excised with the stalk of the granuloma. The underlying subcutaneous tissues are typically normal in appearance and recurrence is not expected.[42] The wound can be closed primarily or left to heal by secondary intention.

Fig. 16.18 Pyogenic granuloma of finger after previous superficial trauma.

Pyoderma gangrenosum

This ulcerative skin lesion expands centrifugally with a necrotic center. It is associated with systemic diseases including ulcerative colitis and Crohn's disease in addition to diabetes and rheumatoid arthritis. When recognized, pyoderma gangrenosum is managed with corticosteroids and local would care. Surgical debridement, although contraindicated, has often occurred prior to establishing the diagnosis.

Patient selection

A thorough history and physical as well as a high index of suspicion is required when evaluating patients who present with a painful, erythematous and swollen hand. The diagnosis of a hand infection has to be based not only on anatomical knowledge, but also on medical knowledge to distinguish surgical problems from rheumatological ones. The key to improved outcomes and decreased morbidity is early identification of infection combined with appropriate medical and surgical management.

Postoperative care

After treating infections surgically, most wounds are left open to drain and allow secondary healing as long vital structures are not exposed. When closure is required, critical structures are covered and drains are placed to allow drainage. For most infections, we recommend soapy water soaks to be completed twice daily starting 1–2 days after debridement. Drains are removed at the first soak. Damp to dry dressings are continued until wounds have sealed.

For substantial infections with planned staged debridements, we recommend either damp to dry dressings or negative-pressure dressings. The negative-pressure dressing is highly effective in drawing out edematous fluid. If using negative-pressure dressings, then daily complete blood counts

should be monitored as hemoglobin values can drift down with the continuous fluid loss.

Outcomes, prognosis, and complications

Most hand infections are readily managed with surgical debridement and antibiotics. Risk factors for poor outcomes or the need for amputation to control infection include immunocompromised hosts (e.g., diabetics, transplant patients, rheumatoid arthritis patients on disease-modifying drugs) and patients that smoke tobacco or have compromised peripheral vasculature. In these patients with impaired healing potential, initial counseling should include the possibility of amputation or other salvage procedures due to inability to heal.

Most abscesses and focal infections will resolve without long-term sequelae. However, stiffness is a common complication following pyogenic flexor tenosynovitis or septic arthritis. This is frequently proportional to the degree of infection and is managed with early range of motion and aggressive therapy following the resolution of infection. However, even with simple "fight bite" infections, lost motion at the injured PIP joint is common with a recent series documenting a mean loss of 24° extension, and a loss of 30° of flexion.[38]

Notably, a septic wrist is a marker of systemic frailty and illness. In a large series of 36 patients with 40 septic wrists both open and arthroscopic treatment were effective. Although repeated irrigation and debridement were frequent, the arthroscopically treated patients had fewer operations and shorter hospital stays. However, the 90 day perioperative mortality rate for this diagnosis was high with 18% in patients treated open and 21% in the patients treated arthroscopically.[39] Similar to the elevated mortality after femoral neck fracture in the older adult, the septic wrist is not the cause of mortality but the systemic illness necessary to produce a septic wrist is substantial.

When considering the ultimate outcome after necrotizing fasciitis, a life saved and a limb salvaged is a success. The incidence of amputation for necrotizing fasciitis is approximately 20–30%. The overall incidence of mortality after necrotizing fasciitis is also 20–30% across series.[33,34,37] The odds of death increase with systemic illness. Anaya *et al.* determined in 166 patients that comorbid cardiac disease, WBC >30 000, and Cr >2 mg/dL were all risk factors for death.[43]

Secondary procedures

Clinical tips

Secondary procedures

- Once the infection is eradicated, secondary procedures can optimize function.
- Scar contractures can be treated with Z-plasty releases to improve joint excursion.
- Flexor tenolysis may improve function after pyogenic flexor tenosynovitis but there must be:
  - Tissue equilibrium
  - Plateaued progression with hand therapy
  - Significantly greater passive than active range of motion of the digit
  - Patient compliance with hand therapy and a home exercise program.
- Arthrodesis is a reasonable solution to the painful stiff joint with arthrosis after infection.
- Amputation is always a consideration as a secondary procedure or immediate salvage depending on the extent of infection.
- When amputating digits for infection, amputate through joints with preservation of the articular surface on the proximal bone to keep that portion of the skeleton sealed.

After eradication or control of infection, secondary procedures may be required to optimize function. Even straightforward soft-tissue infections may leave scars that contract or limit joint excursion. For these superficial scars, we have had good success with standard Z-plasty scar rearrangement to restore tension-free motion. Tenolyses of the flexor or extensor tendons may be needed following either subcutaneous abscesses, deep space infections, or flexor tenosynovitis. When considering tenolysis, it is important that the soft tissues have reached an equilibrium at which point recurrent transient swelling has ceased and the tissues have softened from a hardened or "woody" state common after trauma. Second, patience is warranted in allowing the patient to truly plateau with therapy before adding another surgical insult to the digit. The patient should have significantly more passive than active range of motion to expect improvement from tenolysis. One must also consider each patient's ability to participate in appropriate therapy as the success of tenolyses is strongly dependent on the postoperative course.

Arthrodeses are a more common secondary procedure after intra-articular infections. Arthrodesis is a reasonable solution to the painful stiff joint with arthrosis after infection. The authors recommend performing arthrodeses through prior incisions if possible and taking care to raise full-thickness flaps for exposure. For the interphalangeal joints, these flaps can raise the extensor apparatus with the skin as a single layer. In the hand and wrist, the authors have not routinely considered arthroplasty after infection. Despite being feasible after debridement and a prolonged course of antibiotics, arthroplasty is not expected to increase motion in what are usually stiff affected joints.

Lastly, amputation is always a consideration as a secondary procedure or immediate salvage depending on the infection. Persistent osteomyelitis or recalcitrant soft-tissue infections (e.g., fungal) are certainly well treated with amputation. Likewise, amputation for the post-infected digit that is either persistently hypersensitive or bypassed secondary to pain and stiffness is often the best option for the hand. When amputating digits for infection, the authors prefer to amputate through joints with preservation of the articular surface on the proximal bone to keep that portion of the skeleton sealed. For ray resections after infection, the authors recommend avoiding osteotomy and transposition of an adjacent metacarpal as

that necessitates internal fixation and requires healing at the transposition site.

Future directions

The identification and treatment of hand infections have remained relatively unchanged since first described by Allen Kanavel in 1905. A clear understanding of hand anatomy and pathophysiology is important for early identification and effective medical and surgical management. Over the past few decades, the incidence and prevalence of MRSA infections have risen. As the offending microbial milieu changes, the development of effective antibiotic coverage is imperative for adequate treatment of infections.

Management of Dupuytren's disease

Andrew J. Watt and Jerry I. Huang

SYNOPSIS

- Dupuytren's disease is a benign fibromatosis of the palmar and digital fascia characterized by nodular thickening and subsequent contracture.
- Successful treatment requires a detailed understanding of the normal palmar and digital fascial structures and their corollary diseased states.
- Operative indications are based on the degree of contracture and the resultant functional disability of the hand.
- Palmar fasciectomy remains the mainstay of surgical treatment.
- Increasingly common treatments include percutaneous (needle) aponeurotomy and collagenase injection (enzymatic fasciotomy).
- Despite appropriate management, recurrence and disease progression remain the primary obstacles to treatment.

Introduction

Dupuytren's disease is a progressive disease of the palmar and digital fascial structures characterized by nodular thickening and subsequent contracture. Deformity of the hand occurs primarily at the metacarpophalangeal (MCP) and proximal interphalangeal (PIP) joint level, resulting in functional limitations. This disease process is quite familiar to hand surgeons and presents a challenge in terms of both treatment and prognosis.

Epidemiology

Dupuytren's disease belongs to the overarching category of benign superficial fibromatoses and, as such, is closely related to Peyronie's disease (penile fibromatosis) and Ledderhose's disease (plantar fibromatosis). Historically, Dupuytren's disease has been successively referred to as a Nordic, Caucasian, Anglo-Saxon, and finally a Viking disease.[1–4] Although most prevalent in populations with a strong northern European ancestry, Dupuytren's disease affects populations throughout the world. Critical evaluations of the migrations that have occurred throughout history, particularly those originating in northern Europe, suggest that the disease likely originated among Celtic and Germanic tribes around 1200 BC and dispersed throughout Europe with the great migrations beginning around 200 BC.[5] Few populations are spared at least anecdotal cases of Dupuytren's disease; however, the incidence remains highest among individuals of northern European ancestry, with overall estimates ranging from 2% to 42% depending on the population being studied.[6] Men are six times more likely to develop Dupuytren's disease than are women and typically exhibit an onset in the fifth decade of life, in comparison to onset within the sixth decade for women.[7] Population studies support an autosomal-dominant inheritance pattern with variable penetrance.[6]

Associations with repetitive trauma, alcohol abuse, hepatic disease, diabetes mellitus, smoking, chronic obstructive pulmonary disease, human immunodeficiency virus, malignancy (paraneoplastic manifestation), and epilepsy have been proposed.[8–10] These associations are often weak and most likely represent factors that may increase the penetrance or exacerbate an underlying genetic predisposition.

Palmar and digital fascia

Dupuytren's disease is ultimately manifested as the transformation of the normal palmar and digital fascial structures to thickened diseased cords through the deposition of type I and type III collagen and the contractile forces generated by myofibroblasts. An intimate understanding of both the native and pathologic anatomy is paramount in assessing and appropriately treating patients with Dupuytren's disease.

Palmar fascia

The palmar fascia provides a flexible yet firm framework for the soft tissues of the palm, tethering the skin to the underlying musculoskeletal structures. Classic descriptions of the anatomy of the palmar fascia provided by Legueu, Juvara, and Testut have withstood the test of time.[11,12] The palmar

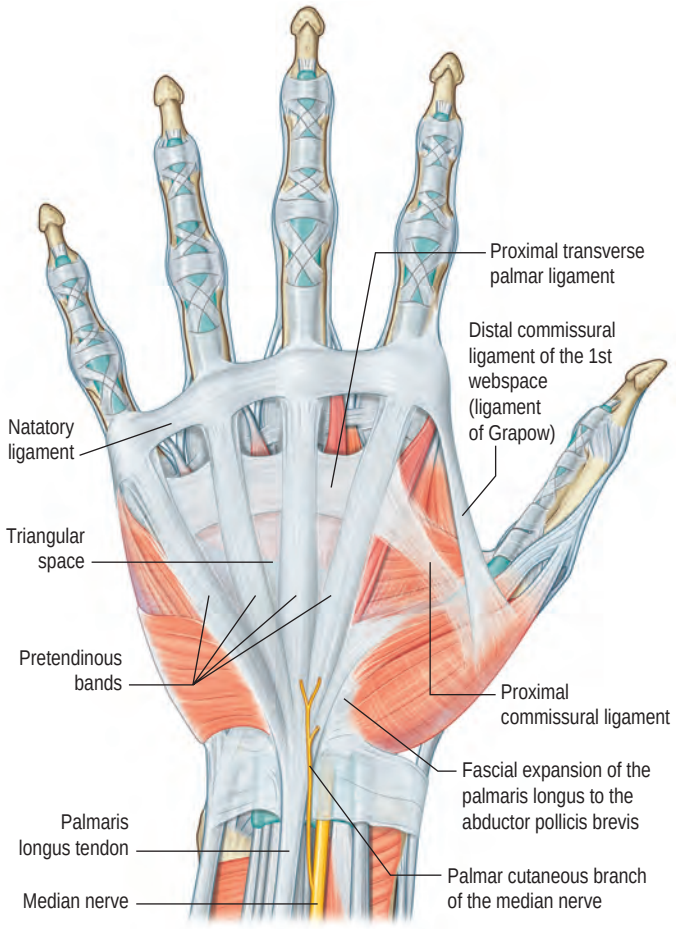

Fig. 17.1 Anatomy of the palmar fascia. *(Redrawn from Tubiana R, Leclercq C, Hurst L, et al. (eds)* Dupuytren's Disease. *London: Martin Dunitz, 2000, p. 22.)*

fascia consists of two distinct layers: the deep fascia and the superficial fascia or palmar aponeurosis. The deep fascia covers the interosseous muscles and is not involved in Dupuytren's disease. The superficial fascia, in contrast, is affected by the pathologic progression of Dupuytren's disease.

The palmar aponeurosis is a triangular-shaped fascial structure consisting of longitudinal, transverse and vertical fibers with its apex in continuity with the palmaris longus tendon (Fig. 17.1). Although these structures are in continuity, the palmar aponeurosis is histologically distinct from the palmaris longus and is invariably present even in patients with an absent palmaris.

The longitudinal fibers course superficial to the flexor retinaculum, and form pretendinous bands. These bands travel distally and insert into the deep surface of the dermis at the distal palmar crease, contribute to the retrovascular fascial structures, and bifurcate around the flexor tendon sheath to insert on the radial and ulnar sides of the MCP joint.[13]

The transverse fibers are characterized by two distinct bands, one proximal and one distal. The proximal transverse fibers, located at the level of the distal palmar crease, course deep to the longitudinal pretendinous bands and are not typically affected by Dupuytren's disease.[14] Radially, these fibers form the proximal commissural ligament of the first webspace. The distal transverse fibers, alternately referred to as the natatory ligament, course superficial to the longitudinal pretendinous bands and are affected by Dupuytren's disease. The natatory ligament extends from the radial border of the index finger to the ulnar border of the small finger. Ulnarly, the natatory ligament divides to envelop the abductor digiti minimi (ADM) and the ulnar neurovascular bundle. Radially, the natatory ligament is continuous with the distal commissural ligament of Grapow within the first webspace.

The vertical fibers of Legueu and Juvara connect the superficial palmar aponeurosis to the deep fascia. These fibers form a series of eight vertical septa on the radial and ulnar sides of the flexor digital apparatus. These septa divide longitudinal compartments containing the flexor tendons from those containing the lumbricals and digital neurovascular bundles.[11,15] Additional vertical fibers connect the superficial palmar fascia to the overlying dermis, providing resistance to shear forces within the palm.[13]

Digital fascia

The palmar and digital fascia is contiguous with a complex digital–palmar junction in which intermediate and deep fibers of the longitudinal bands bifurcate, contributing to the formation of digital retrovascular bands. Anatomic studies have revealed more variability in the anatomy of the digital fascia in comparison with the relatively constant palmar fascial anatomy; however, relative agreement exists over the basic structure. The finger is invested by an elliptical fascial covering consisting of volar and dorsal fascial sheets that lie superficial to the flexor and extensor mechanisms, respectively. These sheets unite along the radial and ulnar aspects of the finger. The volar and dorsal aspects of the finger are separated by a series of lateral structures that envelope the neurovascular structures of the finger.[16] These lateral structures include Cleland's ligaments, Grayson's ligaments, and transverse retinacular ligaments. Cleland's ligaments consist of a series of dorsal fiber bundles that arise proximal and distal to the interphalangeal joint, fanning laterally to insert in the skin. These fiber bundles do not form a contiguous sheet and run within several planes dorsal to the neurovascular bundle. Grayson's ligaments are more distinct, arising from the volar surface of the flexor tendon sheath, fanning laterally to insert into the skin, volar to the neurovascular bundle. The transverse retinacular ligaments originate from the volar capsule of the PIP joint and course dorsally to insert into the lateral margin of the extensor mechanism[17] (Fig. 17.2).

First webspace

The radial longitudinal fibers of the superficial palmar aponeurosis extend distally into the thumb, inserting into the dermis at the level of the MCP joint. Additional fibers insert into the intermuscular septum between the adductor pollicis and the first dorsal interosseous muscles while additional fibers insert into the flexor tendon sheath of the index finger.

The natatory ligament is contiguous radially with the distal commissural ligament within the first webspace. The proximal transverse fibers are contiguous with the proximal commissural ligament (Fig. 17.3).

Historical perspective

Baron Guillaume Dupuytren did not provide the first description of Dupuytren's disease; however, his description was the most thorough. Felix Plater provided the first description of palmar contracture in his 1614 work *Observationum in hominis affectibus*. The original Latin text has been interpreted variably in translation; however, Plater's anatomic dissections support a role for the palmar fascia in progressive contracture of the palm.[18]

Henry Cline clearly described the pathologic anatomy and clinical findings present in Dupuytren's disease in notes that have been discovered in the library of St. Thomas' Hospital in London.[19] Cline's pupil, Astley Cooper, discussed the condition in his *A Treatise on Dislocations and Fractures of the Joints*, advocating fasciotomy.[20]

Guillaume Dupuytren was unaware of these original descriptions when he first described the condition in a lecture delivered on December 5, 1831 at the Hôtel-Dieu, Paris. He described the case of a wine merchant with contracture of the ring and small fingers that he successfully treated with open fasciotomies. His lecture notes were subsequently published in *Leçons orales de Clinique Chirurgicale faites à l'Hôtel-Dieu de Paris in 1832*.[21,22]

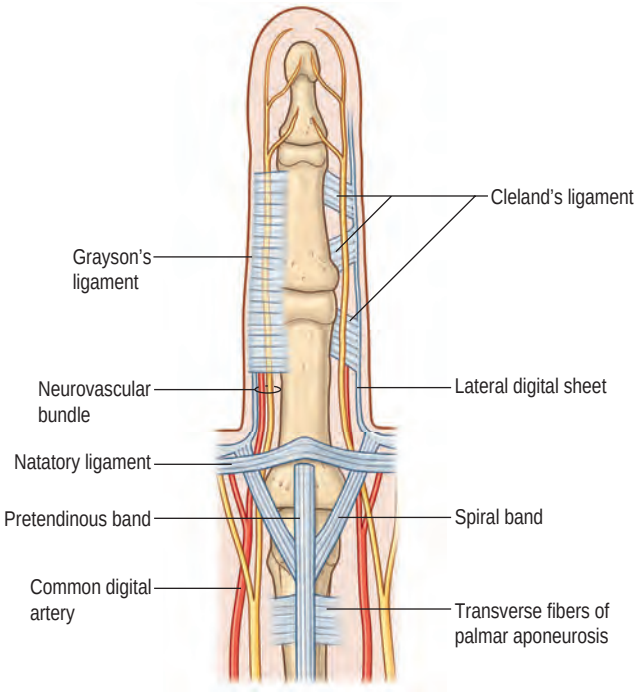

Fig. 17.2 Normal fascial anatomy of the digit.

Basic science and disease process

Basic science

Although Dupuytren's disease has been formally recognized and clinically treated for over two centuries, the etiology and pathogenesis of the disease remained a matter of both speculation and incidental correlation. It has been only over the past 30 years that surgeons and scientists have begun to unravel the cellular mechanisms that contribute to the development of the disease.

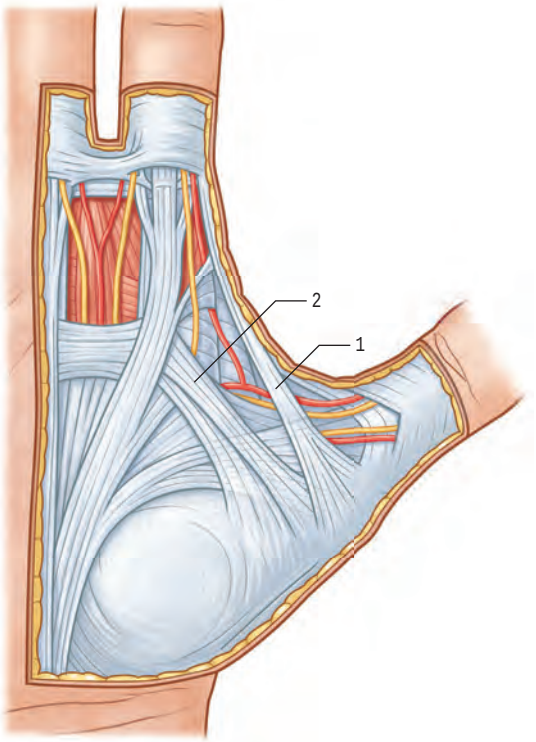

Fig. 17.3 Normal fascial anatomy of the first webspace. 1, Distal commissural ligament (ligament of Grapow). 2, Proximal commissural ligament.

Histopathologic studies have provided the foundation of scientists' nascent understanding of Dupuytren's disease. Initial studies have demonstrated not only involvement of the palmar aponeurosis but also absence of adipose tissue, a paucity of sweat glands, and increased vascularity within the affected palm.[23] Histologically, nodular rests of myofibroblasts surrounded by dense collagen characterize affected tissue. Molecular analysis reveals a preponderance of type III collagen, which is not typically observed in mature palmar fascia, and increased concentrations of prostaglandins as well as several subtypes of transforming growth factor-β (TGF-β).[24,25] DNA microarray analysis comparing diseased and control palmar fascia has revealed a host of gene expression changes, including both up- and downregulation of expression. These include genes previously implicated in the pathogenesis of Dupuytren's disease, including fibronectin, tenascin C, TGF-β, collagen III, IV, and VI, as well as novel genes, including musculoaponeurotic fibrosarcoma oncogene homolog B (MafB).[26] Although the intricate interrelationship between these gene expression patterns remains a field for future inquiry, this knowledge has provided potential clinical targets for pharmacologic intervention in halting or potentially preventing Dupuytren's disease.

In 1959, Luck described the pathogenesis of Dupuytren's contracture in pathologic terms consisting of proliferative, involutional, and residual phases. This description has provided a framework within which molecular advances may be analyzed as well as a foundation for clinicians' understanding of disease progression. The proliferative phase is characterized by nodule formation within the palmar fascia and biochemically by increased fibrinolytic activity. At this stage, fibroblasts differentiate into myofibroblasts and comprise the majority of nodular architecture. Myofibroblasts are fibroblastic in origin; however, they contain an actin microfilamentous structure analogous to smooth-muscle cells. These actin microfilaments are arranged in bundles oriented along the long axis of the cell and communicate with the extracellular matrix fibronectin, thereby allowing transmission of intracellular contractile forces to the extracellular tissues. Marked nodular thickening and signs of early joint contracture characterize the involutional phase. Throughout the involutional phase, type III collagen is synthesized and the myofibroblasts reorient along the lines of tension within the palm. Type III collagen deposition continues and is gradually replaced with type I collagen throughout the residual phase. Myofibroblasts have largely disappeared by the residual phase, resulting in a relatively hypocellular amalgam of type I and type III collagen.[27–29]

The inciting event resulting in myofibroblast proliferation remains unknown. Authors have suggested multiple hypotheses, including trauma, focal ischemia, and a host of growth factor and cytokine aberrations. Murrell *et al.* hypothesize that ischemia within the palmar fascia results in the generation of free radicals that damage the surrounding tissue. This damage incites repair with the deposition of collagen and the proliferation of myofibroblasts, and leads to further ischemia and disease progression.[30] Mechanical stress has been shown to upregulate myofibroblast differentiation and supports the

traumatic theory.[31] Myofibroblast proliferation is also stimulated by a number of growth factors and cytokines, including TGF-β_2 and inhibited by platelet-derived growth factor (PDGF), basic fibroblastic growth factor, interleukin-1α, and interleukin-1β.[32] Actin expression may also play a pivotal role in the progression of Dupuytren's disease and is increased by TGF-β_2 and degreased by PDGF-BB.[33] The expression of androgen receptors within Dupuytren's nodules has also raised the question of hormonal influence on disease development and progression. Myofibroblasts from Dupuytren's patients stimulated with 5α-dihydrotestosterone demonstrated higher rates of proliferation than myofibroblasts from control subjects, suggesting that androgens may play a role in disease progression. This theory gains support from the male predominance of the disease. Ultimately, none of these theories and biomolecular interrelationships is mutually exclusive and Dupuytren's disease may very well represent the culmination of a host of environmental and cellular events in a genetically prone individual.

Disease process

The net effect of these cellular and pathologic mechanisms is the transformation of normal palmar and digital fascial structures into fibrotic diseased cords. Each normal anatomic structure within the palmar and digital fascial system maintains a pathologic correlate. Diseased components may be further subdivided into palmar, palmodigital, digital, first webspace, and hypothenar cords (Table 17.1).

Within the palm, involved pretendinous bands become pretendinous cords. These cords course distally and insert into the deep surface of the dermis at the distal palmar crease, resulting in pitting of the palmar skin. They are also continuous with the retrovascular fascial structures and contribute to formation of the spiral cord.[13] The remaining fibers contribute to the formation of the central cord within the finger itself. The pretendinous cord is the primary contributor to MCP flexion contracture and is located superficially, leaving the deeper neurovascular structures undisturbed. Dissection within the palm, proximal to the distal flexor crease, is therefore relatively safe with respect to neurovascular bundles. The vertical fibers of McGrouther and the septa of Legueu and Juvara also become involved and may result in painful triggering with extension of the finger following full flexion (Fig. 17.4).

Two key cords are located within the palmodigital region. The spiral cord forms from the diseased confluence of the pretendinous band, spiral band, lateral digital sheet, and Grayson's ligament. The spiral cord wraps around the neurovascular bundle, displacing the digital nerve and artery medially, superficially, and proximally, placing them at risk for injury during skin incision and dissection (Fig. 17.5). The spiral cord not only displaces the neurovascular bundle, but also results in significant PIP joint contracture.[34] The natatory ligament, which traverses the palm transversely at the level of the metacarpal heads, is transformed into the natatory cord. The natatory cord results in webspace adduction contracture.

Table 17.1 **Fascial anatomy of Dupuytren's disease**

Diseased structure	Anatomic origin	Clinical significance
Palmar cords		
Pretendinous cord	Pretendinous band	MCP joint flexion contracture
Vertical cord	Vertical fibers of McGrouther or septa of Legueu and Juvara	Causes painful triggering
Palmodigital cords		
Spiral cord	Pretendinous band, spiral band, lateral digital sheet, Grayson's ligament	Displaces the neurovascular bundle medially and superficially (spiral nerve)
Natatory cord	Natatory ligament (distal fibers)	Webspace adduction contracture
Digital cords		
Central cord	Pretendinous cord (digital extension)	PIP joint flexion contracture
Retrovascular cord	Retrovascular band of Thomine	PIP and DIP joint flexion contracture; prevents full correction of PIP joint contracture
Lateral cord	Lateral digital sheet (often closely associated with pretendinous and natatory cord)	PIP and DIP joint flexion contracture; displaces neurovascular bundle medially
Abductor digiti minimi cord	Abductor digiti minimi tendon	PIP joint flexion contracture
Thumb and first webspace cords		
Proximal commissural cord	Proximal commissural ligament	First-web adduction contracture
Distal commissural cord	Distal commissural ligament	First-web adduction contracture
Thumb pretendinous cord	Pretendinous band	MCP joint flexion contracture

DIP, distal interphalangeal; MCP, metacarpophalangeal; PIP, proximal interphalangeal.

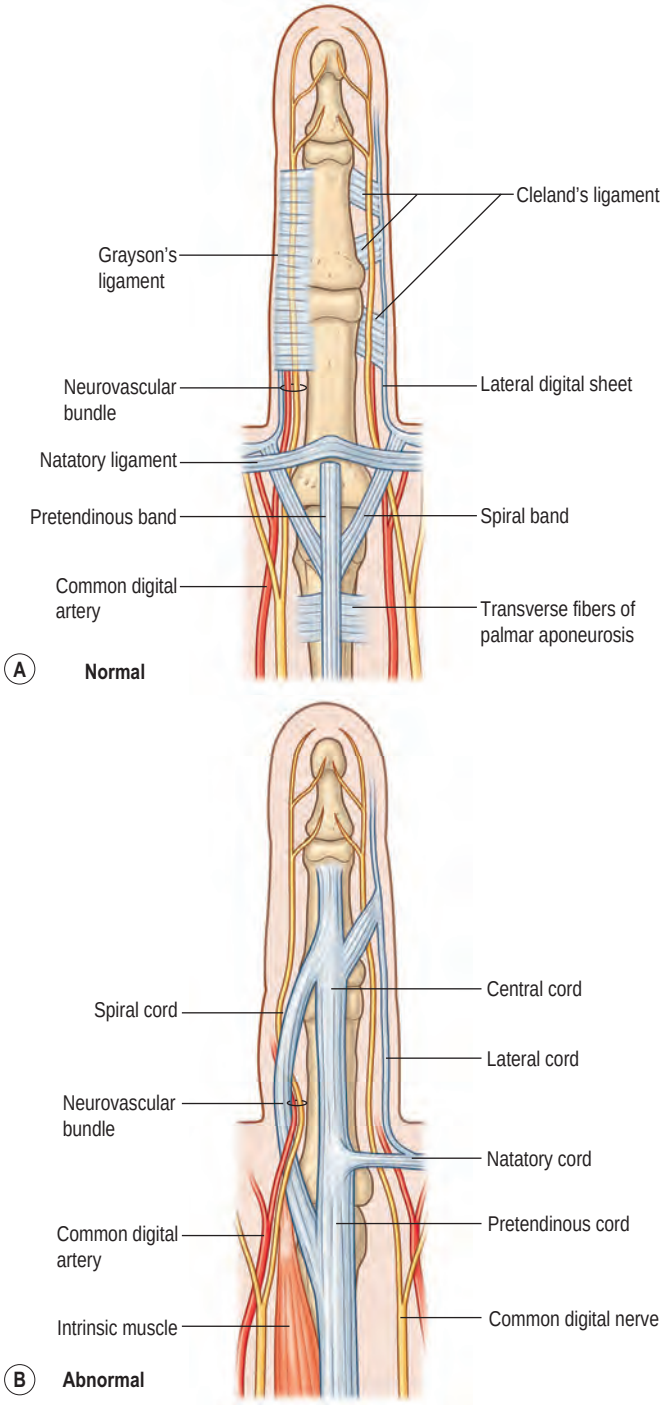

Fig. 17.4 Normal (**A**) and pathologic (**B**) palmodigital anatomy.

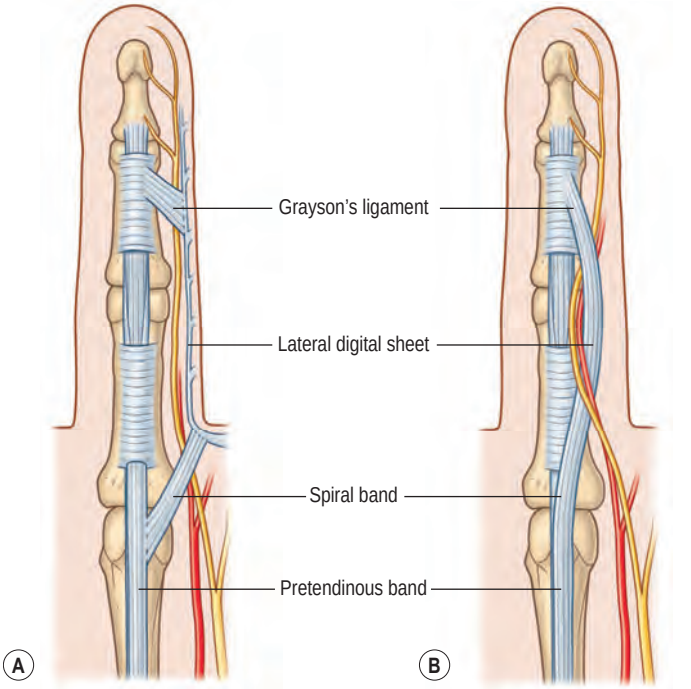
Within the finger, involved pretendinous bands become central cords. These cords are contiguous proximally with the pretendinous cords of the palm and insert laterally on the radial and ulnar side of the PIP joint and on the flexor tendon sheath of the middle phalanx. The central cord acts in concert with the spiral cord, contributing to PIP joint contracture. Additionally, the retrovascular band of Thomine becomes the retrovascular cord, which contributes to PIP and distal interphalangeal (DIP) joint contracture. The lateral digital sheet may also become involved in disease progression as the lateral cord, contributing to the spiral cord and resulting in PIP and DIP joint contracture.[35]

The first webspace may also be involved in Dupuytren's disease. The proximal and distal commissural ligaments, which represent the radial extension of the proximal transverse fibers of the palmar aponeurosis and the natatory ligament, respectively, become the proximal and distal commissural cords. These cords contribute to first-webspace adduction contracture. A thumb pretendinous band, analogous to the longitudinal pretendinous fascial structures of the fingers, evolves into a pretendinous cord and results in MCP joint contracture (Fig. 17.6).

In addition to the palmar and palmodigital cords analogous to those of the index, long, and ring fingers, the small finger



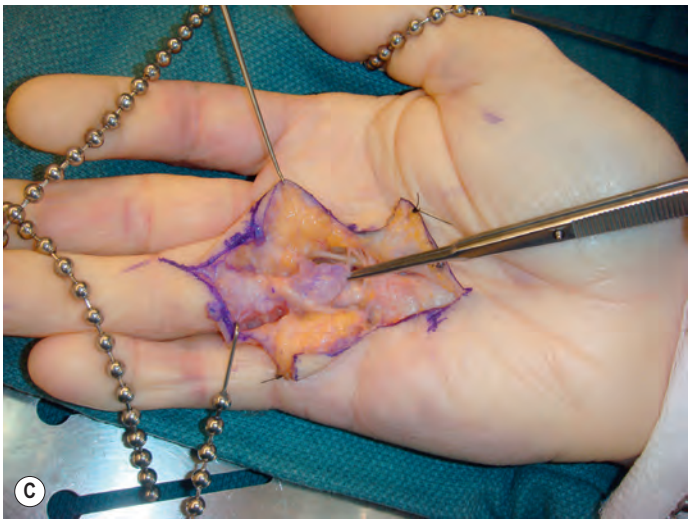


Fig. 17.5 Spiral cord. **(A)** Normal fascial palmodigital fascial structures contributing to the formation of the spiral cord. **(B)** Spiral cord. **(C)** Spiral cord: note displacement of the ulnar neurovascular bundle radially.

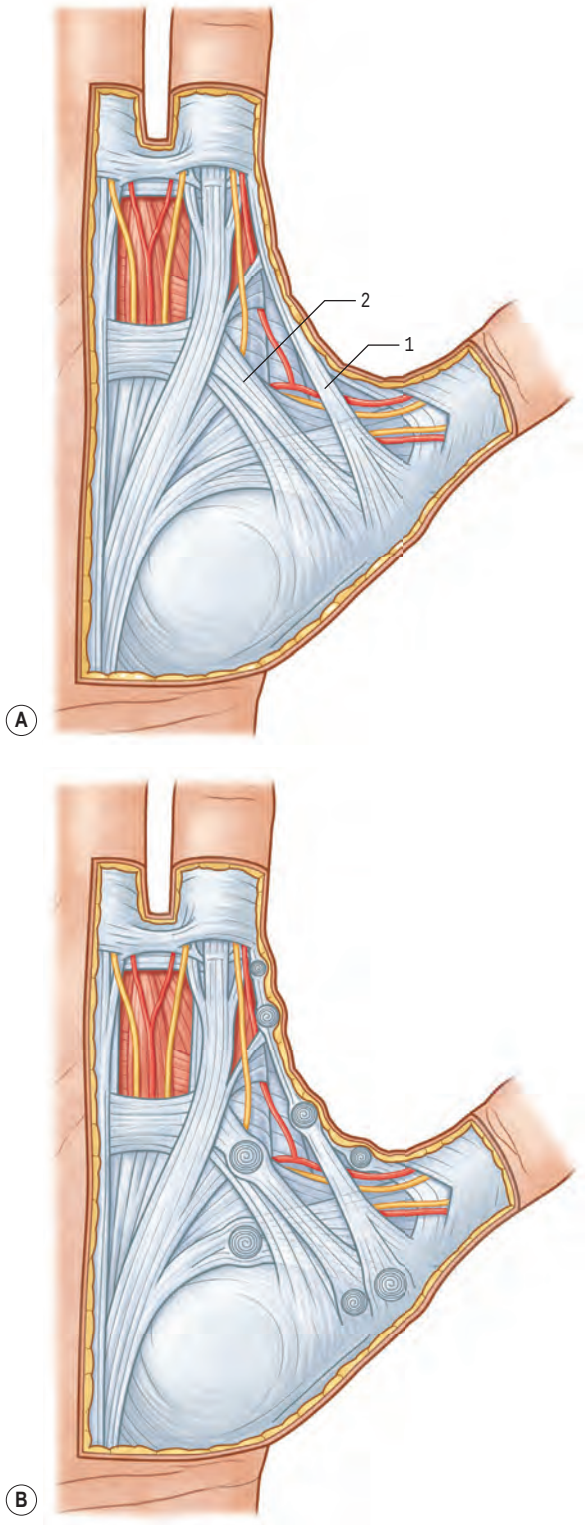

Fig. 17.6 Normal and pathologic anatomy of the first webspace. **(A)** Normal anatomy. **(B)** Pathologic anatomy. 1, Distal commissural ligament (ligament of Grapow). 2, Proximal commissural ligament.

has a unique ADM cord. This cord represents pathologic involvement of the fascia associated with the ADM tendon and results in an abduction contracture of the small finger.

Diagnosis/patient presentation

Clinical presentation

Patients with Dupuytren's disease present throughout the spectrum of disease progression, and diagnosis is made based upon history and clinical examination. The characteristic progression from nodule to fibrotic cord with contracture of the affected palm and digits is pathognomonic for Dupuytren's disease. Onset is typically insidious with progressive contracture and disability developing over the course of years. The earliest signs of disease consist of pitting or dimpling of the palm with distortion of the distal palmar crease resulting from connections between the dermis and longitudinal fibers of the palmar aponeurosis[13] (Fig. 17.7). Distortion of the skin creases can appear as a deepening of the crease or widening of the crease (Hugh Johnson sign).[36] These skin changes are typically the first signs of the disease, preceding the development of nodules. Nodules develop within the palm and are the palpable manifestation of myofibroblast proliferation. These nodules are most commonly located within the ulnar aspect of the palm overlying the ring-finger ray at the level of the distal palmar crease and at the PIP joint level within the finger. Nodules may develop anywhere within the finger, palm, and, rarely, as proximal as the wrist. The nodules are typically painless; however, some patients note discomfort, particularly with grip, and a sensation of tension within the palm.

Disease progression is characterized by the development of longitudinal cords, most commonly in the ulnar aspect of the palm and extending distally into the fingers. The overlying skin is typically undisturbed in the proximal palm and increasingly adherent to the underlying cord distally (Fig. 17.8). The ring finger is most commonly affected, followed in prevalence by the small finger, thumb, middle, and index

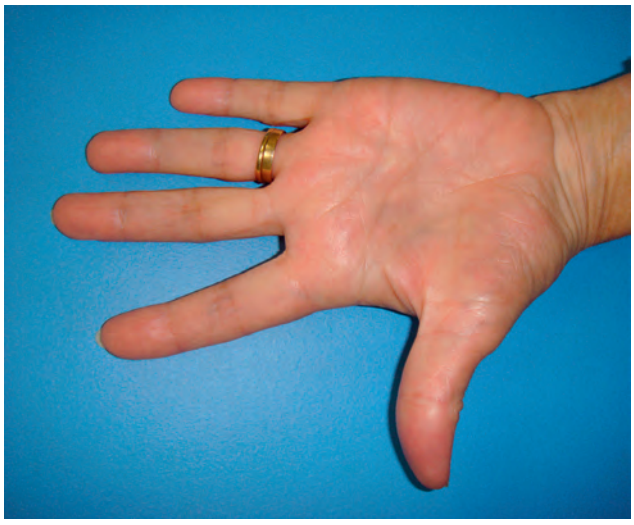

Fig. 17.7 Early Dupuytren's disease: note the nodule formation within the ring ray at the level of the distal palmar crease.

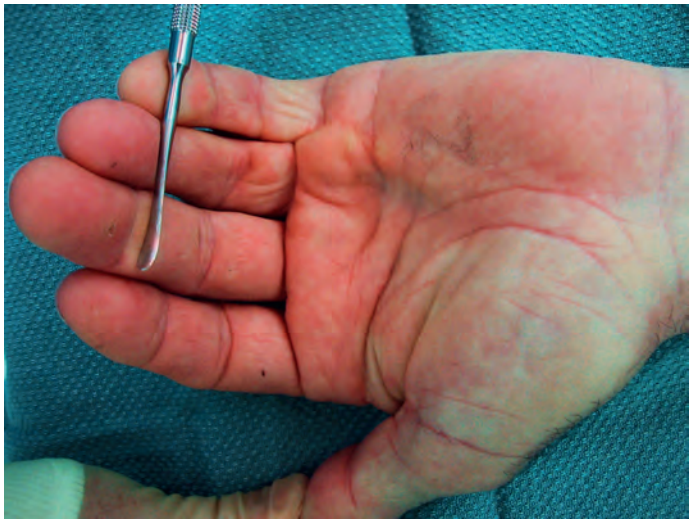

Fig. 17.8 Palmar and palmodigital disease.

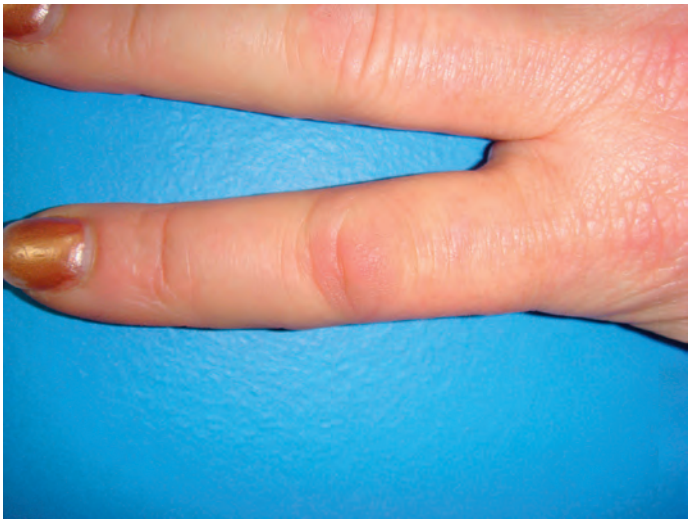

Fig. 17.9 Garrod's nodules.

fingers. A soft palpable fullness immediately adjacent to the cord at the level of the MCP joint may indicate displacement of the neurovascular bundle by a pathologic spiral cord (Short–Watson sign).[34]

The distal course of the cord varies. The cord may terminate in the dermis at the distal palmar crease, laterally on each side of the MCP joint, or continue distally as the central digital cord. The digital cord typically terminates just distal to the PIP joint, either centrally or laterally. A large volar nodule located at the level of the proximal phalanx often becomes intimately associated with the dermis of the overlying skin. These relationships are discernible with palpation of the cords or clinical examination. Cords are unusual distal to the middle phalanx. When present, they often lie along the radial and ulnar aspects of the finger, crossing the DIP joint. Nodules and cords strictly isolated to the finger in the absence of palmar involvement are rare but may occur.

The net effect of myofibroblast activity within palmar nodules and the deposition of collagen as pathologic cords is progressive joint contracture. The MCP joint is typically involved first, followed, in more severe cases, by PIP joint contracture. Initially, joint contracture presents as limitation in hyperextension at the MCP joint and progresses to a permanent lack of extension. MCP and PIP joint contracture result in progressive disability of the hand. Common complaints include impairment in hand shaking, fitting of gloves, difficulty placing the affected hand in a pocket, and impairment in grasping large objects. The DIP joint is typically unaffected by Dupuytren's disease; however, deformities of both flexion and extension may occur. Flexion deformity results from involvement of the lateral and retrovascular cord. DIP hyperextension, in contrast, is compensatory in the setting of PIP flexion contracture, and results from imbalance of the flexor and extensor mechanisms.

Patients may also present with Garrod's nodules, or knuckle pads located dorsally over the PIP joints (Fig. 17.9). Garrod's nodules suggest a higher likelihood of bilateral hand involvement; however, their presence does not suggest stage or severity of disease, nor do they result in any functional limitation themselves.[37] Knuckle pads have been reported in 15% of patients with Dupuytren's disease and may occur in isolation.[38,39] Knuckle pads suggest a higher likelihood of concomitant fibromatoses, including Peyronie's (penile fibromatosis) and Ledderhose's disease (plantar fibromatosis). Peyronie's disease affects the tunica albuginea of the corpora cavernosa of the penis and is present in 1–3% of patients with Dupuytren's disease.[40,41] Fibrosis develops as a well-circumscribed plaque, usually on the dorsum of the penis. The disease is generally painless; however, discomfort may occur with erection.[42] Plantar fibromatosis is present in 5–20% of patients with Dupuytren's disease, presenting as a nodular thickening within the nonweight-bearing (arch) portion of the sole of the foot[43] (Fig. 17.10). These lesions are typically asymptomatic; however, they may produce discomfort or even severe pain with ambulation in a select number of cases.[44,45] Contracture of the toes does not develop. Additional presentations of Dupuytren's disease include triggering secondary to involvement of the vertical palmar septa, and an isolated tender palmar nodule whose discomfort will typically dissipate with time.

Several other lesions have been reported in association with Dupuytren's disease; however, no clear relationship has been established. Matev reported involvement of the auricular concha.[46] Allen reported the presence of nodules within the

Fig. 17.10 Plantar fibromatosis.

tensor fascia lata in patients with Dupuytren's disease, and Hueston has described involvement of the Achilles tendon.[44,47]

Differential diagnosis

Differential diagnosis of Dupuytren's disease includes camptodactyly, traumatic scar contracture, burn scar contracture, Volkmann's ischemic contracture, intrinsic joint ankylosis, locked trigger finger, and spastic digital contracture. Callous formation, foreign body, desmoid fibroma, nodular fasciitis, and fibrosarcoma should also be considered in the differential for a primarily nodular palm. The classic history of nodule appearance with insidious progression to cord formation and joint contracture is pathognomonic for Dupuytren's disease. Diagnosis is further bolstered in the setting of a family history or in the presence of knuckle pads, Peyronie's disease, or Ledderhose's disease. No radiographic imaging or tissue diagnosis is required to confirm a diagnosis of Dupuytren's disease.

Patient selection

The primary objective of treatment in patients with Dupuytren's disease is correction of deformity, thereby reducing disability and restoring hand function. It therefore follows that the degree of joint contracture, and, more importantly, the extent of functional disability, are the primary indications for intervention. Commonly accepted surgical indications include greater than 30° of MCP joint contracture and any degree of PIP joint contracture, as these degrees of joint contracture are functionally limiting. The urgency of operative intervention is also related to the degree of joint involvement and, more critically, to the joint involved. Surgical intervention for MCP joint contracture is not urgent as the collateral ligaments are taut in MCP joint flexion. This position is protective with respect to joint motion. Surgical intervention may therefore be delayed without compromising functional outcome. In contrast, PIP joint contracture necessitates expeditious operative attention. Longstanding PIP joint contracture results in shortening of the collateral ligaments and precipitates articular changes with loss of subchondral bone resulting in a recalcitrant flexion contracture of the joint. In an effort to preserve functional PIP joint motion, surgery is indicated with any degree of contracture.

Additional operative indications include a functionally limiting first-webspace adduction contracture, small-finger abduction contracture, unremitting tenosynovitis secondary to a palmar nodule overlying the A-1 pulley, and palmar contracture resulting in maceration of the distal palmar crease.

Few contraindications to surgery exist beyond those considerations that would preclude regional or general anesthesia. Poor operative candidates include those patients with longstanding PIP joint contracture and documented underlying articular changes. These patients may require PIP arthroplasty, musculotendinous lengthening, joint fusion, or even amputation in more severe cases. Special consideration must be given to patients with a history of complex regional pain syndrome (CRPS). These patients should receive preoperative neuropathic medication therapy and operation should be performed under regional anesthesia. Relative contraindications also include conditions in which the micro- or macrovascular circulation may be impaired, including tobacco abuse, peripheral vascular occlusive disease, and diabetes mellitus. Anticoagulants should be held in the preoperative period in order to minimize the risk of palmar hematoma. Antiplatelet agents, including aspirin and clopidogrel, should be discontinued 7–9 days prior to operative intervention, while warfarin should be held 3–5 days prior to surgery so as to allow for normalization of the patient's international normalized ratio.

Treatment

Treatment of Dupuytren's disease may be subdivided into modality therapy, injection, and surgical intervention. Although promising interventional treatments, including enzymatic lysis of diseased tissue with collagenase and percutaneous needle aponeurotomy, are emerging, treatment remains primarily surgical, and results for all interventions are tempered by high rates of disease recurrence and progression.

Modality therapy

A host of nonoperative treatments have been explored for the treatment of Dupuytren's disease. This array of therapies underscores both a physician and patient desire to develop nonoperative alternatives to palmar fasciectomy as well as the general ineffectiveness of these modalities. Extension splinting may prevent contracture; however, the splint must be worn continuously and is incompatible with functional use of the hand. Intermittent splinting has not demonstrated effectiveness in preventing the progression of Dupuytren's disease. Ultrasound therapy has been reported to soften palmar nodules but has not been effective in the treatment of cords or contracture.[48] External-beam radiation therapy has been advocated for the treatment of Dupuytren's disease; however, this therapy presents significant risk for the treatment of a benign condition and has not proven effective.[49–51] Additional therapies, including the use of dimethyl sulfoxide, vitamin E, methylhydrazine, allopurinol, colchicine, and interferon-γ, have been investigated without beneficial results.[52–56]

Injection treatment

Injection therapy has demonstrated greater promise than topical and modality therapies. Authors have investigated both the use of corticosteroid injection as well as enzymatic fasciotomy with a host of degradative enzymes, including trypsin and, most recently, clostridial collagenase.

Steroids have demonstrated a restrictive effect on the formation of fibrous tissue and scar. The use of corticosteroids as a postoperative adjunct was first reported in 1952.[57] The efficacy of steroid therapy remains a subject of debate with reports ranging from no efficacy to complete resolution of palmar nodules.[52,58,59] Corticosteroid injections maintain complications, including dermal atrophy, skin depigmentation, and flexor tendon rupture. In general, corticosteroid injection may have a role in the treatment of a symptomatic palmar nodule; however, no efficacy in the treatment of Dupuytren's cords or joint contracture has been established, except as a potential adjunct to needle aponeurotomy.

The concept of targeting abnormal collagen deposition via enzymatic degradation followed by manual rupture is not novel. Reports of attempted enzymatic fasciotomy appear as

early as 1907, and over the past century greater refinement in the activity and specificity of the enzyme injected has occurred.[60] In 1965, Bassot reported his technique of "exerèse pharmodynamique", utilizing a mixture of trypsin, alphachymotrypsin, hyaluronidase, thiomucase, and lidocaine. Bassot reported correction of severe contracture in 34 patients.[61] In 1971, Hueston reported his experience with a simplified formula consisting of trypsin, hyaluronidase, and Xylocaine, achieving favorable initial results.[62] McCarthy reported his experience with enzymatic fasciotomy in 14 patients, noting recurrence of initial contracture in 75% of patients at an average of 2–3-year follow-up. He concluded that there was a similar rate of recurrence with both enzymatic fasciotomy and surgery.[63] This technique subsequently fell into disfavor given concerns for neurovascular injury and tendon rupture with the use of nonspecific degradative enzymes. Collagenase emerged as a candidate for enzymatic fasciotomy in 1996 and was approved by the FDA for clinical use in 2010.

Injection in enzymatic fasciotomy is performed with 0.58 mg clostridial collagenase diluted in 0.25 mL (MCP joint) or 0.20 mL (PIP joint) of sterile diluent. The cord is located by manual palpation and injection is performed at three points along the length of the cord via a single puncture with a 25-gauge needle. Care is taken to inject within the midsubstance of the cord as lateral injection may result in neurovascular injury, while deep injection results in intratendinous injection (Fig. 17.11). Patients generally return to clinic on postinjection day 1 for manual manipulation (Fig. 17.12). While manipulation on postinjection day 1 remains the manufacturer recommendation, Mickelson *et al*. demonstrated equivalent efficacy and safety of manipulation performed at day 1 versus day 7 in a randomized, prospective trial, suggesting that manipulation may be performed at the convenience of both the surgeon and the patient within a week of injection.[64] Night extension splinting is performed for 4 months following injection. A 1-month interval is allowed before repeat injection is attempted. Long-term disease recurrence rates as well as the clinical role of collagenase injection are evolving (Box 17.1).

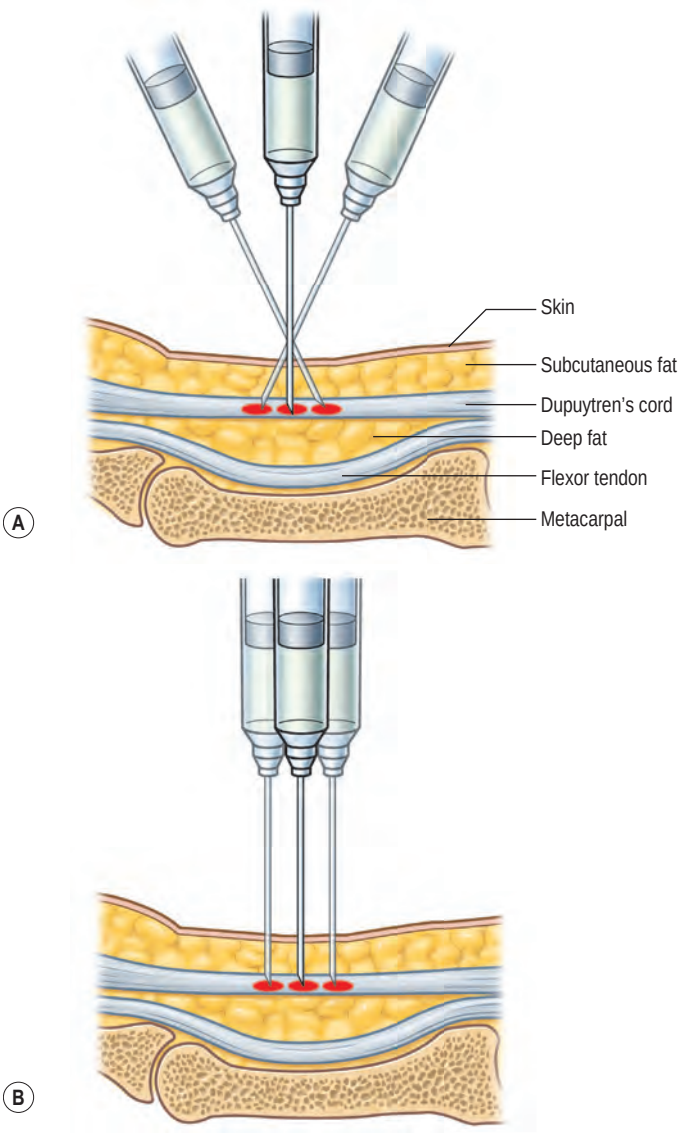

Fig. 17.11 Collagenase injection technique.

BOX 17.1 **Clinical tips: enzymatic fasciotomy**

Enzymatic fasciotomy offers an alternative to open surgical treatment of Dupuytren's contracture. Successful treatment involves appropriate patient selection and adherence to proper injection technique.

1. Appropriate patients include those with a palpable Dupuyten's cord resulting in symptomatic MCP or PIP contracture.
2. Reconstitution should be meticulous and varies depending on the level of contracture.
3. The injector's nondominant hand provides traction on the finger, displacing the cord away from the underlying flexor tendon.
4. The dose is divided into thirds injecting in multiple locations along the cord.
5. Tactile feedback is critical. The cord is firm and resists easy injection.
6. Manipulation is performed in a controlled fashion. Placing the wrist in flexion for MCP manipulation and the MCP in flexion during PIP manipulation relieves stress of the underlying flexor tendons, isolating the cord.

Surgical treatment

Surgical treatment of Dupuytren's disease consists of both fasciotomy and fasciectomy. Fasciotomy involves division of the diseased cords without excision and may be performed via an open technique or percutaneously. Fasciectomy involves excision of the diseased cords. Fasciectomy varies in the treatment of the skin as well as the extent of surgical dissection (Table 17.2).

Percutaneous fasciotomy (needle aponeurotomy)

Percutaneous fasciotomy represents the least invasive operative modality for the treatment of Dupuytren's disease and was first described by de Seze and Debeyre in 1957.[65] The original technique described direct injection of corticosteroid into the affected cord followed by division of the cord via scoring with a 15-gauge needle and manual manipulation.[66] This technique has been modified and further refined by Foucher and its clinical utility is expanding as practitioners become more accustomed to the technique and comfortable

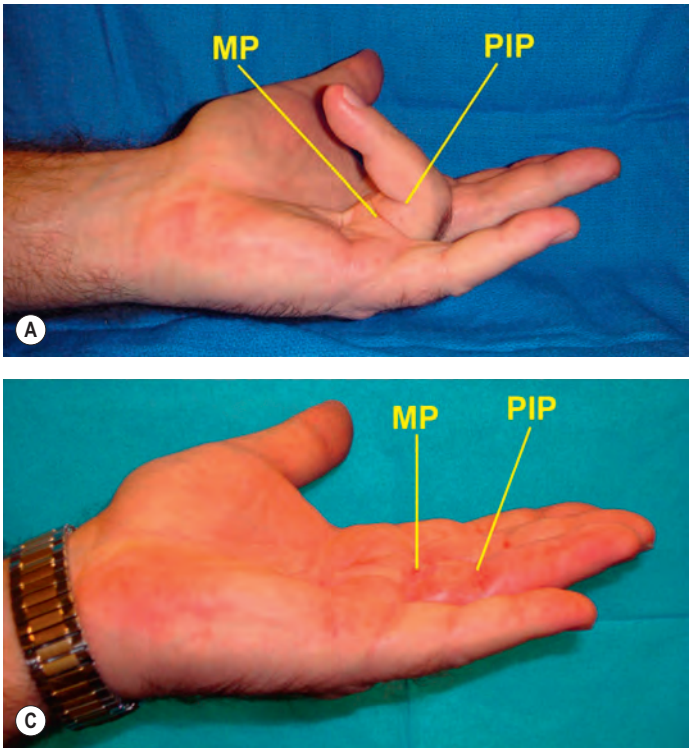

Fig. 17.12 Collagenase treatment of Dupuytren's disease. **(A)** Metacarpophalangeal and proximal interphalangeal joint contractures prior to collagenase injection. **(B)** Manipulation following collagenase injection: note ecchymosis-associated edema. **(C)** Correction of metacarpophalangeal and proximal interphalangeal joint contractures 1 month following treatment with collagenase.

with the pathologic anatomy. Using local anesthetic and a forearm tourniquet, a 19-gauge needle is used to score and divide the involved cords (Fig. 17.13). No corticosteroid is utilized to weaken the cord structure and division is carried out in a distal to proximal manner to avoid disappearance of the digital cord following proximal division.[67]

Percutaneous fasciotomy is best suited for isolated palmar cords with moderate flexion at the MCP joint level. Distal fasciotomies, including treatment of PIP contractures and spiral cords, are being performed by practitioners familiar with the percutaneous technique and anatomy with increasing clinical efficacy and success. Diffuse infiltrating cords, nodules, postsurgical recurrence, longstanding PIP flexion contracture, and deep lateral cords are poor indications for percutaneous treatment and carry a higher risk of complications (Box 17.2).

Table 17.2 **Surgical options for the treatment of Dupuytren's disease**

Surgical technique	Description
Fasciotomy	Division of diseased cords without excision.
Local fasciectomy	Removal of segment of diseased cord.
Regional fasciectomy	Removal of all diseased fascia as well as local region of grossly normal tissue.
Radical fasciectomy	Removal of the entire palmar and digital fascia.
Open-palm technique (McCash)	Division of the palmar aponeurosis without closure of the skin deficit created.
Dermatofasciectomy	Removal of the diseased fascia as well as the overlying skin. Closure typically obtained with the use of a full-thickness skin graft.

Open fasciotomy

First described by Dupuytren, open fasciotomy consists of division of the diseased cord under direct vision.[68] A limited longitudinal incision is made over the affected cord. The cord is visualized, isolated, and divided transversely. The resultant defect may be closed directly, rearranged with a Z-plasty incorporating the cord and skin, or closed with a skin graft.[69–72] Open fasciotomy techniques reliably provide for correction, particularly in the setting of isolated MCP contractures; however, recurrence sufficient to warrant reoperation is reported in 43% of patients.[73]

BOX 17.2 **Clinical tips: percutaneous (needle) aponeurotomy**

Percutaneous aponeurotomy involves division of Dupuytren's cords with a beveled needle under local anesthetic. Successful release requires detailed knowledge of the pathologic anatomy, meticulous technique, and a reliance on sensory feedback.

1. Extension of the involved finger by an assistant places traction on the cords within the finger and palm.
2. Only distinctly palpable cords should be addressed percutaneously.
3. The bevel of the needle is used to scrape and progressively weaken the involved cord in a longitudinal fashion.
4. Work on several areas of the same cord prior to rupturing or dividing the cord in order to maintain tension.
5. Avoid transverse movements as these present the greatest risk of neurovascular injury.

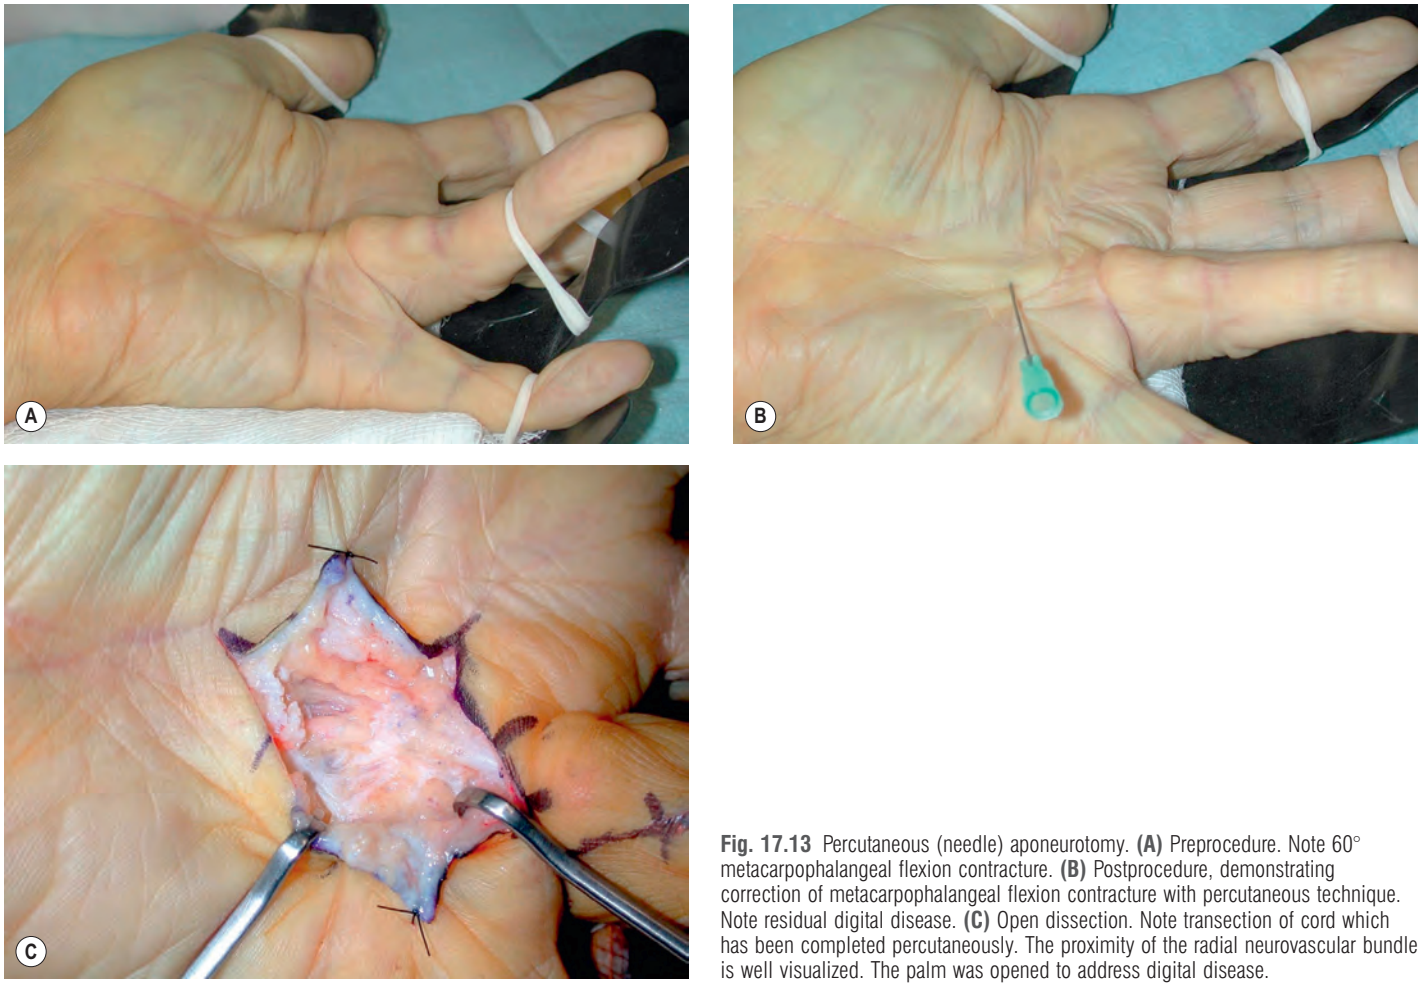

Fig. 17.13 Percutaneous (needle) aponeurotomy. **(A)** Preprocedure. Note 60° metacarpophalangeal flexion contracture. **(B)** Postprocedure, demonstrating correction of metacarpophalangeal flexion contracture with percutaneous technique. Note residual digital disease. **(C)** Open dissection. Note transection of cord which has been completed percutaneously. The proximity of the radial neurovascular bundle is well visualized. The palm was opened to address digital disease.

Fasciotomy is a simple and safe technique when performed within the palm. Its primary utility remains in elderly patients with an isolated palmar cord in whom substantive health problems preclude a more extensive procedure. Use of fasciotomy within the finger presents some risk of neurovascular injury and the technique has been largely supplanted by increasing familiarity with needle aponeurotomy.

Local fasciectomy

Local or limited fasciectomy is a technique designed to remove a portion of the diseased aponeurosis, disrupting continuity of the diseased tissue. This procedure is a compromise between removal all of the diseased aponeurosis via extensive palmar and digital dissection and fasciotomy. Theoretically, local fasciectomy limits the risk of complications associated with dissection, including palmar hematoma and neurovascular injury, while addressing the possibility of local recurrence by creating discontinuity of the diseased tissue.

A longitudinal or Z-plasty incision is performed over the involved cord analogous to that performed in an open fasciotomy. The cord is isolated and divided with resection of 1–2 cm of the cord itself. Residual diseased aponeurosis is left behind. The role of local fasciectomy is limited and overlaps with that of fasciotomy.

Regional (partial) fasciectomy

Until recent developments with needle aponeurotomy and enzymatic treatment, regional fasciectomy has provided the mainstay of operative treatment in Dupuytren's disease. Regional fasciectomy consists of excision of all macroscopically abnormal fibrous tissues within the palm and finger. Successful operative intervention requires an intimate understanding of the normal palmar and digital fascial anatomy as well as the pathologic correlates. This technique limits palmar dissection while disrupting the continuity of the aponeurotic tissue and limiting focal recurrence. By leaving residual aponeurosis, the possibility of disease progression remains. This technique is performed under regional or general anesthesia with a brachial tourniquet placed sufficiently high as to allow access to the medial arm should a skin graft be required. The arm is abducted, supinated on a hand table. A lead or Tupper hand is a valuable adjunct to allow the surgeon to work with minimal assistance. Loupe magnification is invaluable in allowing fine dissection of the common and proper neurovascular bundles.

Digital and palmar disease may be approached through a variety of incisions either separately or conjunction (Fig. 17.14). The skin incision should provide adequate exposure for dissection of the disease tissues and the neurovascular

Fig. 17.14 Surgical incisions for regional fasciectomy. Thumb illustrates T- with Z-plasties at the flexion creases, long finger illustrates Y to V advancement, ring finger illustrates traditional Brunner incision, and small finger illustrates axial incision with Z-plasties at the flexion creases.

bundles in the palm and fingers, preserve vascularized skin flaps to avoid skin necrosis, allow skin lengthening along the longitudinal axis of the finger, and avoid scar contractures. Although some surgeons advocate transverse palmar incisions, longitudinal incisions are more useful for digital exposure and may be extended into the palm for exposure of the aponeurosis. Longitudinal incisions with Z-plasties at the flexion creases or a zigzag Brunner-type incision both provide excellent exposure. Closure with Y to V tissue rearrangement provides for additional length and is particularly useful in patients with significant contracture in which a relative deficiency of skin exists upon correction of the contracture. Contracture of the first webspace is best approached through a T-incision combined with Z-plasties to prevent scar contracture. Transverse incisions within the palm allow for excellent palmar exposure and present no risk of flexion contracture; however, this approach typically requires relatively extensive undermining and does not lend itself to facile proximal or distal extension. When the skin is markedly adherent to the underlying diseased aponeurosis, the incision should pass through the center of this region to avoid extensive devascularization.

Following skin incision, dermal flaps are developed sharply with preservation of the subcutaneous tissue. A scalpel is used to sweep the skin/subcutaneous flaps sharply off the cord in the palm region. Proximal to the distal palmar crease, the digital neurovascular structures are safely deep to the cord itself, and are therefore protected. With the cord skeletonized, the digital nerves and arteries may be identified proximally and traced distally. All abnormal tissue is excised, including the involved vertical fibers of Legueu and Juvara. The proximal transverse metacarpal ligament is preserved as it is not affected by Dupuytren's disease. The aponeurosis may be in intimate association with the underlying flexor tendon sheath and pulley system; however, a natural plane of dissection exists and the sheath is preserved. Once the palmar aponeurosis and pretendinous cords have been disrupted, the MCP joints will extend without constraint, allowing for more facile dissection within the finger.

Distal to the proximal transverse metacarpal ligament, the diseased tissue becomes increasingly adherent to the overlying dermis, necessitating sharp dissection. From this point distal, the dissection is focused on the neurovascular structures, and excision of diseased tissue is performed only after the nerve and artery have been identified and protected. Of particular note, the common digital arteries lie superficial to the common digital nerves within the palm, while the proper digital arteries lie deep to the digital nerves within the finger. The digital nerves bifurcate more proximally than the arteries, crossing over the digital arteries at the level of the metacarpal heads.

The termination of the pretendinous cords is variable, and each termination should be dissected separately and divided. Once the pretendinous cord has been divided, MCP extension is typically full. The natatory ligament, which crosses the tendons and neurovascular bundles superficially, is excised, thereby allowing release of any adduction contracture.

At the digital–palmar junctions, multiple anatomic components converge. The pretendinous cord, spiral cord, lateral digital sheet, and Grayson's ligament may coalesce to form a spiral band, displacing the neurovascular bundle medially, superficially, and proximally. Meticulous care is exercised in order to avoid damage to a displaced neurovascular bundle resulting from the presence of a spiral cord. Removal of diseased tissue within the finger is the most delicate portion of the operation. The path of the neurovascular bundles, altered by an assortment of fibrous cords, is unpredictable. The digital artery may, on occasion, be separated from its companion nerve by a sheet of fibrous tissue. To navigate this anatomy successfully and to avoid injury to the digital neurovascular structures, the digital artery and nerve should be identified distally within uninvolved tissue and traced proximally (Box 17.3).

Retrovascular cords are notoriously occult, and failure to recognize this structure often results in residual PIP contracture. DIP joint hyperextension is infrequent and is often associated with severe PIP contracture. Release of the PIP contracture typically corrects the distal deformity. Residual DIP hyperextension may require oblique tenotomy of the lateral bands of the extensor apparatus. Release of the lateral

BOX 17.3 **Clinical tips: dissection of a spiral cord**

Safe dissection of the neurovascular bundle which has been displaced proximally, medially, and superficially by a spiral cord is the most technically demanding component of an open fasciotomy. Several key techniques will ensure clinical success:

1. Identify the involved neurovascular bundle proximally within the normal tissue of the palm (outside the zone of disease).
2. Identify the involved neurovascular bundle distally within the normal tissue of the finger (outside the zone of disease).
3. Dissect from proximal to distal between these two "known" regions.
4. Division of the cord proximally may assist in distal dissection.
5. Avoid undue traction on the neurovascular bundle.

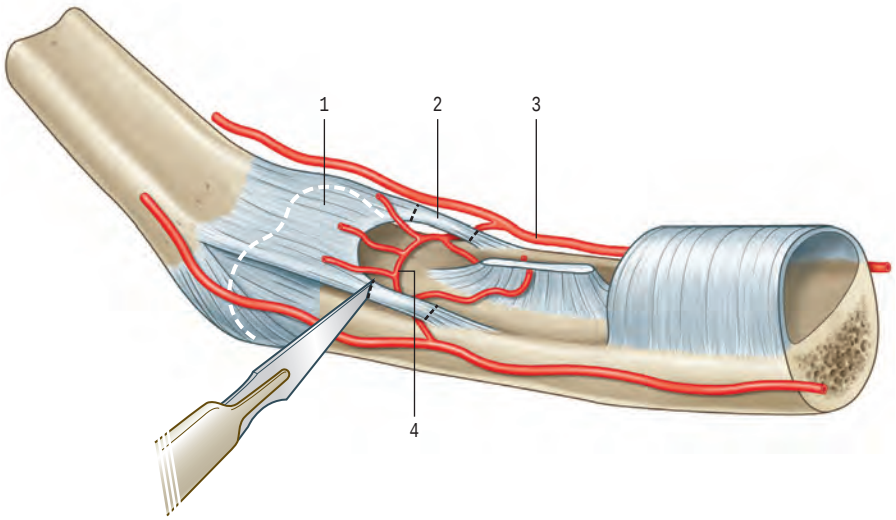

Fig. 17.15 Technique of check rein release. 1, Volar plate. 2, Check rein ligament. 3, Collateral artery. 4, Transverse arterial branch. *(Redrawn after Tubiana R.* The Hand. *Philadelphia: WB Saunders, 1999, p. 463.)*

bands is performed over the middle phalanx through a dorsal incision. The bands are allowed to slide distally, restoring DIP flexion.

Fasciectomy within the small finger and first webspace require special attention due to the unique pathologic anatomy in these regions of the palm. The small finger is often severely involved in the disease process and dissection is particularly difficult given the diminutive size of the ulnar digital artery and nerve. Fascia surrounding the ADM and its retrovascular correlate are routinely affected. This structure originates from the muscular fascia of the ADM immediately superficial to the ADM tendon and is frequently mistaken for the ADM tendon itself. The cord is usually deep and ulnar to the neurovascular bundle; however, the bundle may spiral dorsal to or through the cord. The dorsal ulnar sensory nerve may also be displaced volarly and should be identified prior to division of the ADM cord.

Although radial-sided palmar involvement in Dupuytren's disease is rare, a marked first-webspace adduction contracture and thumb MCP contractures may be quite functionally limiting. Contracture of the first webspace is best approached through a T-incision combined with Z-plasties to prevent scar contracture or a four-flap Z-plasty.[74] The neurovascular bundles should be carefully identified and preserved. The ulnar bundle is reliably found at the base of the thumb. The radial bundle, in contrast, may be quite difficult to localize as it is covered with decussating fibers at the level of the MCP joint, and should be identified more proximally within the thenar eminence. The proximal and distal commissural cords should be excised. In longstanding contractures of the first webspace, the dorsal structures may become contracted secondary to positional deformity rather than involvement of the Dupuytren's disease process, and may require release.

Several additional techniques may be required when complete range of motion cannot be restored with fasciectomy alone. These procedures should be employed judiciously with consideration given to the fact that a finger with mild residual PIP deformity is more functional than a stiff finger with full extension. Residual deformity may be attributed to shortening of the flexor tendon sheath, capsular contracture of the PIP joint, or articular changes within the PIP joint. The latter is not amenable to further correction with manipulation of the soft tissue alone and requires arthrodesis or arthroplasty to address residual deformity. Shortening of the tendon sheath is addressed by making one or two transverse incisions within the sheath at the level of the PIP joint to allow for lengthening. The pulley system should be preserved. PIP joint contracture presents a more formidable challenge. Complete capsulectomy should be avoided in favor of a limited arthrolysis, which involves selective division of the volar plate check rein ligaments.[75,76] Check rein division should be performed just proximal to the arterial branch for the vinculum longum, which is preserved[77] (Fig. 17.15). Once full passive extension is achieved, the integrity of the central slip should be assessed. If the central slip is deficient, the PIP joint should be immobilized postoperatively in static extension for 3 weeks. Alternatively, gentle passive manipulation under anesthesia may be performed.[78] This method does not allow for dramatic correction, but minimizes trauma and potential complications of recurrent PIP joint capsular contracture.

Radical fasciectomy

Radical fasciectomy involves extensive dissection of the palm and digital fascial structures in an effort to remove both normal and diseased palmar and digital fascia. This procedure has been proposed and advocated by several surgeons with the theoretic advantage of eliminating the risk of disease progression and recurrence.[79] This theoretic advantage has not been borne out in practice.[80,81] The procedure has been plagued by significant postoperative complications, including hematoma and skin necrosis, and has largely been abandoned in favor of regional excision.

Dermatofasciectomy

Dermatofasciectomy involves excision not only of the involved facial structures of the palm and fingers, but the overlying skin as well. This practice has its foundation in the histopathological studies of Meyerding *et al.* that demonstrated pathologic changes in the palmar fascia, thinning of the subcutaneous tissue, and a reduction in the number of dermal sweat glands.[23] The dermis is often thought to

represent a repository for active disease and the nidus for disease recurrence. Although this relationship has never been definitively established, dermatofasciectomy retains a role primarily in the treatment of recurrent disease or in cases with extensive cutaneous involvement. Excised skin is allowed to heal secondarily (open-palm technique of McCash) or replaced with a full-thickness skin graft obtained from the groin or medial arm.[82] The open-palm technique alleviates the risk of hematoma; however, it is complicated by prolonged healing times and scar contracture. This technique is advocated only for small lesions within the palm. Skin grafts provide a viable alternative to the open-palm technique; however, no skin graft can adequately replace the glabrous skin of the palm. Skin grafts have, however, been demonstrated to prevent local recurrence in several studies.[83–88] A single series of 103 patients published by Logan and colleagues noted only nine histologically confirmed recurrences in patients treated with dermatofasciectomy.[88] Dermatofasciectomy is most clearly indicated in cases of recurrent disease and in patients with early-onset primary disease with significant skin involvement.

Postoperative care

Postoperative therapy in Dupuytren's disease couples early motion to maintain joint mobility with extension splinting to reduce the risk of early contracture. The interrelationship between these two opposing regimens is dictated by the procedure performed.

Patients undergoing enzymatic or percutaneous fasciotomy are placed in a soft, bulky dressing postoperatively in order to provide mild compression and for comfort. This dressing is removed 1–3 days after the procedure and patients are encouraged to use their hand normally as tolerated by level of comfort. Hand therapy is rarely required in order to facilitate mobilization and extension night splinting is encouraged for 3–4 months following contracture release.

Patients undergoing fasciectomy typically have more discomfort and postoperative stiffness compared with those undergoing percutaneous techniques. A volar splint is placed with the MCP and PIP joints in maximal extension, leaving unoperated fingers free. The fingertips should be visible to allow for assessment of perfusion. In the absence of a skin graft, this splint is taken down and physical therapy for active and passive range of motion is begun at 3–5 days after surgery. The suture lines are dressed daily with antibiotic-impregnated gauze and sutures are left in place for 14 days. Skin grafts are held in place with tie-over bolsters consisting of antibiotic gauze and this dressing is taken down after 5 days. In these patients, range of motion is delayed until postoperative day 7 to allow for sufficient revascularization of the graft.

Hand therapy is generally required in patients with severe MCP and any degree of PIP joint contracture and should be initiated as early as possible as allowed by postoperative pain and edema. Therapy first targets recovery of full finger flexion, followed by progressive restoration of finger extension. If articular interventions are performed, including check rein release, early dynamic splinting should be instituted. If central slip tenodesis was performed, immobilization must be continued for 3 weeks prior to the initiation of dynamic splinting.

Outcomes, prognosis, and complications

Percutaneous interventions in Dupuytren's disease seek to minimize wound complications and recovery. Complications arise as a consequence of the blind nature of these techniques. The short-term efficacy and complications of enzymatic fasciotomy have been well quantified in the phase III evaluation of clostridial collagenase. Edema (73%), bruising (51%), and injection site pain (32%) were the most commonly reported complications. Patients also noted discomfort with manual manipulation. No systemic side effects or type IV hypersensitivity reactions were noted. Serious complications included two tendon ruptures and one case of CRPS in 308 patients. Overall 64% of patients met the primary endpoint of correction of contracture to within 0–5° of full extension within 30 days of injection with an improvement of range of motion from 44° to 81°. When subdivided according to the joint treated, 76% of MCP contractures and 40% of PIP contractures met the primary endpoint with less severe contractures more reliably exhibiting correction.[89]

With widespread use of collagenase, increasingly reliable data regarding efficacy has been published. The CORDLESS study provides 5-year follow-up on 644 patients who were successfully treated (met the initial primary endpoint of less than 5° of contracture following treatment) for MCP and PIP contracture with collagenase. At 5 years, 47% of joints demonstrated recurrence defined as 20° degrees or more loss of extension and 32% demonstrated greater than 30° loss of extension. Recurrence was 39% in MCP joints and 66% in PIP joints. 16% of patients required a secondary intervention within 5 years. Some 47% underwent surgical fasciectomy and 30% underwent additional collagenase injection. To date, there are no reported antibody-mediated reactions to collagenase despite the formation of antibodies to the enzyme isolated in 93% of patients.[90]

Percutaneous (needle) aponeurotomy has been more widely employed and data regarding efficacy and prognosis have been established. In a multicenter trial in which 3736 percutaneous aponeurotomies were performed, 70% correction was reported in 93% of patients with stage I disease (less than 45° of flexion at the MCP and PIP), 78% of patients with stage II disease (45–90° of flexion at the MCP and PIP), 71% of patients with stage III disease (90–135° of flexion at the MCP and PIP), and 57% of patients with stage IV disease. Immediate failure to correct the underlying contracture is reported in 15–19% of patients.[91,92] Two large series have evaluated complications in percutaneous fasciectomy. The first evaluated complications in 138 patients undergoing needle fasciotomy. Complications were reported as skin ruptures (16%), nerve transections (2%), and infections (2%).[91] A larger multicenter study evaluating 799 patients undergoing 3736 percutaneous aponeurotomies reported complications including cutaneous rupture (2%), flexor tendon rupture (0.8%), and nerve transections (0.8%). Long-term data regarding recurrence and progression are sparse; however, Foucher *et al.* report a recurrence rate of 58% of patients undergoing needle aponeurotomy with a reoperation rate of 24% at 3.2 years.[67] Van Rijssen *et al.* evaluated recurrence in 115 patients treated with either needle aponeurotomy or limited fasciectomy and found an 85% recurrence

rate (defined as a greater than 30° increase in total passive extension deficit) compared with a 21% recurrence rate with limited fasciectomy at 5 years.[93]

Techniques aimed at decreasing this high rate of recurrence have emerged as adjuncts to needle aponeurotomy including autologous fat injection and corticosteroid injection.[94,95] While demonstrating some initial promise, both techniques are currently being evaluated more rigorously in randomized trials.

Complications in the surgical treatment of Dupuytren's disease may be categorized as perioperative, early postoperative, and late postoperative complications. Operative complications most commonly involve damage to the neurovascular bundle. Experienced surgeons have reported rates of arterial and nerve injury less than 0.4% and 2.3%, respectively.[96] Damage to the neurovascular bundle may be avoided by maintaining a high suspicion for a spiral nerve in all patients and particularly in those patients with PIP joint contracture. Dissection between the distal palmar crease and proximal digital crease should be specifically directed at identifying and preserving the neurovascular bundle. Nerve or vascular injury should be recognized and repaired immediately should it occur. The surgeon should be particularly vigilant during reoperation for recurrent contracture as a single digital artery may supply the digit. Digital ischemia is addressed intraoperatively by: (1) minimizing compression from skin closure and dressings; (2) infiltrating agents (papaverine, lidocaine) to decrease vasospasm; (3) decreasing extension of the digit to prevent unaccustomed stretch on the digital vessels; and (4) microsurgical exploration and repair as necessary (Box 17.4).

Early postoperative complications include infection, hematoma, skin necrosis, and postoperative flare reaction. Postoperative wound infection typically occurs in 1–4% of patients, but has been reported to be as high as 9.5%.[97] Infections are likely attributable to bacterial overgrowth within the macerated distal palmar crease as well as to tenuous blood supply to the palmar flaps. Another common complication of palmar dissection is postoperative hematoma, which often results in palmar skin necrosis if not identified and evacuated. The reported incidence in populations undergoing a variety of surgical techniques is 2%; however, the risk with radical fasciectomy is significantly higher.[97] The risk of palmar hematoma may be minimized by obtaining hemostasis with the tourniquet deflated, prior to application of the final dressing, and by minimizing palmar dissection. Some authors advocate application of a pressure dressing; however, this intervention is unnecessary if meticulous operative hemostasis is obtained. The incidence of palmar hematoma may also be reduced with the use of the open-palm technique of McCash.[82,96] Postoperative flare reaction may also occur. Flare reaction consists of significant pain, swelling, and joint stiffness, characteristically occurring in the third to fourth week following surgery. Flare reaction is significantly more common in women and its incidence is further increased with concomitant procedures, including carpal tunnel release.[97,98] For this reason multiple procedures should not be performed at time of operation for Dupuytren's disease. This syndrome may be a precursor of CRPS, and the incidence is minimized with operation under regional anesthesia.

Late postoperative complications include CRPS, scar contracture disease recurrence, and disease progression. CRPS refers to a syndrome characterized by pain, allodynia, and hyperalgesia disproportionate to the extent of inciting injury accompanied by evidence of vasomotor instability. The reported incidence of CRPS in patients undergoing fasciectomy for Dupuytren's disease ranges between 4.5 and 40%, and varies on the choice of anesthetic. Regional analgesia provides the lowest postoperative incidence, with comparable results achieved with intravenous regional anesthesia accompanied by clonidine. The highest reported incidence occurs with general anesthesia.[99] For this reason, infraclavicular or axillary block should be considered the anesthetic method of choice when operating for Dupuytren's disease. Scar contracture occurs with longitudinal digital incisions. The risk of contracture is minimized by careful incisional planning, the use of Z-plasties at the flexion creases, or Brunner's incisions. Prolonged postoperative stiffness is reported in 10% of patients. The most common complication of Dupuytren's disease is recurrence. Recurrence is distinct from disease progression and is defined as the reappearance of Dupuytren's disease, nodules or cords, in a region previously cleared of abnormal fascia via operative excision. The incidence of recurrence varies with technique and ranges between 32 and 40% with open techniques, and is reported to be as high as 58% with percutaneous fasciotomy of the diseased cords.[100,101] In general, recurrence may be minimized with appropriate digital dissection coupled with more extensive palmar dissection. The benefits of more extensive dissection must, however, be weighed against higher incidence of wound complications. Interestingly, most severe recurrences develop early, whereas later recurrences typically remain discrete, resulting in little or no functional disability.[102] Recurrence does not invariably require additional surgery. Rodrigo and colleagues found that only 15% of patients required re-excision following disease recurrence.[73]

BOX 17.4 Clinical tips: treatment of arterial insufficiency in Dupuytren's contracture release

Arterial insufficiency is a known surgical complication in the treatment of Dupuytren's disease. Ischemia may result from direct trauma to the digital artery as a consequence of dissection or, more commonly, as a result of traction and vasospasm as a previously contracted finger is straightened. The surgeon should have a methodical approach to the treatment of arterial insufficiency.

1. Flex the finger to alleviate traction on the digital artery.
2. Warm the finger with warm irrigant solution.
3. Apply topical papaverine (30 mg/mL) to facilitate smooth-muscle relaxation (lidocaine may be used alternatively or in addition to papaverine).
4. Be patient. Allow the relaxation, warming, and antivasospasm interventions time to work. The artery may require up to 10 minutes for the restoration of perfusion.
5. If arterial insufficiency persists beyond 10 minutes, explore the digital artery throughout the extent of dissection. Repair of a partial or complete laceration should be performed under the operating microscope. A vein graft may be necessary if undue tension is present.

Secondary procedures

Disease recurrence and progression are common in Dupuytren's disease and, consequently, operation for disease recurrence is the most common secondary procedure performed.

Severely contracted, functionally limiting fingers may require ray amputation; however, several alternatives to amputation exist and have gained an integral role in the treatment of recalcitrant disease. These procedures include skeletal traction, wedge osteotomy, total volar tenoarthrolysis, and PIP arthrodesis.

Skeletal traction

Severe PIP joint contractures may be addressed with the application of a dorsally based external distraction device. Described by Messina in 1989, the continuous elongation technique involves application of progressive continuous extension via an adjustable external device.[103] Full extension is typically achieved over the course of 2–4 weeks. This technique allows for ready access to the palm and a regional or dermatofasciectomy is performed concomitant with removal of the distraction device.

Biochemical studies have demonstrated an increase in the enzymatic activity of fibroblasts and increased collagen deposition in response to skeletal traction.[104] If left unaddressed, this stimulus results in disease progression, and, therefore, distraction alone is contraindicated unless coupled with subsequent fasciectomy. This technique is a useful addition to the surgeon's repertoire in addressing advanced Dupuytren's disease and may provide salvage in settings under which amputation might be considered.

Wedge osteotomy

Wedge osteotomy provides for a more functional range of motion in recalcitrant PIP contractures with residual flexion deformity despite attempts at surgical release. The operation consists of removal of a dorsal wedge from the proximal phalanx placing the PIP joint into a position in which the existing range of motion is functionally useful. Although advocated by some, wedge osteotomy maintains a very limited role in the treatment of advanced Dupuytren's disease.[105]

Total volar tenoarthrolysis

Analogous to wedge osteotomy, total volar tenoarthrolysis redistributes the existing PIP range of motion to within a more functional range. Via a lateral digital approach, the volar plate and flexor digitorum superficialis and profundus are sectioned. This leaves the extensors and intrinsics as the only active determinants of digital motion. The finger passively falls into flexion due to the contracture of the palmar fascia.[106,107]

PIP arthrodesis

Arthrodesis is indicated in patients with severe PIP joint contracture that has proven recalcitrant to surgical correction. Underlying articular or degenerative change, pain upon restoration of motion, and immobility in a nonfunctional position are clear indications favoring PIP arthrodesis. MCP arthrodesis should be avoided as articular change does not occur with prolonged contracture at this joint and fusion at the MCP joint level is functionally limiting.

Amputation

Although commonly employed in the past in cases of severe primary contracture and recurrent, severe secondary contracture, amputation is now a relatively rare treatment of Dupuytren's disease. Skeletal traction has emerged as a useful adjunct in treating patients who might otherwise be considered candidates for amputation. Clear indications for amputation exist, including multiply recurrent contractures and in severely contracted fingers with nerve or vascular lesions. Ray amputation is preferable for the index, long, and ring fingers. Amputation at the MCP joint level is indicated to address small-finger contracture. Thumb amputation is contraindicated regardless of the severity of contracture. Dorsal skin should be preserved and may be useful in resurfacing the palm.

Future direction

The management of Dupuytren's disease remains a challenging problem for hand surgeons. Operative results are tempered by relatively high rates of disease recurrence and each subsequent operation affords a narrower margin for functional improvement and higher risk to the neurovascular structures of the hand. Novel techniques, including percutaneous aponeurotomy and enzymatic fasciotomy, have afforded new treatment options for both patients and surgeons. As these techniques are utilized over the coming years, their respective niches and relative weaknesses and strengths will become further defined.

Despite these advances in surgical and nonsurgical techniques, no modality offers a cure. The ultimate treatment is, as yet, undiscovered but will likely rely on arresting the underlying disease process, rather than attempting to treat the sequelae. Bench and clinical research continue to identify and evaluate new clinical targets and novel therapeutic interventions. The opportunity to modify the underlying disease process via pharmacotherapeutics and interventional treatments offers the greatest promise for functional preservation and disease prevention.

Occupational hand disorders

Steven J. McCabe

SYNOPSIS

- Upper extremity problems that are attributed to the workplace require experience, a knowledge base, and skill set that set them aside from non-occupational injuries.
- To evaluate causation requires a careful history and physical examination as well as knowledge of the disease process and literature.
- The workers' compensation environment creates external forces on the provider and patient that can adversely affect patient management and recovery.
- Management of work-related upper extremity disorders should include non-surgical care when it is known to be efficacious.
- Return to meaningful employment and high quality of life are the desired outcomes.

Introduction

There are several reasons why upper extremity problems relating to work activities are considered as a distinct entity. The surgeon is frequently called upon to judge the validity of work attribution. Some upper extremity problems are closely identified with work activity and hence could correctly be called occupational injuries. High pressure injection injuries and vibration induced problems are closely identified with a certain occupational activity. In addition to these problems that are closely identified with specific work, there are upper extremity problems that seem to occur in greater than expected numbers, i.e., their incidence rate may be higher, in certain working populations. Although tendon entrapments are often seen in the non-working population, their occurrence is often attributed to work activity. The surgeon is often called upon to determine causation or if the upper extremity problem is related to the work activity. Second, illness related to the work place requires considerations for management not needed in problems unrelated to work. Documentation and justification of attribution to the workplace, guiding the return to some form of modified work and full duty work are examples of issues in management that are more profound in the work-related injury. Finally, the outcomes of treatment in upper extremity problems related to the workplace are qualitatively and quantitatively different than similar problems not related to the workplace. Return to previous work is an outcome of interest unto itself. The surgeon will be involved in determining the return to regular or modified work activities, the completion of active medical care, and the assignment of a permanent impairment rating.

Hints and tips

- Some upper extremity problems are closely associated with work activity.
- Work-related upper extremity disorders require management considerations that are different than non-work-related problems.
- Return to full activity at work is one important outcome goal.

Causation

Physicians and surgeons are often called on to judge whether a specific work activity could cause the upper extremity problem of a patient. To do this, the surgeon must bring to bear all the evidence that is available from the history of injury, the time course of events since the injury, the physical examination, information from diagnostic tests, as well as knowledge of the upper extremity problem diagnosed in the patient.

Patient history

Initial events

The history must be detailed and thorough. It is important to consider the sequence of events, the history of injury, the

behavior of the patient, co-workers, and medical providers at the time of the injury. Often a careful history will reveal features of the injury that were previously unclear such as the nature of a crushing injury or the lack thereof. A severe injury will usually demand an immediate response and care. When a patient was able to complete vigorous work for the remainder of the day following an injury and reported the injury some days later, many severe injuries can be excluded. Similarly, a review of the original medical records is often informative. The description of the emergency room doctor or first examining physician provides contemporaneous information on the severity of injury. Severe swelling, bruising, or radiographic evidence of soft-tissue swelling or fracture at the time of the injury will all document the nature of the original injury. Similarly, a lack of physical findings at the time of the injury may be important for lingering symptomatic problems. The initial behavior of the patient and documentation of the injury before the initiation of the workers' compensation system of care and the influence of society will be informative for future management. For an observed traumatic event, immediate contemporaneous actions and information are the result of the injury whereas later behavior is a result of the injury and the influence of a number of other societal factors that have to be considered.

The course of illness

Through education and experience, surgeons understand the expected course of an illness and can detect when there is variation from this. When the course of illness varies to some large degree it is sometimes possible to determine that the symptoms and physical findings of a current evaluation could not be consistent with an injury that is described in the history and verified by review of initial medical records. In other words, knowledge of the natural course of an injury can be used to make strong statements about the lack of causation.

Physical examination

A detailed perceptive history and physical examination are required for careful evaluation of a work-related injury. The surgeon must use all of her senses to gather information. Open-ended questions, active listening, and fact checking are all important. Classic techniques such as repetition to check important physical findings, distraction, and use of a tool box of physical examination skills specific to the situation must be developed and practiced. Adequate time must be devoted to obtain accurate impressions and information.

Knowledge of the disease process and its causation

The concept of causation has evolved as our understanding of illness has changed. The concepts of Hill have stood the test of time as guidelines to evaluate associations as possibly causative, however it is clear there are no single or combination of characteristics of an association that can prove causation. The concept of causation requires in-depth knowledge of the content of the research to measure associations as well as their context and characteristics. It is difficult to suggest associations are causative from observational data alone. Therefore for many illnesses of the upper extremity related to the workplace there will always be some uncertainty as to the accuracy of their attribution. This problem is magnified when considering an individual patient.

Hints and tips

- A detailed history, physical examination, and review of medical records surrounding the injury and the immediate following events are highly informative and important.
- The use of a special toolbox of physical examination skills can be used to evaluate the veracity of physical examination findings.
- Knowledge of the disease process and literature must be combined with the history and physical examination findings as noted above to make the best decision regarding attribution to the workplace.

The role of force and repetition

In 1991, Gerr and associates reported that: "Sufficient evidence is available at this time to conclude that several well-defined soft-tissue disorders of the upper extremities are etiologically related to occupational factors. These disorders include tendinitis of the hand and wrist, CTS, and hand–arm vibration syndrome. Force, repetition, and vibration have been established as risk factors in the etiology of these disorders."[1] These conditions are discussed further below.

Szabo has well advised against the use of "*cumulative trauma disorder*" or "*repetitive strain injury*" as diagnostic labels, suggesting the term "*work-related musculoskeletal disorders*" to describe an amorphous category of upper extremity problems, often characterized by pain, with no clear diagnosis or anatomic basis for symptoms, and clinical course that is not easy to understand given the traditional concepts of illness and injury.[2] It is plausible that highly repetitive activity of high enough force can lead to symptoms and disorders of the upper extremity but it seems most appropriate to consider these as attributes leading to potential causation rather than a diagnosis of an illness. Upper extremity pathology with a clear clinical diagnosis such as carpal tunnel syndrome (CTS) or de Quervain's tendonitis should be managed according to the standards available for the problem. A new diagnostic category is not required and confuses the management of the patient. Upper extremity problems without a clear diagnosis should be dealt with as such. A pseudo-diagnostic label will not help the patient recover from an illness.

Although the concept of causation is philosophical, practically, the best evidence that can be gathered would be the results of a randomized experiment where the causative agent is randomly distributed to two otherwise equivalent groups. Unfortunately, it is typically not possible to randomize the exposure to work activities. Failing this, it is important to understand this uncertainty and try to understand the consequences and minimize the negative impacts of this uncertainty.

What is the purpose of this attention being delivered to determine if the upper extremity problems are related to work and why is it the surgeon's responsibility to arbitrate this decision?

1. To provide the best management, the surgeon should have an accurate evaluation of the patient's illness,

which includes the pathology located in the upper extremity, how that is experienced by the patient, and the external factors that can influence the management and recovery.

2. It is important to the patient. In a work-related disorder the financial benefits of the workers' compensation system may be the only source of financial security for the patient.
3. An accurate and definitive decision about work attribution may be the best way to avoid the negative effects that accompany the workers' compensation system of insurance coverage. A rapid and accurate decision either affirmative or negative will reduce the potential for conflict and will be in the patient's best interest.
4. The surgeon is in the best position to gather and weigh all the evidence that is available.

Clinical care in illness related to the workplace

Injuries at the workplace can be broadly divided into acute traumatic injuries and those without a single identifiable traumatic incident.

When a worker suffers a verifiable traumatic injury at the workplace that is directly observed and an injury is present under any reproducible and acceptable method to define its presence, the attribution to work is not an issue. Efforts are provided at the best management and rehabilitation of the injured worker.

Millender *et al*. has divided the more chronic occupational injuries of the musculoskeletal system into four categories that provide a useful framework for discussion (Table 18.1).[3]

In category one, most patients are highly motivated and when the appropriate treatment is provided for the patient, the upper extremity problem resolves. The patient can resume work and there are no lingering effects. Happily in my experience this includes most injured workers.

In category two, some difficulties may arise as permanent impairment is possible. When the patient is left with permanent impairment the easiest resolution is for the injured worker, upon recovery, to return to the same regular duty work that pre-dated the injury. If this is not possible, then a modified job with the same employer may be possible. Failing this, the worker may have to consider new work with a new employer, or retirement. This can be a difficult decision that requires coordination with a case manager or rehabilitation counselor. There are some patients with conditions usually well treated either non-surgically or surgically by the hand surgeon, who do not seem to have the capacity to recover to the extent that would let them return to their original job. This group of people may be difficult to identify before treatment begins but eventually they can be identified by a recovery that falls below the threshold that allows them to return to their pre-injury job. This group of patients is difficult for the hand surgeon to manage, and care should be taken to avoid a repetitious exposure to invasive treatments and repeated surgeries that never quite reach the expected result.

Table 18.1 **Chronic occupational injuries of the musculoskeletal system**

Category 1	Diagnosis is easily established, good methods are available for treating the condition, and the prognosis for returning to work is good.
Category 2	Diagnosis is established, but neither non-surgical nor surgical treatment is always successful in returning the patient to the original job.
Category 3	The condition combines definite physical problems and additional non-medical issues.
Category 4	Diagnosis is unclear

(Reproduced from Millender LH, Louis DS, Simmons BP (eds). *Occupational Disorders of the Upper Extremity*. New York: Churchill Livingstone; 1992.)

In category three, the patients may have pain that is out of proportion to their physical injury. They can be angry and frustrated at the lack of improvement, despite adequate medical care. Patients may have definite upper extremity pathology but this is difficult to improve to a degree that will be satisfactory to the patient. Surgeons will immediately recognize this group of patients, as features of the history and physical examination will be identified as falling outside the expected norms for the conditions being cared for. This embellishment of symptoms and physical findings may represent frustration on the part of the patient, an attempt to make the surgeon realize the depth of their problem, or conscious magnification of symptoms and findings. Unfortunately, this is a group of patients that is difficult for the surgeon to manage. An honest approach will result in anger on the part of the patient, but management that deals with the upper extremity problem as an isolated independent part of the patient will not succeed.

In category four, the diagnosis of the upper extremity problem is unclear. Many of these patients will have vague diagnoses and may have had surgical procedures. They may have previous experience with other workers' compensation injuries and may have seen other hand surgeons. For example the patient may present with a problem whose existence is controversial, its pathology unproven, its treatment ill-defined, and its outcome uncertain. The patient may be in conflict with their employer and may be terminated from employment. When the worker has this type of an upper extremity disorder, there may be conflict at every aspect of the patient's interaction with the surgeon and healthcare system. The role of the hand surgeon is to take a careful history, perform a physical examination, recommend the appropriate diagnostic tests and provide honest recommendations for further management. Going for a surgical "Hail Mary" will be a disappointing misadventure.

At each step of care, the surgeon must be aware of the play of internal and external forces that promote and limit recovery. The structure of the workers' compensation system can create perverse incentives the surgeon must be perceptive about and must guard against. The surgeon may have perceived or real pressures to do things that are uncomfortable from an ethical standpoint. For example the surgeon may be pressured to return the injured worker back to the workplace early after surgery on limited work such as "one-hand duty". Workers with pain in one extremity from a workplace injury

or recent surgery may be required to go to the workplace and answer the phone or even perform useless or demeaning tasks or simply sit in a room or lie on a stretcher. This so-called presenteeism is a warping of societal norms that has occurred to circumvent the negative impact of workers' compensation protections. The physician wants to do the best for the patient but feels those decisions are beyond the scope of their influence. The presence of "one-hand work" creates the aura of reasonableness creating a plausible justification for the surgeon to agree to this. An alternative perspective to the potential harm caused by early return to work is a belief that the early return to the workplace is important in the recovery of the injured worker. Although the literature is sparse in this area there is a belief that returning an injured worker to a routine including work will be beneficial and minimize illness behavior.

If pushed back to work early, the patient may feel trapped in a closed system. The patient can be suspicious of the compensation system and lose the sense of control of their healthcare. Attempts to recover this control can be self-destructive and misunderstood.

An awareness of these forces will help the surgeon provide the best care for the patient and prevent a fatalistic approach by both. A clear focus should be on providing the best possible care for the upper extremity problem with perception of and attention applied to the other concerns of the patient.

Hints and tips

- Clinical problems associated with occupational disorders have been observed to fall into specific patterns that can lead to frustration and uncertainty.
- Early return to modified work is a "double-edged sword" that requires further research evaluation.

Tendinopathy

Medial and lateral epicondylitis

Van Rijn and associates have reviewed the literature evaluating the associations between lateral and medial epicondylitis and work-related factors such as force, repetition, posture and psychological issues.[4] They report that handling tools of weight >1 kg; repetitive movements >2 h/day; low job control, and low social support, are associated with lateral epicondylitis. Handling tools >5 kg two times, at a minimum of 2 h/day, or tools >20 kg at least 10 times per day; high-hand grip forces for >1 h/day; repetitive movements for >2 h/day and working with vibrating tools, are associated with medial epicondylitis. The clinical management of these conditions have recently been reviewed by Rineer and Ruch.[5]

Lateral epicondylitis

Lateral epicondylitis, tennis elbow, presents with well-localized lateral elbow pain that is exacerbated by certain activities such as gripping. The diagnosis is made by history and physical examination. Physical examination will show point tenderness directly over the lateral epicondyle. Pain will be increased with resisted wrist extension, especially in elbow extension.

A cross-sectional study of 3710 workers in France revealed that 90 (2.4%) had lateral epicondylitis. Age, BMI >25, and low social support (for men) were significant risk factors. Hard perceived physical exertion combined with elbow flexion/extension (>2 hr/day) and wrist bending (>2 hr/day) was a strong significant risk factor for elbow pain and epicondylitis.[6]

Interestingly, from 1994 to 2006 there was an increase in ambulatory surgery rates for lateral epicondylitis from 7.29 to 10.44 per 100 000 persons.[7]

More recently, however, there is heightened interest is non-surgical management of lateral epicondylitis as it has become disseminated that this condition will resolve over time. Treatment is therefore used to temporize symptoms.

Splinting, counterforce bracing, non-steroidal anti-inflammatory drugs (NSAIDs), physical therapy, steroid injection, or simple observation without intervention have all shown to result in satisfactory results for a majority of patients. In addition, new modalities are being evaluated continuously. Surgical treatment is reserved for long time failures. Recently studied predictors of failure of non-surgical treatment include a workers' compensation claim, prior injection, the presence of radial tunnel syndrome, previous orthopedic surgery, and duration of symptoms greater than 12 months.[8]

A variety of surgical techniques that typically include debridement or tenotomy of the extensor carpi radialis brevis origin are used with reported good success.

Tendinopathy at the wrist and hand

In a review of data collected in 1988, Tanaka *et al*.[9] reported that the period prevalence for tendinopathies, including tendonitis, synovitis, tenosynovitis, de Quervain's, or epicondylitis, ganglion cyst, or trigger digit was 0.46% of the population working within the previous year. Of these, 28% were thought to be work-related. The authors found bending and twisting of the wrist at work and female gender were associated with reporting these disorders.

De Quervain's tenosynovitis

Tenosynovitis of the first dorsal compartment is the signature work-related tendinopathy (Fig. 18.1). Interestingly, this condition is commonly seen in new mothers and in the worker.

Symptoms of de Quervain's are typically well localized to the radial side of the wrist. The Finkelstein's test is a sensitive

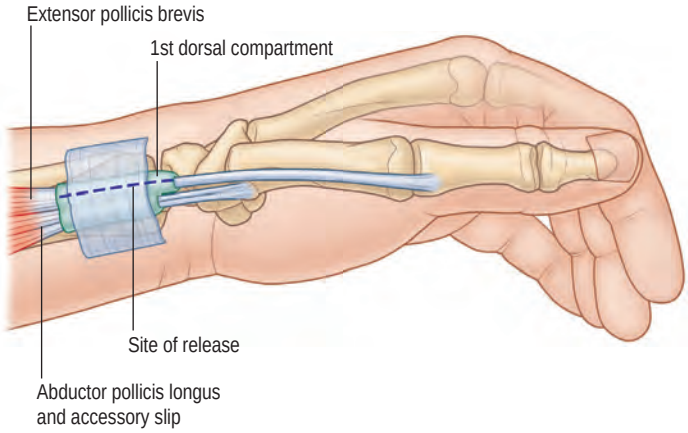

Fig. 18.1 De Quervain's tenosynovitis. Tendons of first dorsal compartment and planned release on dorsal half of sheath.

test for this problem and point tenderness is a specific test. The diagnosis is made by history and physical examination. Occasionally there will be a small ganglion overlying the first compartment.

Non-surgical treatment, including oral non-steroidal anti-inflammatory medication, steroid injections, splinting and therapy are often used to treat de Quervain's tenosynovitis. A recent review by Ilyas, of non-surgical treatment, pointed out the lack of randomized trials for this common condition.[10] Nevertheless, one randomized trial of injection of triamcinolone versus placebo showed benefit from the active drug.[11]

The anatomy of the first dorsal compartment, specifically the presence of a septum between the extensor pollicis brevis and abductor pollicis longus is an interesting finding more prevalent in de Quervain's tenosynovitis requiring surgical treatment than in cadaveric dissection. This anatomic feature has direct surgical importance as each tendon must be identified and released during surgery (see Fig. 18.1).

Surgery is performed using local anesthesia. A longitudinally oriented zigzag incision is made directly over the first dorsal compartment. The subcutaneous tissue is gently spread to avoid injury to small branches of the radial nerve and the medial antebrachial cutaneous nerve of the forearm. The first dorsal compartment is identified and opened dorsal to the midline. After complete release, each tendon is identified making sure the extensor pollicis brevis is released. If it is not identified, it will lie in a separate tunnel on the dorsal margin of the open first compartment. This is easily released from within the first dorsal compartment. The tourniquet is released before wound closure and a short thumb spica splint is worn until suture removal about 10–14 days later.

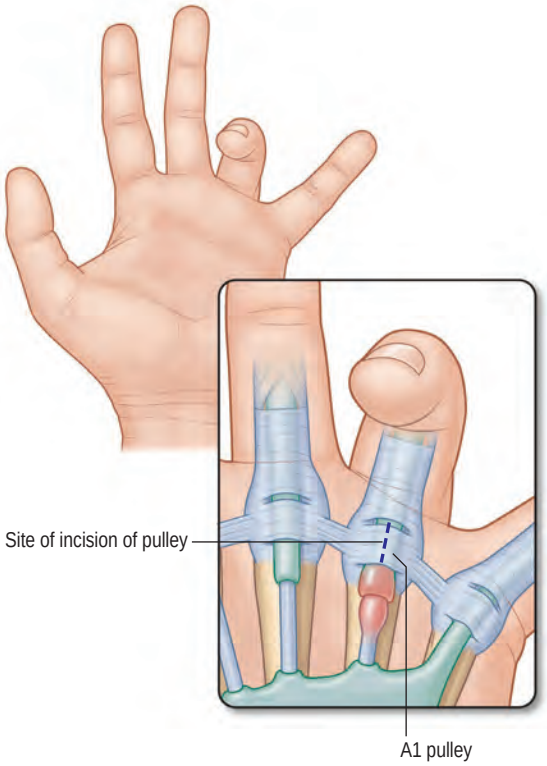

Fig. 18.2 Trigger digit. Location of A1 pulley and planned incision on radial side of the pulley.

Trigger finger

Trigger digit is one of the most common disorders of the hand. A comprehensive review with extensive references has been published by Moore.[12] A case–control study found associations of trigger digit with female gender (OR 7.57, 95% CI 5.07–11.31); diabetes (OR 3.72, CI 2.43–5.70); obesity (OR 1.49, CI 1.02–2.19); occupation as a homemaker (OR 2.44, 95% CI 1.62–3.69); seamstress (OR 4.8, CI 1.3–21.6); and secretary (OR 2.74, CI 1.38–5.52). It is not clear from the abstract if gender was controlled for in these calculations although it would seem to be difficult to accomplish.[13] A study in a meat packing plant found a person-year incidence rate of 12.4% for workers using tools and 2.6% for those without tool use. The authors believe high worker turnover may cause an underestimation of the rate in the workplace.[14]

The diagnosis of trigger digit is relatively straightforward and relies on history and physical examination. Triggering will usually be demonstrable in the office. The patient who presents with no active triggering and work attribution should be managed without invasive intervention. These patients may have triggering in the morning or heightened sensitivity to symptoms. The author recommends initial management with a night-time splint and re-evaluation of these patients. Patients who present with triggering and the presence of a flexion contracture of the proximal interphalangeal (PIP) joint can present a challenge. The surgeon must point this out before treatment starts and combine treatment of the trigger digit with splinting and mobilization of the PIP joint (Fig. 18.2).

Treatment for trigger digit includes rest, splinting, steroid injection, and open or percutaneous surgery. Splinting can be used at any joint and is primarily used at night. This is particularly valuable if the finger is locked upon waking in the morning as night-time splinting can prevent this problem. Steroid injection is the mainstay of initial management for trigger digit. A Cochrane review supports the use of steroid as an efficacious treatment.[15] Kerrigan and Stanwix used decision analysis and showed that management with one or two injections prior to surgery minimizes the cost of management.[16]

To inject the A1 pulley, I have the patient's hand resting palm up on the examining table with the fingers pointed to my left. This allows me to position my hand over the patient's wrist and angle the needle in a slight proximal to distal direction. I identify its position in the tendon by gentle passive flexion and extension of the digit with my left hand. Using gentle pressure on the syringe the needle is slowly withdrawn until there is a drop in resistance to injection. The injection can also be performed at the digital palmar flexion crease with the needle tip angled in a proximal direction.

Surgical treatment is performed using local anesthetic. The A1 pulley is released under direct vision and unrestricted motion of the digit is demonstrated in the operating room. Percutaneous release of trigger digit has been reported in the literature and can be performed in the office with lower cost than traditional surgery. One randomized trial found a high success rate in both treatment groups without serious complications.[17] Like many other surgical procedures, the choice of procedure will depend on surgeon training and experience and the wishes of the informed patient. The proximity of the

digital nerves to the A1 pulley in the index and the thumb must be considered.

Nerve compression

The work attribution of nerve compression has a well-documented history and is still the object of intense research effort. As research designs are improved the relationship of carpal tunnel syndrome to keyboard use, for example, has become less certain. A recent review of the literature reveals the association between keyboard use and CTS has been based on epidemiologic studies with significant flaws.[18] In fact, Atroshi *et al*. recently reported a study where use of a keyboard was found to be protective of CTS.[19]

Additional evidence exists confirming the relationship between force and repetition and CTS[20] and lack of an association with computer use.

Subsequently a review of systematic reviews and meta-analysis of current research concluded "there is high evidence for an increased risk of CTS in activities requiring a high degree of repetition and forceful exertion. The evidence for vibration is moderate … There is no further evidence that CTS is caused by working with a computer keyboard or mouse."[21]

One other systematic review and meta-analysis has agreed with this lack of association between computer use and carpal tunnel syndrome[22] while another suggests that "excessive computer use, particularly mouse usage, might be a minor occupational risk factor for CTS".[23]

It is clear from the literature there is an inverse relationship between the specificity of the diagnosis of a disorder and the prevalence of the disorder. In other words, as the diagnostic criteria become more specific, i.e., other non-carpal tunnel syndrome causes of symptoms are ruled out, the prevalence of CTS is reduced. The incidence rate of CTS when it is diagnosed with high specificity is quite low even in the population of patients using a keyboard suggesting that this is unlikely to be a major work-related condition in keyboard users.

A recent review of CTS and its epidemiologic associations suggested occupational factors play a minor and debatable role in the etiology of CTS. In spite of some objections to the development of a scorecard based on the characteristics of an association defined by Hill, this review is a comprehensive and thought-provoking discussion of the potential causation of work-attributed CTS.[24]

Even if work-attributed CTS is an upper extremity problem defined administratively and not by causative mechanism or pathology, it has been found the attribution to the workplace results in inferior outcomes compared to non-work-related surgical care for CTS.[25] Manktelow and colleagues, in reviewing a large population of CTS patients, found that residual symptoms after release of the carpal tunnel are common.[26]

For CTS that has been attributed to the workplace, I recommend the patient proceed with a course of non-operative treatment before surgery is considered. Non-surgical treatment is efficacious and the improvement after splinting and/or injection is a good diagnostic test of the ability of the patient to obtain improvement from further intervention. If the diagnosis is correct, then any improvement following efficacious non-surgical treatment will be a good indicator that the patient has at least some potential for improvement.[27] If absolutely no benefit is achieved from non-surgical care, then the surgeon should confirm the diagnosis as much as possible and recommend a thorough course of non-surgical treatment. Further detailed information on nerve compression syndromes can be found in Chapter 24.

Hints and tips

- Evidence is accumulating to show the lack of association between keyboard use and carpal tunnel syndrome.

Vascular disorders

In some occupations, the heel of the hand is used as a hammer to push objects into place. Some commonly recognized activities are "hammering" a board into place or putting on a hub cap. The ulnar artery and ulnar nerve pass through Guyon's canal and are susceptible to injury in the hypothenar area. Thrombosis, pseudoaneurysm formation, embolic phenomena, and nerve symptoms are possible.

The history is usually highly suggestive of ulnar artery or nerve problems. Examination of the fingers may show signs of emboli and the Allen's test may show occlusion of the ulnar artery. The history will likely be specific if a pseudoaneurysm is present and it will usually be obvious on physical examination.

Treatment of the so-called hypothenar hammer syndrome is based on the presence of symptoms. The presence of an ulnar artery occlusion on the Allen's test without symptoms or peripheral signs does not necessitate surgical intervention. If there are compression symptoms and findings related to the ulnar nerve in Guyon's canal or evidence of ischemia or emboli, then imaging is indicated. Magnetic resonance imaging (MRI) will define localized vascular pathology as well as masses within or deep to Guyon's canal. Surgery will usually be indicated in the presence of neurologic or vascular symptoms.

Surgery for hypothenar hammer syndrome will start with release of the ulnar artery and nerve from the wrist crease to distal to Guyon's canal. The motor branch of the ulnar nerve should be identified and followed deep into the palm. For ulnar arterial lesions, the area of obstruction is resected and the flow in the hand is evaluated. Resection of the artery alone has been reported to increase flow to the hand by way of a regional sympathetic effect. Treatment of choice is to perform an interposition vein graft with a short saphenous vein or a forearm vein. Further detailed information on hand ischemia syndromes can be found in Chapter 22.

Hand–arm vibration syndrome (HAVS)

The relationship of vibration to upper extremity pathology has been the subject of extensive literature and regulatory interest. For the upper extremity surgeon, there are criteria that score the vascular and neurologic components of vibration injury.

The classification scheme that was produced at a workshop in Stockholm bears its name as the Stockholm Workshop Scale (Table 18.2) and is divided into neurologic symptoms and vascular symptoms.[28]

Although there is clear experimental evidence that vibration can cause injury to tissues, many of the symptoms of vibration-induced injury can be caused by other means. For

Table 18.2 Stockholm Workshop Scale

Neurologic symptoms		
0 SN	Exposed to vibration but no symptoms	
1 SN	Intermittent numbness, with or without tingling	
2 SN	Intermittent or persistent numbness, reduced sensory perception	
3 SN	Intermittent or persistent numbness, reduced tactile discrimination and/or manipulative dexterity	
Vascular symptoms		
0	–	No attacks
1	Mild	Occasional attacks affecting only the tips of one or more fingers
2	Moderate	Occasional attacks affecting distal and middle (rarely also proximal) phalanges of one or more fingers
3	Severe	Frequent attacks affecting all phalanges of most fingers
4	Very severe	As in stage 3, with trophic skin changes in the fingertips

(Reproduced from McGeoch KL, Lawson IJ, Burke F, et al. Diagnostic criteria and staging of hand-arm vibration syndrome in the United Kingdom. *Ind Health*. 2005;43:527–534.)

example, the vascular symptoms of vibration injury can also be caused by smoking, something that is highly prevalent in some populations. The relationship of vibration to vascular disorders is also potentially confounded not only by smoking but also other problems such as peripheral vascular disease of other etiologies. The neurologic symptoms of vibration injury are typical of peripheral nerve compression so there is often confusion between a diagnosis of CTS and vibration-induced injury. The relationship between vibration injury and nerve compression is not clearly elucidated. For patients with nerve compression symptoms, however, it seems prudent to limit exposure to future vibration.

Patient management

When a working patient has a vascular complaint or a history of numbness or tingling, the surgeon should enquire about vibration in the workplace as well as other potential causative mechanisms for the symptoms including a cardiovascular history, a smoking history, and a family history. Similarly, a detailed history related to nerve symptoms may be helpful. If the worker has been exposed to vibration, it is important to create a temporal history of the time and degree of exposure over their entire work history.

The physical examination will evaluate the upper extremity for evidence of vascular and neurologic findings. This will include measuring the blood pressure in each arm, listening to the heart and for bruits along the major vessels, palpating pulses at various levels, performing an Allen's test, and evaluating the fingertips for color, trophic changes, and temperature. The examination of the peripheral nervous system includes measuring sensory and motor function, and evaluation for sites of nerve compression.

Additional evaluations will often include electrodiagnostic testing and non-invasive vascular testing. Angiograms are not indicated unless there is evidence of a structural problem that may require surgical planning.

Patients presenting with vascular or neurologic symptoms should be advised to avoid exposure to vibration. This advice does not implicate vibration as a cause of their symptoms but seems prudent, given the experimental evidence of the potential for vibration to cause injury.

Management of the patient further depends on the accurate diagnosis and management of other pathology such as CTS.

Hints and tips

- There continues to be a great deal of confusion surrounding the relationship between HAVS and nerve compression disorders.

Return to work

Keeping the injured worker in the workplace or reintegration of the injured worker into the workplace, is a vital outcome of management of occupational illness of the upper extremity. When an injury forces a patient to leave the workforce, even temporarily, the surgeon should be aware of several possible points of view: (1) The injury or illness may be more severe causing symptoms that make work impossible. This can have implications in the application of more invasive treatment at an earlier stage of management. (2) The patient's work activities may be more physical, requiring more intense use of the upper extremities, something that will influence their potential for return. (3) The financial stakes for the employer become higher, as salary replacement and a history of lost time injury may be important. (4) When the injured worker is unable to work, a set of emotional circumstances is potentially set into play that can possibly make it difficult for the worker to return to work.

In trying to return the patient to work, the first consideration is whether the patient has the ability to work in any capacity. The second consideration is whether the change in ability to work is either permanent or temporary. For temporary changes in the ability to work, restricted duty work is often available if the employee has a work-related injury. This may take the form of one-hand work if the injury is limited to one extremity and the patient's general condition allows safe return. For a patient who has a temporary inability to work in any capacity the surgeon will need to follow the patient closely and communicate with the workplace about return to work when the medical situation allows. If the patient has an injury or illness that permanently prevents unrestricted work, the surgeon will play an important role in returning the patient to gainful employment. The first step is to determine the permanent restrictions that will be recommended to the patient to keep him/her safe in the workplace. For practical purposes, this is done when the patient has reached their level of maximum medical improvement. Further active medical management would not be expected to increase the patient's status. At this time, the patient can have an impairment rating

calculated to facilitate compensation for the permanent effects of the injury. The second step is to return the patient to the workforce. Given a permanent impairment the first choice of return to the workplace is the previous employer and return to the pre-injury work. If this is not possible due to the restrictions, then return to the previous employer in a modified work capacity is often the easiest plan. This may not be possible and the injured worker may be required to search for a new job, limited by the restrictions that have been imposed to ensure safety. It is obvious each step of the process can have a big influence on the patient's return to the workplace and the ability to find future employment.

Measuring impairment

In measuring permanent impairment, the surgeon is providing a basis for financial compensation of the patient for the permanent effects of an injury in the workplace. This measurement is often performed by hand therapists. This measurement is indicated at the time when no further diagnostic testing or interventions are planned for the patient. It is meant to be a tally of the permanent effects of an injury after all steps have been taken to minimize them. Often, when the surgeon perceives the patient has reached this stage of maximum medical improvement, the evaluation of permanent impairment and the decision about permanent work restrictions will be accomplished simultaneously. If this is straightforward and without conflict, this can be done by the surgeon at the time of a final visit. If there is conflict, or if the return-to-work restrictions are complicated, a hand therapist may be of assistance.

In some situations of work-related upper extremity illness, the patient may have prolonged symptoms and an inability to work, despite maximum care, the determination that the patient is at maximum medical improvement, the assignment of permanent restrictions, and the determination of an impairment rating can allow the patient to move on with their life and provide a stopping point for further non-beneficial interactions with the surgeon.

The most recent version of the *Guides to the Evaluation of Permanent Impairment*, 6th edn, put forward by the American Medical Association has a fundamental change in the evaluation of permanent impairment, shifting to the ICF model, *The International Classification of Functioning, Disability and Health*.[29] This is outlined in the first chapter, "Conceptual Foundations and Philosophy".

"In this edition there is a paradigm shift, which adopts a contemporary model of disablement: it is simplified, functionally based, and internally consistent to the fullest extent possible."

"The vision … is articulated in terms of five specific new axioms":

1. The terminology and conceptual framework of the ICF are adopted
2. Diagnosis and evidence-based where possible
3. Simplicity and ease of application
4. Functionally based
5. Conceptual and methodological congruity between and within organ systems.

Measures of permanent impairment are primarily based on diagnosis and then modified, based on several factors such as severity and functional limitation. Whether these new guides will supplant the 5th edition is not yet clear.

Use of the 5th or 6th edition of "The Guides" will bring objectivity to the measurement of permanent impairment and protects the surgeon from influence of the patient or the employer and insurance carrier.

Summary

The care of the injured worker mirrors the care of all patients with upper extremity injury and illness. The additional superimposition of the legal framework of workers' compensation adds an extra dimension to the care of the injured worker. The upper extremity surgeon must be knowledgeable of the local regulations and must be perceptive to their influence on the patient, the workplace, and the surgeon, and maintain the ability to take the best care possible of the patient.

Future directions

The increased use of valid clinical research methods by hand surgeons continues to change our understanding of so-called occupational upper extremity disorders. A clear example of this is the elucidation of the relationship between keyboard use and carpal tunnel syndrome. The application of valid research methodology will continue to advance our understanding and care of the working patient. The concept of presenteeism as it pertains to the injured worker and to the aging worker is an area for fruitful research. Surgeons must be cautious to insure their actions are in the best interest of the patient, requiring perception of sometimes conflicting interests of patients, employers, and insurance carriers.

Rheumatologic conditions of the hand and wrist

Douglas M. Sammer and Kevin C. Chung

Access video content for this chapter online at expertconsult.com

SYNOPSIS

- Rheumatoid arthritis is a systemic autoimmune inflammatory disease that affects the joints of the hand and wrist. Rheumatoid arthritis also affects the soft tissues, and can cause disease processes such as trigger finger and carpal tunnel syndrome.
- The diagnosis of rheumatoid arthritis is primarily clinical, and is supported by radiographic and laboratory studies. Although symptoms can usually be managed effectively with newer biologic medications, some patients require surgery to treat refractory pain or to improve hand function.
- Operations for rheumatoid arthritis can be broadly categorized into five groups: synovectomy, tendon surgery, soft-tissue rebalancing, arthrodesis, and arthroplasty. Specific techniques described include: wrist synovectomy, tendon transfers for tendon rupture, soft-tissue rebalancing, management of the distal ulna and distal radio-ulnar joint (DRUJ), wrist arthrodesis and arthroplasty, small joint arthrodesis and arthroplasty, and treatment of trigger fingers and carpal tunnel syndrome.

Introduction

Rheumatoid arthritis (RA) is a systemic autoimmune disease that affects 1% of adults (ranging from 0.33% to 6.8%, depending upon the population).[1] Although RA has many diverse clinical manifestations, the single underlying pathologic process is synovial inflammation, which progressively destroys joints and soft tissue leading to deformity and disability. Over the last 20 years, many advances in the medical management of RA have been made. New medications have improved the ability to control rheumatoid inflammation, and can dramatically slow or prevent disease progression.[2] In spite of these tremendous advances the hand surgeon continues to play a crucial role in treating RA. Many patients continue to suffer from recalcitrant pain or disability despite maximal medical management, and may benefit from surgical intervention.

In addition to RA, there are a number of diverse rheumatologic disorders that commonly affect the hand and wrist. These include systemic lupus erythematosus (SLE), scleroderma, gout, and others. These disorders frequently require surgical intervention.

Basic science/disease process

Etiology

Though much is understood about the pathogenesis of RA, the cause remains idiopathic. That being said, RA is known to have a genetic component. This is demonstrated by the fact that RA has a much higher concurrence rate in monozygotic twins (15–20%) than in dizygotic twins (5%), with susceptibility transferred in an autosomal recessive mode.[3–5] In addition, there are certain ethnic groups such as the Pima Indians that exhibit a greater incidence of RA than the rest of the population, providing further evidence of a genetic component to RA.[6]

Many studies suggest that a multitude of genes play a role in contributing to susceptibility to RA. These include the class II major histocompatibility complex (MHC) genes and many others. The most well-understood genetic association is with the class II MHC genes, which may contribute up to 40% of the genetic component of RA.[7] One class II MHC gene in particular, human leukocyte antigen (HLA) DR4 is associated not only with increased risk of disease, but also with increased disease severity.[4]

In addition to genetics, gender influences the development of RA. RA is more common in women than in men, with a ratio of 2:1 to 3:1. Multiple laboratory and clinical studies suggest that hormones, and estrogens in particular, affect the development of RA. However, the exact role of estrogen in the development of RA is not known.[8]

Although the mechanisms are not well understood, the environment plays a role in the etiology of RA as well. Smoking is a risk factor for the development of RA, particularly in

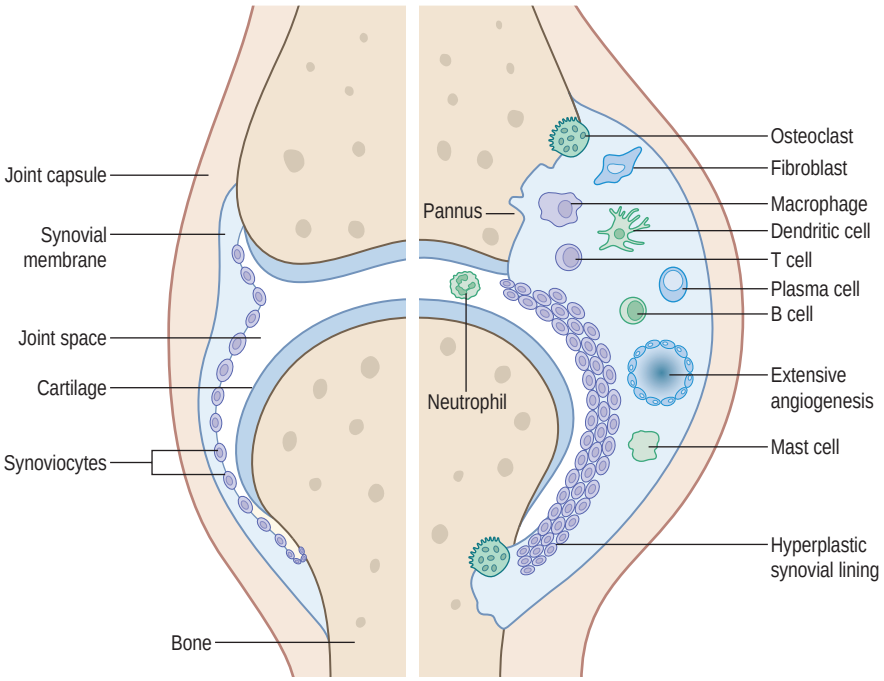

Fig. 19.1 The erosive synovial pannus consists of hypertrophic synovium and inflammatory cells.

susceptible men.[9] Coffee intake and exposure to silica have also been associated with RA.[4] In addition, infectious diseases likely act as a trigger in genetically susceptible individuals. Possible triggering agents include mycoplasma, enteric bacteria, Epstein–Barr virus, and other viral and bacterial triggers.[10–13] In summary, RA is an idiopathic disease, but which is known to have both genetic and environmental components. The genetic susceptibility and environmental triggers are complex and varied, and are not fully understood.

Pathogenesis

The target tissue of RA is the synovium. The disease process begins when an antigen, a trigger for RA, is presented to T-cells within the synovium. A complex interaction between macrophages, B-cells, T-cells, and synoviocytes ensues, orchestrated by systemic inflammatory modulators and local cytokines. The end result is the formation of proliferating inflamed synovium, or pannus (Figs. 19.1 & 19.2). Once initiated, this process becomes systemic and self-sustaining, and does not require the prolonged presence of the trigger antigen. The synovial pannus produces proteolytic enzymes such as metalloproteinases, serine proteases, cathepsins, and aggrecanases that erode cartilage, bone, and supporting soft-tissue structures. Cytokines secreted by the pannus activate osteoclasts in nearby bone, further contributing to bony erosions and joint destruction.[14–16]

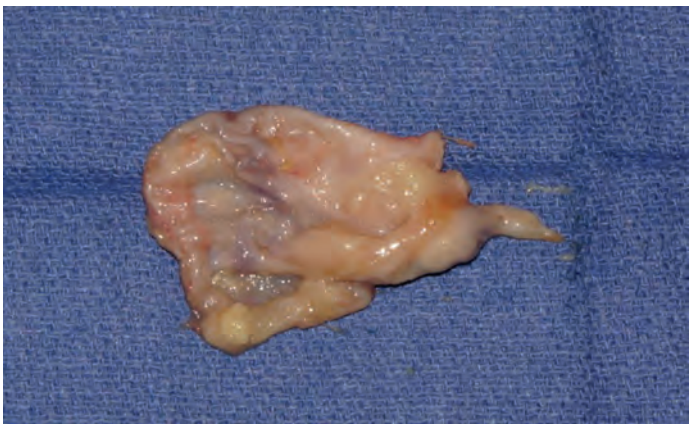

Fig. 19.2 Gross appearance of synovial pannus.

Medical management

The medications used to treat RA include non-steroidal anti-inflammatory drugs (NSAIDs), corticosteroids, and disease-modifying anti-rheumatic drugs (DMARDs). In general, a combination of the above medications, with methotrexate as the basis, is used to control symptoms and the underlying disease. NSAIDs do little to affect the course of the disease, and are rarely used in isolation. They are effective, however, in treating symptoms such as joint pain, but must be used judiciously due to their gastrointestinal and renal side effects. Corticosteroids on the other hand are very effective in treating both the symptoms of RA and the underlying disease process. They can be administered systemically or locally, in the form of a joint injection. However, long-term systemic use is associated with substantial morbidity. Because of this, a minimal clinically-effective dose is used. Often, corticosteroids are used briefly to control acute symptoms or flare-ups, and are then tapered as DMARDs begin to work. DMARDs include a diverse array of medications that can be divided into two groups: conventional DMARDs and biologic DMARDs.

The conventional DMARDs include methotrexate, leflunomide (Arava), azathioprine (Imuran), Plaquenil, and gold.[17] Methotrexate is the most commonly administered DMARD because of its effectiveness and favorable side-effect profile. It is generally taken orally once a week, in combination with folic acid in order to minimize side effects such as

hepatotoxicity and bone-marrow suppression. Leflunomide (Arava) is a daily oral pyrimidine antagonist, with side effects that include hepatotoxicity and marrow suppression. Plaquenil, an antimalarial drug that is effective in the treatment of RA, is taken daily and has few serious side effects. Sulfasalazine is another common daily DMARD, and like many of the other conventional DMARDs it can cause leukopenia. Gold is rarely included in the anti-rheumatic regimen today due to significant side effects and the need for intramuscular injections.

Biologic DMARDs are those that target tumor necrosis factor alpha (TNF-α) and interleukin 1 (IL-1), or the cellular components of the immune system. Etanercept (Enbrel) is an anti-TNF-α that requires once-weekly subcutaneous injections. Infliximab (Remicade) is a TNF-α blocker that is administered every 1–2 months, intravenously. Adalimumab (Humira) is a TNF-α blocker that is injected subcutaneously every two weeks. All three are very effective in treating RA, especially when combined with methotrexate.[18,19] However, the long-term toxicity of these new medications is unknown, and all three result in an increased susceptibility to infections.[20] Anakinra (Kineret) is a biologic DMARD that blocks IL-1 receptors, and requires daily subcutaneous injections. Like the anti-TNF-α biologics, it is associated with an increased susceptibility to infections. Rituximab (Rituxan) is an intravenously administered monoclonal antibody that targets certain B-cells, and lasts from many months up to a year. Abatacept (Orencia) is an antibody that targets T-cells, and requires a monthly intravenous injection.

The surgeon must be aware of the potential toxicities and side effects associated with these medications. The preoperative evaluation of patients on DMARDs should include laboratory panels to screen for hepatotoxicity and bone-marrow suppression. In addition, the surgeon must weigh the risk of increased susceptibility to infection with the benefits of surgery.

The perioperative management of DMARDs and other rheumatoid medications is somewhat controversial and should be coordinated with the patient's rheumatologist. The perioperative cessation of DMARDs or corticosteroids can result in an acute deterioration (rheumatoid flare-up) that is poorly tolerated by the patient. In fact, the flare-up may be so severe that it affects the patient's ability to participate in postoperative rehabilitation.[21–23] In general, methotrexate should be continued throughout the perioperative period at its normal dose. Methotrexate does not appear to increase infection rates in patients with RA undergoing elective surgery.[21,22] Furthermore, corticosteroids, when used alone or in combination with methotrexate, do not affect wound infection rates and should not be stopped in the perioperative period.[23] Data on the other conventional DMARDs are more limited, and their perioperative dosing should be discussed with the patient's rheumatologist.

The appropriate perioperative management of biologic DMARDs, particularly the TNF-α inhibitors, is less clear. There are few data and no large studies to guide perioperative dosing of the biologic DMARDs.[22] Therefore, a conservative approach is recommended at this time. In general, the TNF-α inhibitors should be held 2–4 weeks before and after surgery.[22] Similarly, few data exist regarding the other biologics, and a similar approach is recommended.[24]

Hints and tips

Perioperative management of anti-rheumatic medications

Medication	Recommendation
Corticosteroids	Continue at normal preoperative dosage. Provide stress-dose at time of surgery if taking >5–10 mg/day, or if recently stopped long-term corticosteroid use.
Methotrexate	Continue at normal preoperative dosage.
Other conventional DMARDs	Discuss with rheumatologist, but in general continue.
Biologic DMARDs	Discuss with rheumatologist, but in general hold for 2–4 weeks before and after surgery.

Diagnosis/presentation

The onset of RA is usually in the 3rd to 6th decade of life. The incidence of RA in young men is one-third that of women, but increases to be equal to that of women by the 6th or 7th decades of life. From the onset, RA tends to affect the hands and wrists. In fact, the metacarpophalangeal (MCP) joints, proximal interphalangeal (PIP) joints, and the wrist are often affected earlier and more frequently than other joints in the body.[2]

Diagnostic criteria have been described, and are useful in making the diagnosis of RA. They include: (1) morning stiffness = 1 h; (2) soft tissue swelling of three or more joints; (3) soft tissue swelling of hand joints (PIP, MCP, wrist); (4) symmetrical soft tissue swelling; (5) subcutaneous nodules (rheumatoid nodules); (6) seropositivity for rheumatoid factor (RF); and (7) erosions or periarticular osteopenia in hand or wrist joints. Four of the seven criteria should be present for diagnosis, and criteria (1) through (4) must be present for 6 weeks or longer. Morning stiffness or stiffness after rest is common, and may be present for a number of hours, improving with hand use. The most sensitive findings are symmetric arthritis and arthritis of the hand joints. Classic radiographic changes, and the presence of rheumatoid nodules are less sensitive but very specific findings. RF is not only is a marker for RA, but also correlates with disease severity.[4] Although not one of the classification criteria, anti-citrullinated protein antibodies (ACPAs) are very specific for RA, and are useful in confirming the diagnosis.[4,25] Like RF, ACPA seropositivity also correlates with disease severity.[26] In many cases, seropositivity to RF and ACPA develops prior to the onset of clinical disease. It should be noted, however, that some patients with RA will convert to seropositivity after the onset of disease, and some patients with RA will never become seropositive.

RA usually develops in multiple joints slowly over a period of months, although atypical presentations are not unusual.[27] In some cases, symptoms can occur rapidly over a few days. When symptoms develop rapidly, the diagnosis of RA is often not considered, and septic arthritis or some other cause of acute-onset joint inflammation is initially suspected. In other

cases, symptoms may involve one or two joints for some time before becoming polyarticular, confounding the diagnosis. Less commonly, some patients develop extra-articular disease (rheumatoid nodules, vasculitis, pericarditis, pleural effusion or interstitial disease, peripheral neuropathy, keratoconjunctivitis sicca, and many others), before synovitis and arthritis are evident.[4] Palindromic rheumatism is a rare variant of RA, in which symptoms begin in a single joint. Symptoms worsen and spread to other joints for a few days, then disappear in reverse order. Although the disease resolves in some patients, about half eventually develop classic RA.[28] Finally, it has been noted that some patients tolerate RA quite well; a presentation termed arthritis robustus. This tends to occur in athletes or heavy laborers who have little pain or disability in spite of severe radiographic changes.

Any joint in the body can be affected by RA, including the articulations of the ossicles of the middle ear.[29,4] However, joint involvement tends to follow a predictable pattern. Symptoms often begin in the MCP, PIP and wrist joints first, in part due to their high synovium to joint surface area ratio.[30] Larger joints like the knees, hips, shoulders and elbows are likely to be affected later in the disease process due to their lower synovium to joint surface area ratio.[31] Within the hand, the DIP joints are generally spared, possibly because of their relatively small absolute amount of synovium. The synovial lining of tendons is also affected by RA, and can result in a multitude of symptoms, including carpal tunnel syndrome, tendon rupture, tendonitis, and trigger digits.

It should be remembered that RA is a systemic disease with multiple extra-articular manifestations. Rheumatoid nodules, vasculitis, pericarditis, pleural effusion, interstitial pulmonary disease, peripheral neuropathy, and keratoconjunctivitis sicca are some of the more common extra-articular effects of RA. Although rheumatoid nodules are present in only a minority of patients with RA, they are a common reason for presentation to the hand surgeon. Rheumatoid nodules develop secondary to the same autoimmune process that occurs in the joints. They occur most often on extensor surfaces or areas of contact pressure such as the olecranon process. However, they can appear anywhere, including within internal organs such as the lungs, heart, or central nervous system.[32]

Hints and tips

Diagnostic criteria for rheumatoid arthritis

Criterion	Details
1. Morning stiffness	1 h
2. Soft-tissue swelling	3 or more joints
3. Soft-tissue swelling	Symmetric
4. Soft-tissue swelling of hand	MCP, PIP, wrist joints
5. Subcutaneous nodules	Rheumatoid nodules
6. Seropositivity	Rheumatoid factor (RF)
7. Typical radiographic findings	Periarticular erosions/ osteopenia, hand or wrist

Four of the seven criteria must be present, and criteria 1–4 must be present for at least 6 weeks.

Fig. 19.3 PA radiograph of the left wrist, demonstrating early involvement of the DRUJ, as well as scattered carpal erosions from invasive synovitis.

Wrist involvement

Within the wrist and distal radioulnar joint (DRUJ), cartilage is degraded and bony erosions develop. Bony erosions occur first at sites of nutrient vessels and at the joint margins because there is no protective cartilage at these locations, thereby giving the invading pannus direct access to the bone.[33] Radiographic changes are first noted at the scaphoid waist, the ulnar styloid and the distal radioulnar joint (DRUJ) (Fig. 19.3).[34,35] As the arthritis progresses, the radiocarpal joint becomes involved. Bony destruction tends to be more severe at the radiocarpal joint than the mid-carpal joint, although both joints are often involved.[36] In late stages, the volar lip of the distal radius becomes severely eroded, allowing proximal migration, volar translation and volar angulation of the lunate, with compensatory mid-carpal extension (Figs. 19.4 & 19.5).[35,37]

The ligaments of the wrist and DRUJ are affected as well. As the pannus proliferates, it stretches and then directly invades the intrinsic and extrinsic wrist ligaments. Synovitis occurring at the scaphoid waist weakens the radioscaphocapitate ligament, leading to ulnar translocation of the carpus (Figs. 19.6 & 19.7).[38] Destruction of the scapholunate ligament leads to carpal instability, and further contributes to ulnar translocation of the carpus. At the DRUJ, pannus invades the triangular fibrocartilage complex (TFCC), including the dorsal and palmar radioulnar ligaments, resulting in DRUJ instability and eventually dorsal dislocation of the ulnar head. Pannus also destroys the extensor carpi ulnaris (ECU) subsheath, resulting in volar subluxation of the ECU.[39,40] The ECU's function as a wrist extensor and ulnar deviator is lost, contributing to supination and radial deviation of the carpus. The combination of dorsal dislocation of the ulnar head, carpal supination and volar subluxation of the ECU is termed the "caput ulnae" (Figs. 19.8 & 19.9).

Fig. 19.4 PA radiograph of the right wrist, demonstrating severe involvement of the wrist.

Fig. 19.5 Lateral radiograph of the right wrist, demonstrating destruction of the volar lip of the radius, with volar subluxation of the carpus.

Fig. 19.6 PA radiograph of the left wrist, demonstrating ulnar translocation of the carpus. Note that the lunate no longer sits in the lunate fossa.

End-stage wrist arthritis falls into three different clinical patterns, depending upon the degree of bony destruction and ligamentous instability.[41] These patterns are: (1) ankylosis; (2) arthritic stable; and (3) arthritic unstable (subdivided into ligamentous unstable and bony unstable). In the ankylosing wrist, the carpus undergoes autofusion. Frequently, ankylosis occurs with the wrist in acceptable alignment, although this is not always the case. In the arthritic stable wrist, the arthritis follows a pattern similar to that of osteoarthritis. Ligamentous

Fig. 19.7 PA radiograph of the right wrist, demonstrating even more severe ulnar translocation, and relative preservation of the mid-carpal joint as compared to the radiocarpal joint.

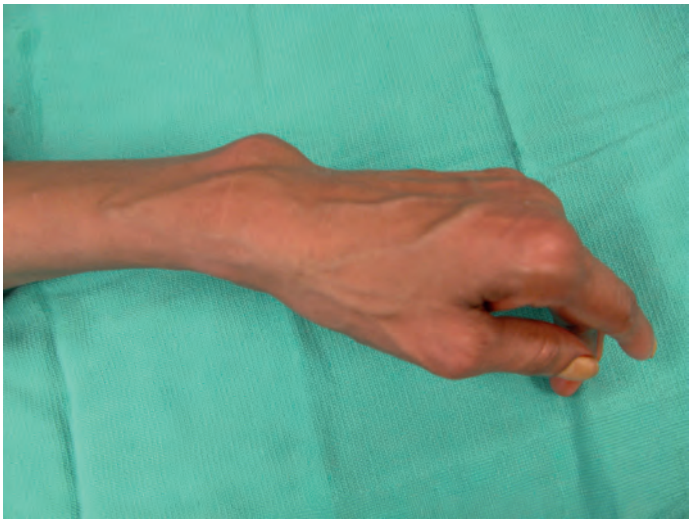

Fig. 19.8 Caput ulnae, with dorsal dislocation of the ulnar head and carpal supination.

Fig. 19.10 Extensor tenosynovitis protruding from under the extensor retinaculum distally.

destruction is limited, and the wrist remains stable over time. In the unstable wrist, there is progressive malalignment. In the ligamentous unstable wrist, bony destruction is minimal, whereas in the bony unstable wrist, there is severe loss of bone resulting in instability and eventually dislocation.

On the dorsal aspect of the wrist, synovitis develops within the extensor tendon compartments (Fig. 19.10). Depending upon the extent of the synovitis, there may be a bulge protruding beyond the distal and proximal margins of the extensor retinaculum, creating an hourglass appearance. Direct invasion of extensor tendons, combined with attritional wear over sharp bony edges at the ulna and DRUJ can lead to tendon ruptures. The extensor tendons to the small finger are usually affected first. Extensor tendon ruptures often progress radially, eventually affecting all digits. This ulnar to radial progression of extensor tendon ruptures is called the Vaughan-Jackson syndrome (Fig. 19.11).[42] Tendon ruptures are sudden, and may not be painful. They can be difficult to identify in patients with severe deformity, and must be differentiated from volar subluxation of the MCP joint, radial nerve palsy, and extensor tendon subluxation at the MCP joint. On the volar aspect of the wrist, sharp erosions on the scaphoid can result in attritional rupture of the flexor pollicis longus (FPL) tendon, known as a Mannerfelt lesion (Fig. 19.12).[43] Within the carpal tunnel, synovial pannus and tenosynovitis proliferate, creating a space-occupying lesion that results in carpal tunnel syndrome (Fig. 19.13).

Fig. 19.9 Lateral radiograph of the wrist, demonstrating a dorsally dislocated ulnar head.

Finger and thumb involvement

In the fingers the MCP and PIP joints are primarily affected, with relative sparing of the DIP joints. As cartilage is degraded,

Fig. 19.11 Patient with Vaughan-Jackson syndrome, demonstrating extensor tendon ruptures associated with a caput ulnae.

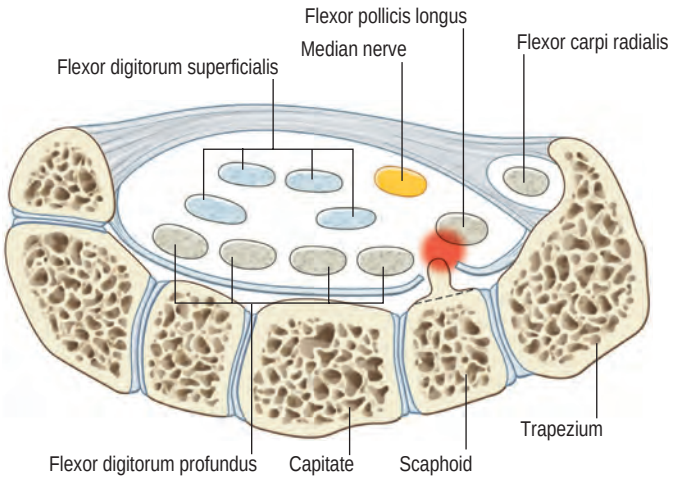

Fig. 19.12 Axial cross-section of the radial side of the wrist, demonstrating the Mannerfelt lesion. Note the proximity of the flexor pollicis longus tendon to the sharp erosion on the volar aspect of the scaphoid.

joint space narrowing is seen. Pannus invades at the margins of the joints, resulting in marginal bony erosions. The joint capsule and collateral ligaments are initially stretched and then directly invaded by the synovial pannus, resulting in instability and deformity.

At the MCP joints, the typical pattern of instability is volar subluxation and ulnar deviation, and is the result of multiple forces.[44,45] Synovitis at the MCP joint erodes the dorsoradial portion of the joint capsule early in the disease process, creating an early tendency towards ulnar deviation (Fig. 19.14) and volar subluxation (Fig. 19.15).[46,47] Radial deviation at the wrist creates an ulnar approach of the extensor tendons to the MCP joints, which further contributes to ulnar deviation (Fig. 19.16).[48] In addition, ulnar deviation forces during oppositional and key pinch stretch the dorsoradial portion of the capsule and the radial collateral ligament, particularly in the index and long fingers.[49] Finally, continued dorsoradial invasion of the pannus weakens the radial sagittal bands, causing ulnar subluxation of the extensor tendons between the metacarpal heads, which further increases ulnar deviation force on the MCP joints, and weakens extension power at the MCP joints (Fig. 19.17).[35,50]

Fig. 19.13 Large proliferative flexor tendon tenosynovitis.

Fig. 19.14 Ulnar deviation at the MCP joints (ulnar drift).

One of two patterns of finger deformity can occur: the swan-neck (Fig. 19.18) or boutonniere deformity (Fig. 19.19). Although swan-neck deformity is more common, either deformity can occur and both can occur in the same hand. Swan-neck deformity can originate from pathology at the MCP joint, the PIP joint, or the DIP joint (Fig. 19.20). At the DIP joint the terminal tendon insertion attenuates or erodes, resulting in a mallet finger. This causes an imbalance in the extensor mechanism, with increased extension force at the PIP joint. MCP flexion also contributes to increased pull of the central slip at the PIP joint. When these increased extension forces are combined with synovial disruption of the PIP volar plate, PIP hyperextension occurs, resulting in swan-neck deformity. Swan-neck deformity can originate at the PIP joint

Fig. 19.15 Radiograph of bilateral hands, demonstrating flexion and volar subluxation of the MCP joints.

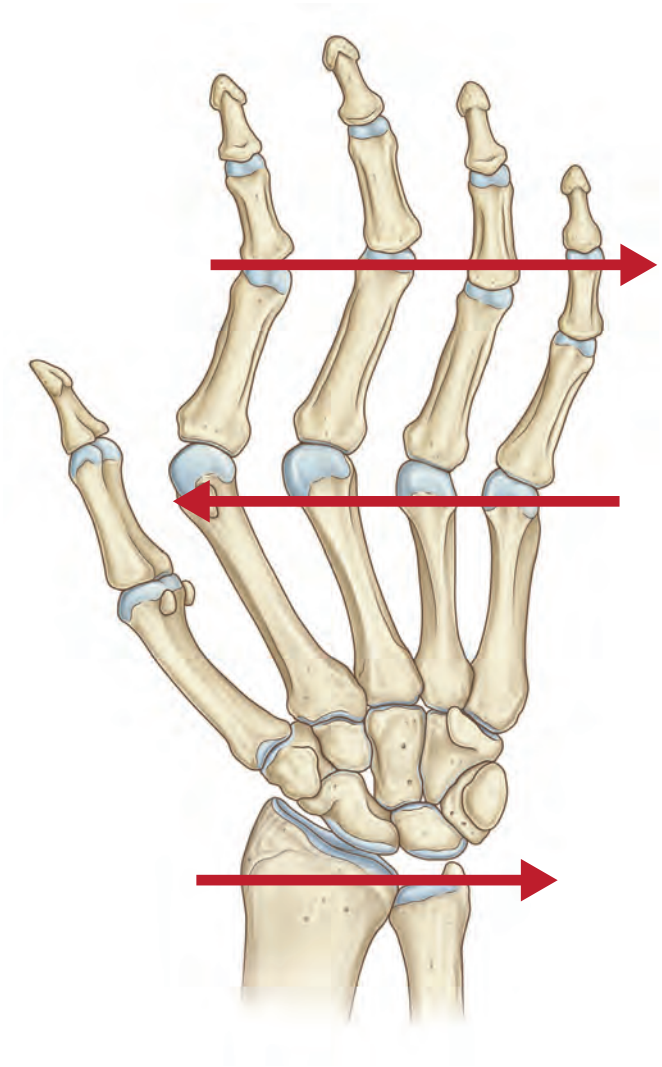

Fig. 19.16 Radial deviation and ulnar translocation at the wrist contribute to ulnar deviation at the MCP joints.

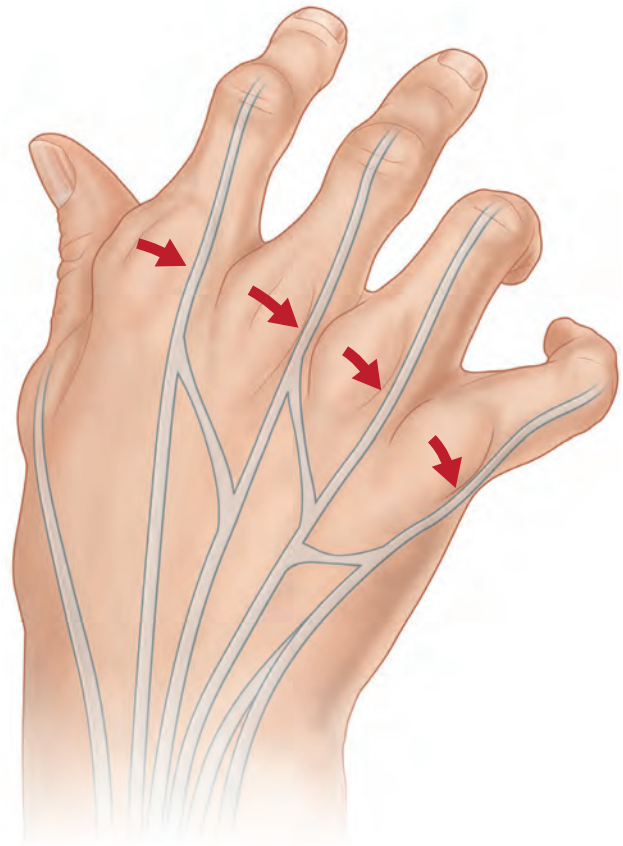

Fig. 19.17 The extensor tendons displace ulnarly and volarly into the space between the metacarpal heads, making them ineffective as MCP extensors, and adding to ulnar deviation force.

as well. Pannus stretches and erodes the volar plate and capsule, allowing hyperextension. Flexor tendon rupture may also contribute to a loss of flexion force at the PIP joint. The lateral bands slide dorsally, limiting PIP flexion. DIP joint flexion is a secondary phenomenon in this scenario, and is due to slack in the extensor mechanism combined with tightening of the flexor digitorum profundus (FDP) from PIP hyperextension. MCP pathology can initiate the development of swan-neck deformity as well. Flexed MCP position results in excessive pull through the extensor mechanism. The intrinsics also tighten over time, thereby hyperextending the PIP joint when MCP extension is attempted. The lateral bands also migrate dorsally, contributing to the deformity. The most debilitating result of swan-neck deformities is loss of flexion at the PIP joints, resulting in an inability to flex the fingers for pinching and grasping.

Boutonniere deformities are usually less debilitating than swan-neck deformities, because pinch and grasp are usually preserved. Unlike swan-neck deformities, boutonniere deformities always begin with pathology at the PIP joint (Fig. 19.21). The initial insult is stretching, erosion, and rupture of the central slip insertion on the base of the middle phalanx. Attenuation of the dorsal capsule, transverse retinacular ligament and triangular ligament allows the lateral bands to sublux volar to the joint axis of rotation, becoming PIP flexors. The volar position of the lateral bands makes them even more effective extensors of the DIP joint, resulting in secondary DIP hyperextension.

Fig. 19.18 Classic swan-neck deformities of all fingers, with MCP flexion, PIP hyperextension, and DIP flexion.

Fig. 19.19 Boutonniere deformity of the right ring and small fingers, and left small finger. Left ring finger demonstrates very early boutonniere deformity.

Synovitis also develops within the flexor tendon sheath, and can lead to triggering or rupture of the flexor tendons. Trigger digits associated with RA are distinct in mechanism and pathology from nonrheumatoid trigger digits, and occur secondary to synovitis or small rheumatoid nodules in the flexor tendon.[51] The specific location of the synovitis or rheumatoid nodules determines the presentation of the rheumatoid trigger finger. A nodule located proximal to the A1 pulley may present like a typical nonrheumatoid trigger finger with locking in flexion, or triggering during extension. A nodule just distal to the A2 pulley can result in the finger locking in extension, or triggering during flexion. Diffuse tenosynovitis or multiple nodules can result in swelling and loss of flexion and extension.[52,53]

The rheumatoid thumb deformity can be organized into five categories. Type I, the most common, is a boutonniere deformity with MCP flexion, IP hyperextension, and radial abduction of the metacarpal (Fig. 19.22). Deformity begins when synovial pannus at the MCP joint erodes dorsally, attenuating and eventually rupturing the extensor pollicis brevis (EPB) tendon insertion, and displacing the extensor pollicis longus (EPL) ulnarly and volarly. Because of the loss of dorsal capsule and the loss of the EPB, the MCP joint flexes and subluxates volarly. Hyperextension at the IP joint occurs secondarily, and can be exacerbated in patients with an FPL rupture. Type III rheumatoid thumb deformity is a swan-neck deformity, and is the second most common deformity, presenting with MCP hyperextension, IP flexion, and metacarpal adduction contracture. This deformity begins at the carpometacarpal (CMC) joint, with attenuation of the volar beak ligament. As the CMC joint subluxates or dislocates, metacarpal adduction occurs in a similar fashion to nonrheumatoid CMC arthritis. MCP joint hyperextension occurs secondarily as the thumb compensates for the adducted metacarpal, and is exacerbated by volar plate attenuation or erosion from pannus invasion.

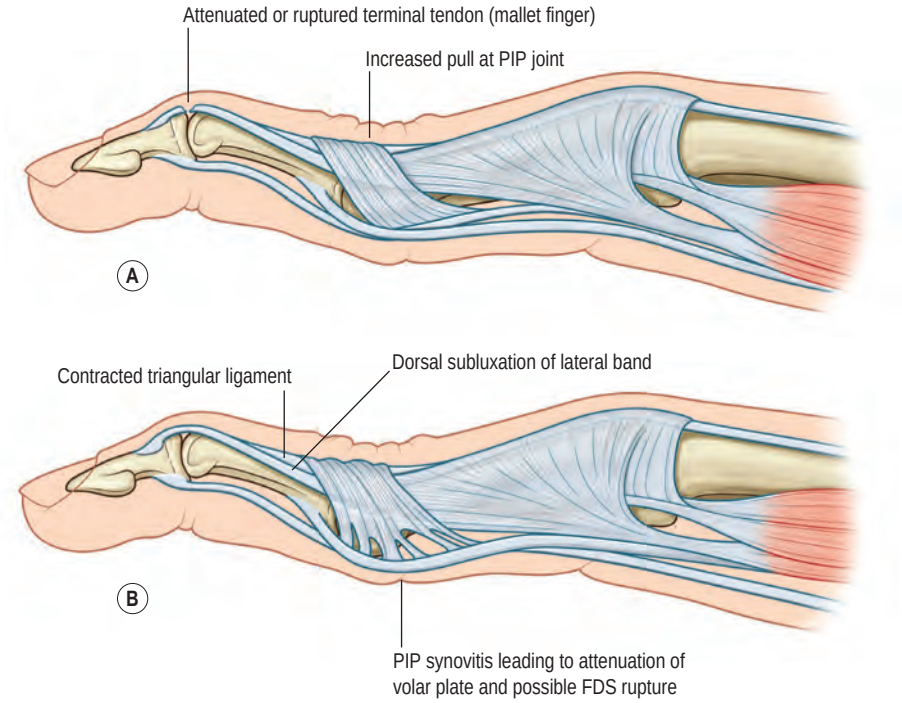

Fig. 19.20 **(A)** Swan-neck deformity originating from a mallet finger, with subsequent increased extension force at the PIP joint. **(B)** Swan-neck deformity originating at the PIP joint, with volar plate attenuation and possible FDS rupture due to PIP synovitis, and subsequent dorsal subluxation of the lateral bands.

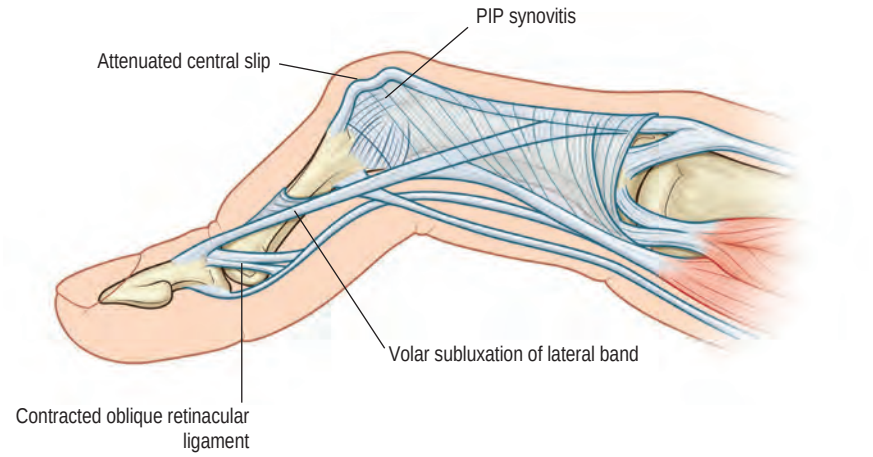

Fig. 19.21 Boutonniere deformity secondary to synovitis at the PIP joint, with attenuation of the central slip, and subsequent volar subluxation of the lateral bands.

Types II, IV, and V are less common, but do occur. Type II rheumatoid thumb includes MCP flexion and IP extension, but unlike a type I boutonniere deformity, there is dislocation or subluxation at the CMC joint. Type IV is a gamekeeper's deformity secondary to synovial pannus destruction of the ulnar collateral ligament. Type V is MCP hyperextension, and compensatory flexion at the IP joint, similar to a swan-neck deformity (type III) but without metacarpal adduction contracture.

Patient selection

Perioperative considerations

Care must be taken during the preoperative workup of RA patients, because many unique problems can impact the safety and timing of surgery. Airway management can be quite difficult. Temporomandibular joint arthritis can limit oral opening, making intubation difficult. Glottic narrowing can also occur due to inflammation or arthritis of the cricoarytenoid joints, creating further difficulty with airway management.[54] Atlantoaxial instability is another concern, and is quite common in patients with RA. Flexion of the neck during intubation in patients with significant instability can cause spinal cord injury or death. Therefore, preoperative cervical spine flexion–extension radiographs should be obtained in all rheumatoid patients preoperatively. Fiberoptic intubation with the patient in a cervical collar is recommended in patients with atlantoaxial instability.[55]

Cardiac function can be affected as well. Pericardial effusion, constrictive pericarditis, or conduction block can occur secondary to RA. In addition, RA patients are at increased risk for coronary artery disease. Pulmonary involvement may include rheumatoid nodules, pleural effusion, and interstitial disease. Patients with long-standing disease are at risk for Felty's syndrome, a combination of splenomegaly, neutropenia, and secondary thrombocytopenia. For the above reasons, RA patients undergoing surgery should have a thorough preoperative anesthesia evaluation including an EKG, metabolic panel, complete blood count and differential, chest X-ray, and cervical spine radiographs.

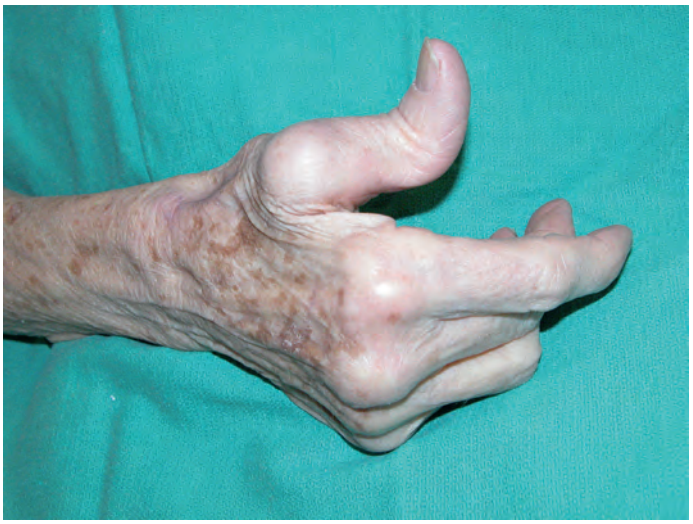

Fig. 19.22 Boutonniere deformity of the thumb.

Hints and tips

- Preoperative anesthesia clinic visit for all, regardless of general medical condition
- C-spine radiographs, including lateral flexion and extension views
- 12-lead EKG
- Chest X-rays
- Complete blood count (CBC) with differential
- Metabolic panel

Goals of surgery

The goals of surgery in RA patients are pain relief, improvement of function, prevention of progression, and improvement of appearance. In general, pain relief can be accomplished reliably by arthrodesis or arthroplasty. Because of this, pain is the primary indication for surgery in the rheumatoid patient. Improvement of function is less reliably accomplished, and

although important, is a secondary indication for surgery. It is important to remember that deformity does not equal loss of function. Many patients have little pain and are able to function quite well in spite of severe deformity. These patients may not benefit from surgery. Slowing the progression of disease is a third priority, and is less often required in the era of effective DMARDs. However, in some situations, surgery is required to prevent progression of disease. For example, a Darrach procedure (resection of the distal ulna) and dorsal tenosynovectomy in the setting of an extensor tendon rupture can prevent or delay additional extensor tendon ruptures. Appearance is considered a last priority. However, aesthetic considerations should not be discounted as these issues are important to RA patients.

Sequence of surgery

In general, proximal problems within the upper extremity should be corrected first, particularly if they affect more distal problems. For example, wrist surgery should be performed prior to finger surgery, because the deformity at the wrist exacerbates the finger deformity. In practice however, the sequence of surgery may be dictated by patient preference. For example, a patient with severe swan-neck deformities and a pain-free but ulnarly subluxated wrist may not accept the idea of wrist surgery before correcting the finger deformity. Another consideration is the mobility of the patient. Many RA patients use crutches or canes for ambulation, or may even be confined to a wheelchair, resulting in a loss of mobility during the recovery period after hand surgery. The surgeon should discuss these issues with the patient preoperatively so that preparations can be made.

Treatment/surgical technique

Operations at the wrist

Wrist synovectomy/dorsal tenosynovectomy

A minority of patients will have persistent wrist synovitis or dorsal tenosynovitis that is painful and unresponsive to at least 6 months of maximal medical treatment. Wrist synovectomy and/or dorsal tenosynovectomy may be effective in improving pain in these patients.[56,57] Whether this significantly slows the progression of disease is unknown.

A midline longitudinal incision is made over the dorsal wrist, and skin flaps are elevated at the level of the extensor retinaculum, preserving the radial and ulnar sensory nerves that lie within the subcutaneous tissue. If there is a large amount of synovitis, it can be seen deep to the attenuated extensor retinaculum (Fig. 19.23). The extensor retinaculum is incised along the radial border of the first extensor compartment, leaving enough substance intact for later closure. The retinaculum is elevated in an ulnar direction to, but not into the sixth extensor compartment, exposing the extensor tendons. The extensor retinaculum is often very attenuated, and care should be taken to preserve its integrity during elevation. Extensor tenosynovectomy is then performed. Working systematically, each extensor tendon is retracted individually and synovium is excised with curved tenotomy scissors (Fig. 19.24).

Fig. 19.23 Extensor tenosynovitis of the right wrist, with severely attenuated extensor retinaculum.

Clinical tip

- Always be prepared to perform tendon transfers when you are doing a tenosynovectomy.
- Ruptured tendons may be held together by thick pannus and adhesions.
- Be sure to talk to tenosynovectomy patients about the possibility of tendon transfer.

After completing the extensor tenosynovectomy, a posterior interosseous neurectomy may be performed to improve pain relief. The posterior interosseous nerve is identified on the floor of the fourth extensor compartment and a 2-cm segment is excised, with cauterization of the proximal stump.

If painful wrist synovitis is present, a ligament-sparing capsulotomy is made. Synovial pannus is identified at the radiocarpal and mid-carpal joints. With the wrist flexed and distracted, a synovial rongeur is used to remove all synovium

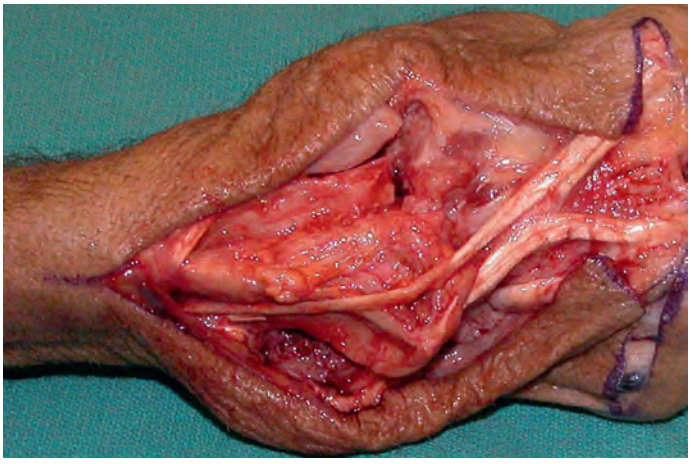

Fig. 19.24 The extensor tenosynovitis has been partially removed. Note the redundancy of the extensor tendons, which have been stretched by the long-standing tenosynovitis.

Fig. 19.25 One retinacular flap (the distal half of the retinaculum) has been placed deep to the extensor tendons to protect them from rough bony surfaces. The other flap (the proximal half of the retinaculum) has been sutured dorsal to the extensor tendons to prevent bow-stringing.

within the radiocarpal and mid-carpal joints. Any sharp edges are smoothed with a curette or rongeur. If DRUJ synovitis is present, a longitudinal incision is made over the DRUJ, in the floor of the fifth extensor compartment. This incision can be extended 90° ulnarly just proximal to the TFCC if necessary for additional exposure. Pronation also improves exposure of the DRUJ. Synovial pannus is removed with a synovial rongeur. Sharp bony edges are smoothed with a rongeur to prevent tendon ruptures. The capsulotomy incisions are closed with 3-0 absorbable suture.

If any rough bony surfaces remain exposed after closure of the capsule, the retinaculum can be divided transversely, creating two ulnarly based retinacular flaps. One flap is sutured deep to the extensor tendons, covering the exposed bony surfaces. The other retinacular flap is closed dorsal to the extensor tendons, leaving the EPL transposed (Fig. 19.25). Alternatively, if the ECU tendon is subluxated volarly, the retinaculum can be used to stabilize it. The ECU tendon is synovectomized and relocated to its normal position dorsal to the ulna. Half of the retinacular flap is placed deep to the ECU tendon, then wrapped back dorsally and radially and sutured to itself at the border of the fifth extensor compartment, securing the ECU dorsal to the wrist axis of rotation.

Clinical tips

- In some cases, the extensor retinaculum is attenuated and cannot be used to pad rough surfaces.
- Be sure to have acellular dermal matrix (dermal allograft) available for padding if needed.

Postoperative care

The wrist is immobilized for 2–3 weeks, followed by initiation of motion. If the DRUJ was debrided a sugar-tong splint should be used to prevent forearm rotation. If the wrist or DRUJ is unstable prior to surgery, a longer period of mobilization may be required.

Outcomes, prognosis, and complications

Synovectomy of the wrist or DRUJ usually relieves pain, but recurrence of synovitis is the rule rather than the exception, although the rate at which synovitis recurs is variable. Whether wrist synovectomy significantly alters the course of the disease is not known. Dorsal tenosynovectomy on the other hand likely prevents or delays the occurrence of extensor tendon ruptures.

Secondary procedures

If the patient develops recurrent painful synovitis after wrist joint synovectomy, a definitive wrist procedure such as arthrodesis may be indicated.

Hints and tips

- Allow at least 6 months of maximized medical treatment prior to considering surgery.
- Concomitant PIN neurectomy may improve pain relief.
- Ensure that all rough bony surfaces are smoothed and covered with soft tissue.

Distal ulna resection (Darrach procedure)

Distal ulna resection may be indicated for painful DRUJ instability, painful destruction of the DRUJ, or caput ulna syndrome with extensor tendon ruptures. It can be performed in isolation, but is often combined with extensor tenosynovectomy, extensor tendon repairs or tendon transfers, wrist arthrodesis, or wrist arthroplasty.

If performed in isolation, a 3-cm longitudinally oriented chevron incision is made over the dorsal aspect of the ulnar head (Fig. 19.26). If combined with another wrist procedure, skin flaps and retinacular flaps are elevated, and extensor tenosynovectomies are performed as described above. A longitudinal incision is made in the floor of the fifth extensor compartment, with a 90° extension ulnarly just distal to the head of the ulna, and just proximal to the TFCC. Although it

Fig. 19.26 Chevron incision made directly over the ulnar head, with skin flaps elevated and extensor retinaculum exposed.

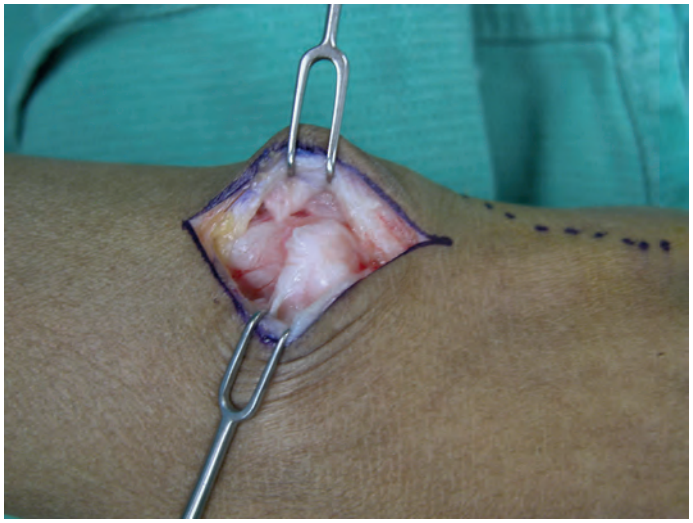

Fig. 19.27 The DRUJ and ulnar head have been exposed through an incision in the floor of the fifth extensor compartment.

Fig. 19.28 The ulnar head has been removed. The distal end of the stump will be beveled dorsally.

is often destroyed, when the TFCC is present, it should be preserved. The capsule is elevated off the ulnar head, and the ulnar head and neck are dissected subperiosteally with a 15-blade and Freer elevator (Fig. 19.27). The ECU is usually subluxed volarly, and is elevated off the ulna during subperiosteal dissection. Hohmann retractors are used to provide exposure of the neck and head of the ulna. Once the ulnar head and neck have been exposed circumferentially, a sagittal saw is used to create a transverse osteotomy at the neck of the ulna, at the level of the proximal margin of the sigmoid notch of the radius. Any remaining soft-tissue attachments are released, and the ulnar head is removed (Fig. 19.28). The dorsal edge of the ulnar stump is then beveled with the sagittal saw, and rasped smooth to prevent tendon abrasion and rupture. Any remaining synovial pannus can now be easily accessed, and is debrided with a synovial rongeur.

Prior to closure, the ulnar stump should be stabilized and the normal relationship between the ulna and the carpus should be re-established or improved. The pronator quadratus is elevated subperiosteally from the volar ulnar aspect of the ulna, leaving its attachment to the radius intact. It is important to keep the periosteum attached to the pronator quadratus. It is then delivered through the interosseous space and draped dorsally over the ulnar stump. The ulna is reduced volarly. While maintaining the ulnar stump in reduction, the pronator quadratus and its periosteum are sutured securely to the dorsal aspect of the ulnar stump, using bone anchors if necessary (Fig. 19.29). In this position, the pronator quadratus serves as a buffer against impingement between the radius and ulna, and also helps prevent dorsal subluxation of the ulna.

Alternatively, a distally based slip of the ECU is elevated. The DRUJ capsule and periosteal flaps are closed with

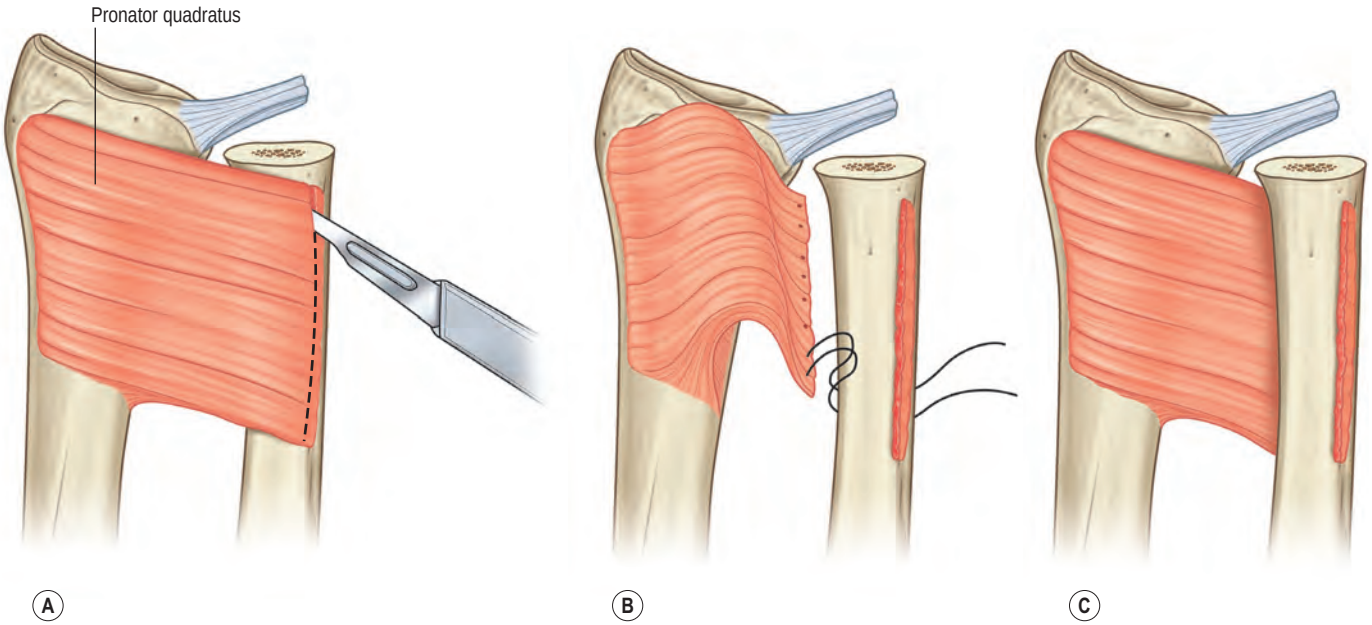

Fig. 19.29 The pronator quadratus is released from the volar aspect of the ulna, passed through the interosseous space, and sutured to the dorsal aspect of the ulna.

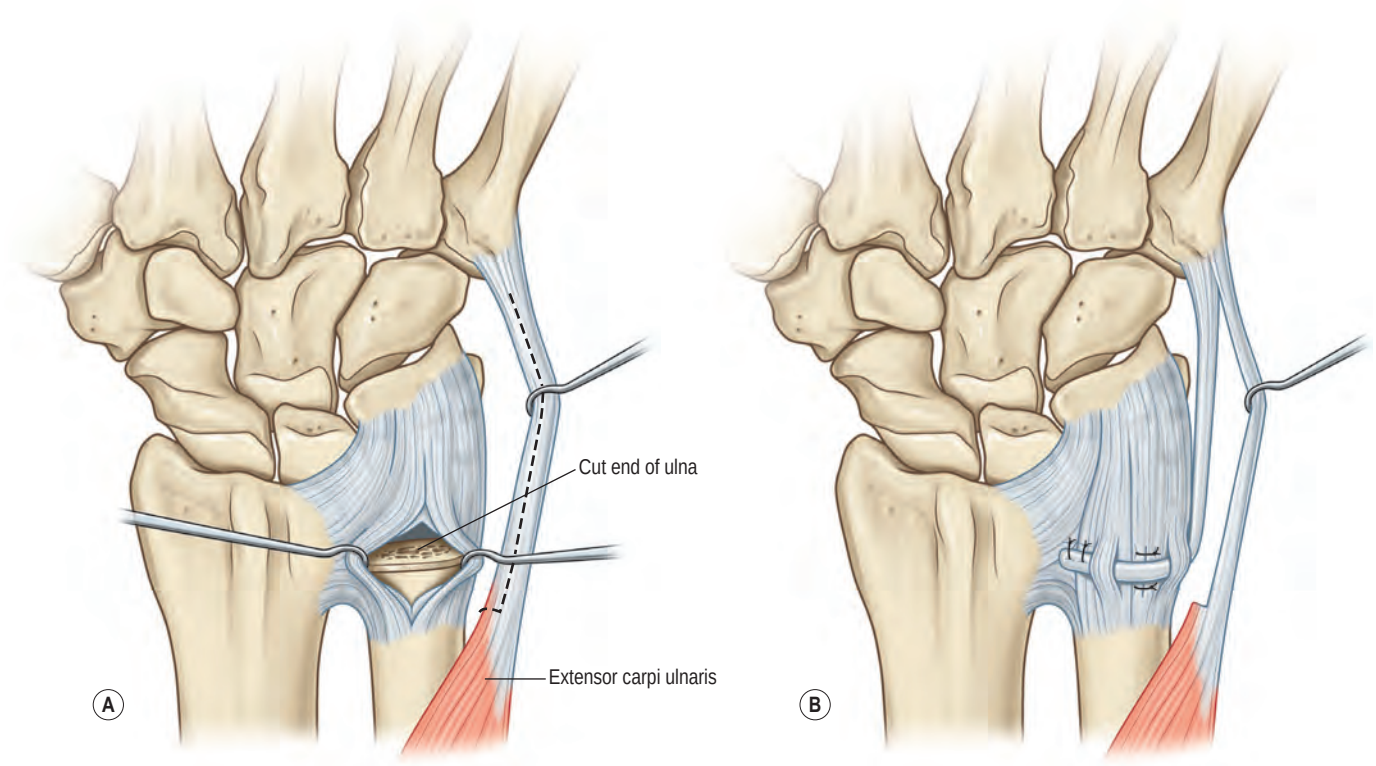

Fig. 19.30 Distally based slip of ECU is used to stabilize the ulnar stump.

non-absorbable sutures, and are imbricated tightly with the ulna reduced volarly. The slip of ECU is then woven through the capsule at the distal end of the ulna, and is then sutured to the dorsal ulnar aspect of the radius. This sling helps stabilize the ulnar stump, and also reduces carpal supination (Fig. 19.30). Pre- and postoperative radiographs are shown in Fig. 19.31.

Postoperative care

The patient is placed in a sugar-tong splint in supination for 2–3 weeks prior to allowing wrist motion and forearm rotation. If a tendon transfer is done, the patient should be splinted for 4 weeks.

Fig. 19.31 Pre- and postoperative radiographs demonstrating resection of the ulnar head.

Outcomes, prognosis, and complications

One potential complication after distal ulna resection is extensor tendon rupture due to attrition over the sharp dorsal edge of the osteotomy. This is prevented by beveling and rasping down the dorsal edge of the osteotomy, and by performing a soft tissue stabilizing procedure at the time of the Darrach procedure, in order to minimize dorsal subluxation of the ulnar stump. Another potential complication is painful radio-ulnar convergence and impingement, which tends to occur during loading. Again, stabilization and/or padding of the distal ulna at the time of Darrach procedure as described above helps to minimize this.

Secondary procedures

Persistent painful instability or radio-ulnar impingement may be treated with a soft-tissue stabilization procedure using the ECU as described above. Alternatively, ulnar head implant arthroplasty may be considered to salvage the failed Darrach complicated by painful radio-ulnar impingement.

Hints and tips

- Create a dorsal bevel after making the transverse osteotomy, and smooth with a rasp to prevent attrition ruptures.
- Distal ulna resection should be performed at the time of extensor tendon transfers if the distal ulna was the source of extensor tendon rupture.
- A stabilizing procedure should be performed to decrease recurrent dorsal subluxation, minimize radioulnar convergence, and reduce carpal subluxation.

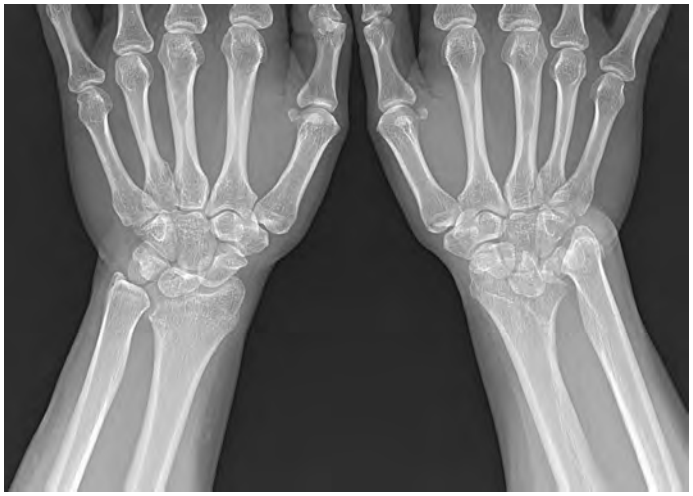

Fig. 19.32 Bilateral wrist radiographs demonstrating severe involvement of the radio-carpal joint, and relative sparing of the mid-carpal joint.

Partial wrist arthrodesis (radioscapholunate arthrodesis)

In some rheumatoid wrists, the radiocarpal joint becomes arthritic with relative preservation of the mid-carpal joint (Fig. 19.32). In these patients, radioscapholunate arthrodesis may be indicated to treat refractory pain secondary to radiocarpal arthritis. Patients should understand that they will lose approximately 60% of wrist flexion–extension, depending upon the quality of the mid-carpal joint. In addition, patients should be consented for the possibility of complete wrist arthrodesis if the mid-carpal joint is found to be substantially arthritic at the time of surgery.

The skin and retinacular incisions are the same as described above. Extensor tenosynovectomies are performed if required, and a posterior interosseous neurectomy is performed. An H-shaped capsulotomy is made, exposing the radiocarpal and mid-carpal joints. Radiocarpal and mid-carpal synovectomies are performed. The quality of the mid-carpal joint is assessed, and the decision to proceed with radiocarpal fusion versus complete wrist fusion is made. The radiocarpal joint is assessed as well. In some cases, the radioscaphoid articulation is preserved, allowing the surgeon to perform a radiolunate fusion, although in most instances the entire radiocarpal joint is arthritic. With the wrist flexed and distracted, a rongeur is used to remove the remaining articular cartilage and subchondral bone from the distal radius and the proximal articular surfaces of the lunate and scaphoid. The articular surfaces are prepared in this manner until bleeding cancellous bone is encountered. During joint surface preparation, the matching concave–convex surfaces of the radiocarpal joint should be preserved. The carpus is then reduced by maneuvering the lunate into neutral flexion–extension, correcting any scapholunate gap, and correcting ulnar translocation if present. The use of 0.062-inch K-wires as joysticks may be necessary for reduction. The scaphoid and lunate are temporarily held in reduction with 0.062-inch radiocarpal K-wires, and a mini c-arm is used to confirm carpal alignment. Next, the distal pole of the scaphoid is resected in order to improve mid-carpal motion. A transverse osteotomy is made at the proximal margin of the distal pole of the scaphoid using a reciprocating saw. The distal pole is then removed piece-meal with a rongeur.

Autologous cancellous bone graft is packed into the fusion site. This should be obtained from the iliac crest, or from the resected distal pole of the scaphoid and from the distal ulna if a Darrach procedure has been performed. Bone graft should not be harvested from the distal radius, as this reduces the stability of the radioscapholunate fixation. Fixation is achieved with headless compression screws that are inserted into the dorsal aspect of the distal radius, and driven distally and volarly into the scaphoid and lunate. Three or four compression screws are used, with two passing from the radius into the scaphoid, and one or two passing from the radius into the lunate (Fig. 19.33). It is usually necessary to back out the temporary fixation K-wires in order to achieve compression. In addition, in order to achieve even compression when two screws are placed across one articulation, the screws should be simultaneously advanced. After screw placement, final c-arm views are used to confirm carpal alignment and screw position. The mid-carpal joint is directly examined to ensure that there is no screw penetration. If there is any concern about the stability of the fixation, supplemental K-wires can be placed. If the bone quality is too poor to support compression screws, as it often is in patients with rheumatoid arthritis, fixation can be performed with K-wires alone (Fig. 19.34). Other alternatives for fixation include staples or a T-shaped plate. The capsule is closed and the extensor retinaculum is closed with the EPL transposed.

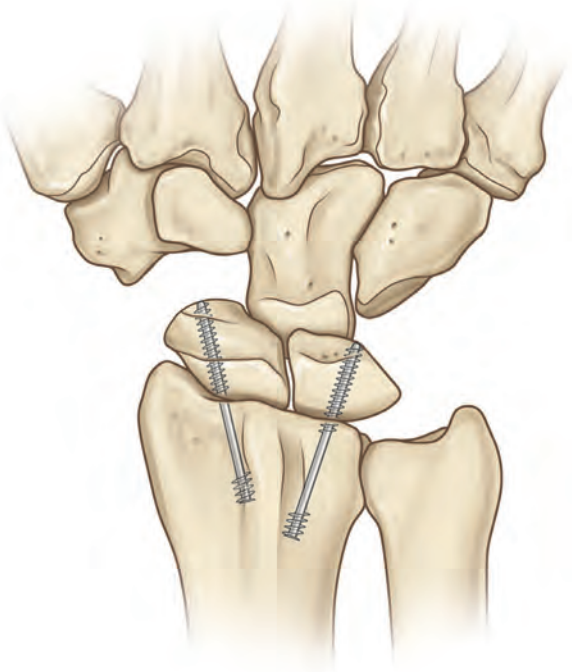

Fig. 19.33 Radiocarpal arthrodesis, with compression screws. The distal pole of the scaphoid is resected to preserve mid-carpal motion. Triquetrum excision is optional.

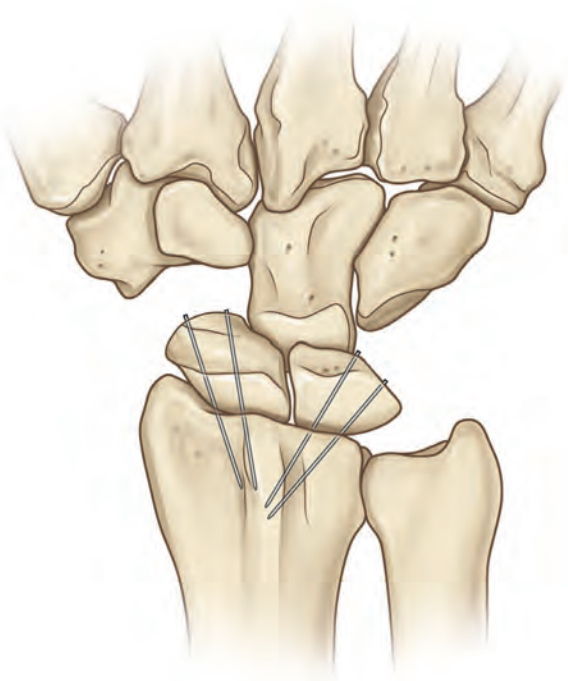

Fig. 19.34 Radiocarpal arthrodesis with K-wires.

Fig. 19.35 Wrist arthrodesis with fusion plate. Use of a plate and screws is limited to patients with good bone quality.

Postoperative care

The wrist is immobilized until bony union occurs. Active and passive range of motion and strengthening exercises are initiated after bony union occurs.

Complete wrist arthrodesis

Complete wrist arthrodesis is an effective treatment for the painful and unstable wrist. However, the loss of wrist motion after complete arthrodesis can cause significant functional difficulty, particularly if the patient has a stiff contralateral wrist. Because of this, it should be reserved for patients with recalcitrant pain or debilitating instability or malalignment, in spite of maximum medical management, steroid injections, and wrist splinting.

In patients with high quality bone, a dorsal wrist fusion plate or headless compression screws can be used (Figs. 19.35 & 19.36). However, if bone quality is poor, Steinmann pin fixation may be performed.[58,59] The wrist is exposed as described above for radioscapholunate fusion. If indicated, a Darrach procedure is performed as described above. The radio carpal and mid-carpal joints are exposed. With the wrist flexed and distracted, a synovial rongeur is used to debride synovial pannus, allowing access to the articular surfaces. A rongeur is then used to remove articular cartilage and subchondral bone from the opposing articular surfaces, until bleeding cancellous bone is encountered (Fig. 19.37). A small Steinmann pin is drilled retrograde into the radius in order to create a track for the final Steinmann pin. The starting point on the radius is chosen carefully, in order to allow the Steinmann pin to pass directly into the isthmus of the medullary canal without any angulation. The correct starting point is usually in the dorsal half of the radius articular surface, and near the interval between the scaphoid and lunate fossae. Fluoroscopy is used to confirm the position of the Steinmann pin. The small Steinmann pin is removed and exchanged for the largest diameter Steinmann pin that will fit into the medullary canal of the radius. The large Steinmann pin is removed from the radius and then it is drilled antegrade through the carpus, exiting the carpus at the 2nd or 3rd intermetacarpal space, and exiting the skin between the MCP joints. With the radius and carpus reduced, the Steinmann pin is tapped retrograde back into the radius, and through the isthmus of the medullary canal (Fig. 19.38). It is cut distally at the skin, and then tapped 2–3 cm proximal to the level of the skin. If necessary, additional fixation with temporary K-wires can be used. Cancellous autograft is packed into the radiocarpal and mid-carpal joints. The

Fig. 19.36 Wrist arthrodesis with headless compression screws in a patient with good bone quality.

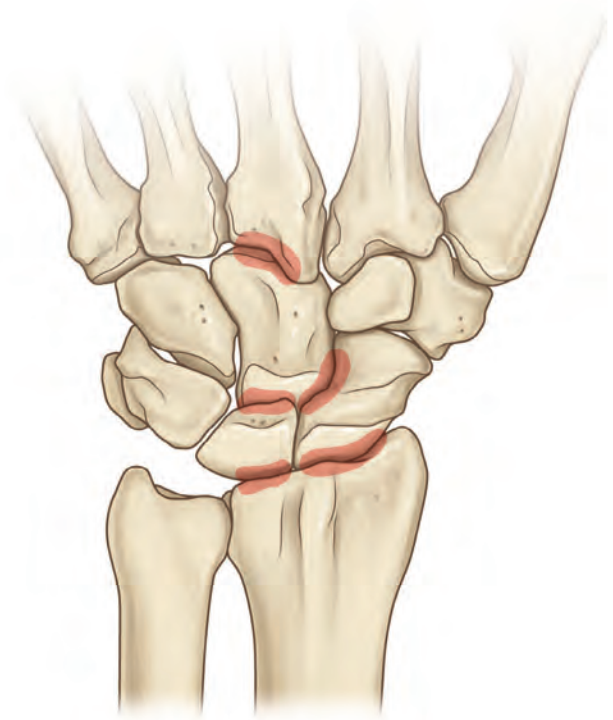

Fig. 19.37 Shaded areas represent the articulations that should be prepared for a complete wrist arthrodesis.

capsule is closed with 3-0 absorbable sutures, and the retinaculum and skin are closed as described above. The wrist is immobilized until union occurs.

An alternative is to use two smaller Steinmann pins. The technique is similar to that described above, except that one pin passes through the second intermetacarpal space, and one passes through the third intermetacarpal space. An oblique K-wire can be added to augment the fixation. The pins are cut deep to the skin, and can be removed after bony union is achieved (Figs. 19.39 &, 19.40). If future MCP arthroplasty is planned, and there is no reason to preserve the articular surface of the metacarpal head, one pin can be advanced through the medullary canal of the long finger metacarpal, exiting the metacarpal head distally, and then tapped proximally into the radius after reduction. If a Steinmann pin is placed in the medullary canal of the long finger metacarpal, it should be tapped proximally to allow enough room for future MCP arthroplasty (Figs. 19.41 & 19.42). As noted above, in patients with high quality bone, a dorsal wrist fusion plate can be used. These plates allow compression across the wrist, and result in very stable fixation.

Postoperative care

The wrist is immobilized until bony union occurs.

Outcomes, prognosis, and complications

Limited or complete wrist arthrodesis reliably treats pain in RA when used for appropriate indications. Although the complication rate is less than that for total wrist arthroplasty, minor complications such as delayed skin healing, prominent hardware, tendon irritation, neurapraxia, and pin-site issues are not uncommon. Potential major complications include infection, loss of fixation, and nonunion. A deep infection requires hardware removal, serial debridement, and intravenous antibiotics. Nonunion, if it occurs, may or may not be symptomatic.

Secondary procedures

In some cases prominent hardware requires removal. Unless there is an indication for more urgent removal, this should be delayed for a year after union is achieved. After hardware removal, the wrist should be protected in a splint or cast for a minimum of 6 weeks.

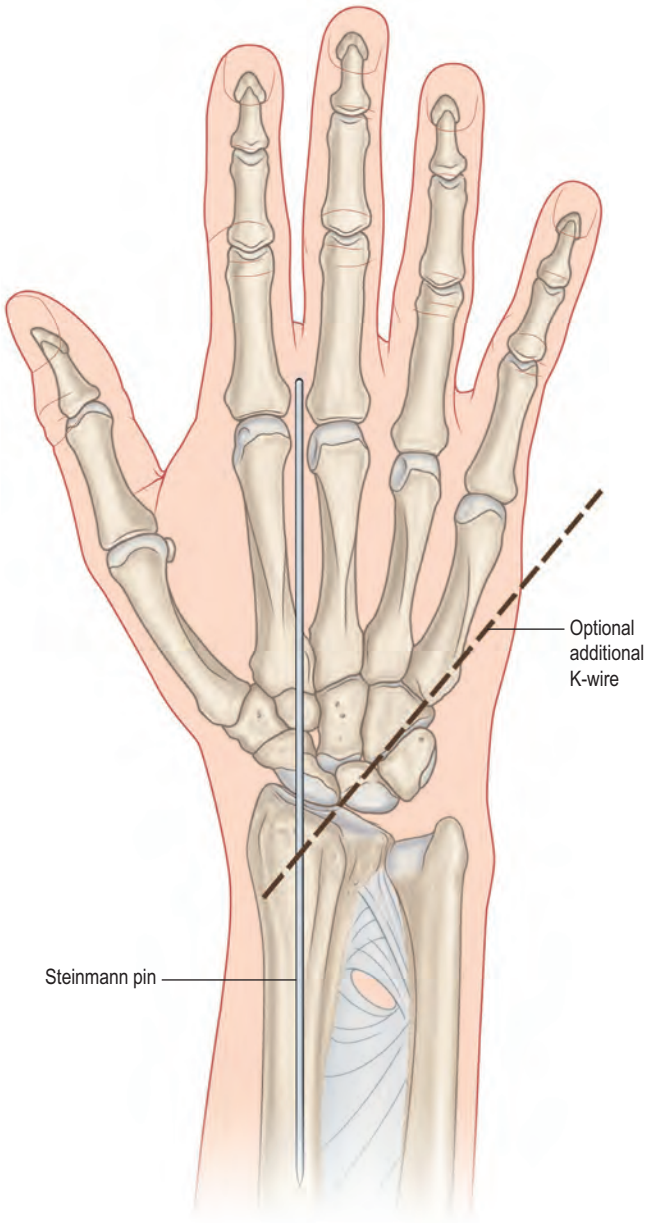

Fig. 19.38 Wrist arthrodesis with a single Steinmann pin. The pin exits the carpus in the second intermetacarpal space, and is cut just below the skin for later removal. The oblique K-wire is optional.

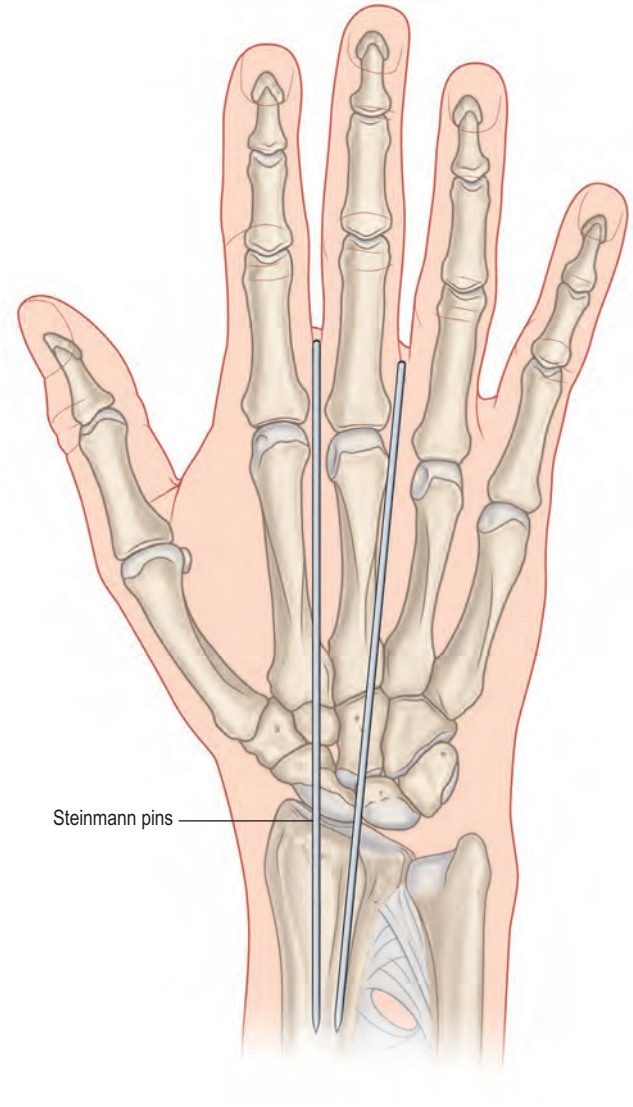

Fig. 19.39 Wrist arthrodesis with two Steinmann pins. The pins exit the carpus in the second and third intermetacarpal spaces, and are cut just below the skin for later removal.

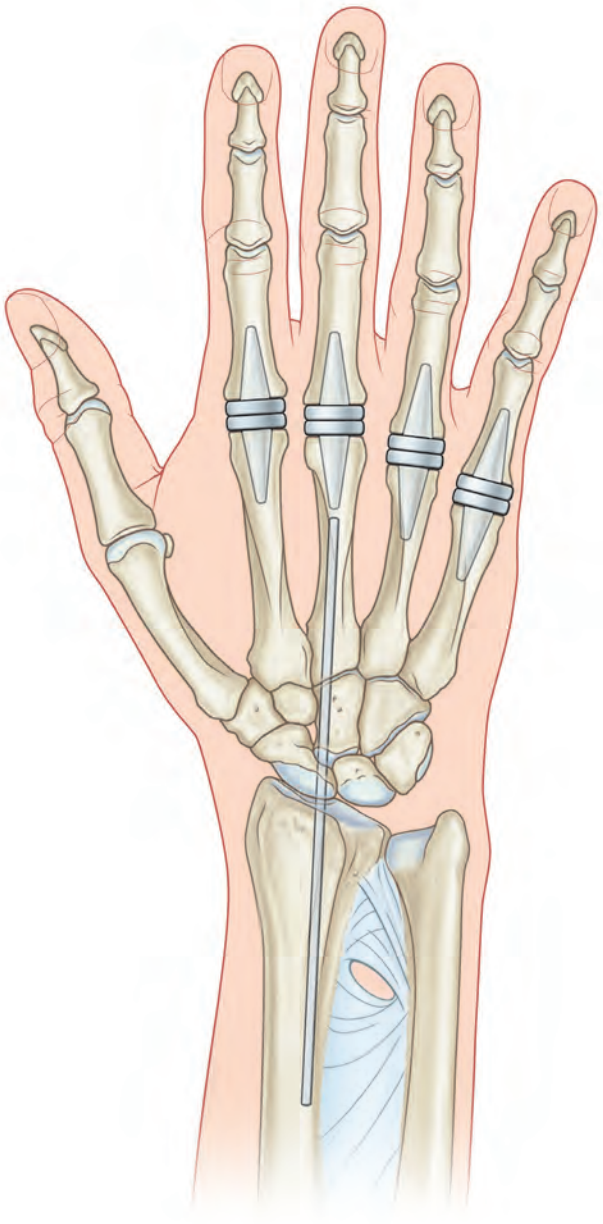

Fig. 19.41 Wrist arthrodesis with a single Steinmann pin placed in the medullary canal of the long finger metacarpal. Note that the length of the Steinmann pin should not prohibit future MCP arthroplasty.

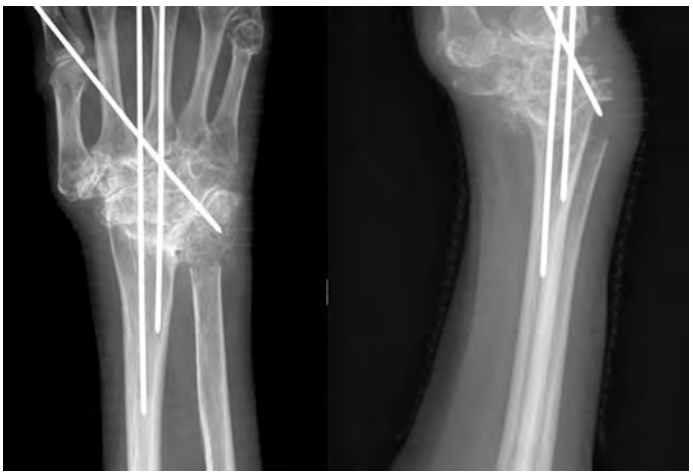

Fig. 19.40 Wrist arthrodesis with two longitudinal Steinmann pins, and a third oblique pin for added fixation.

Hints and tips

- Resection of all cartilage and subchondral bone, with exposure of bleeding cancellous bone, is critical in order to achieve union.
- Compression screw or plate and screw fixation should be used only if bone quality is good, otherwise K-wires or Steinmann pins may be used for fixation.
- Assessment of bony union may be difficult with plain radiographs. In this situation, computed tomography (CT scan) is ideal for confirming union.

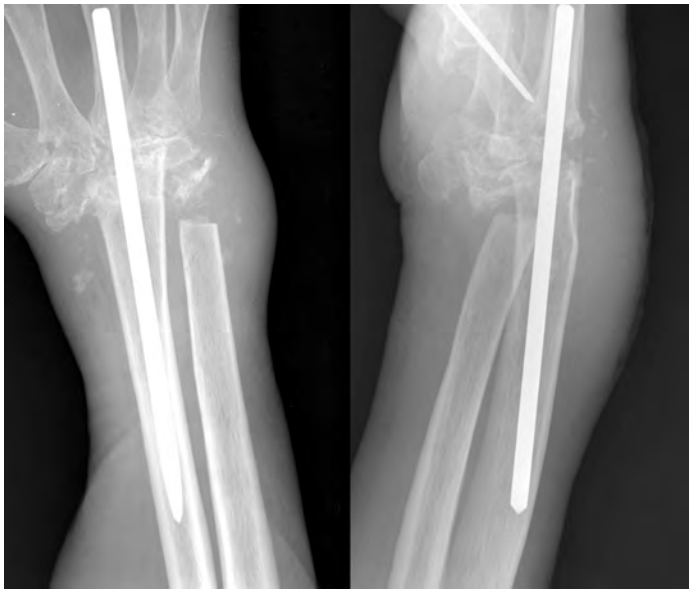

Fig. 19.42 PA and lateral radiographs demonstrating wrist arthrodesis performed with a single intramedullary pin. Note the large caliber of pin required to fill the medullary canal of the radius.

Total wrist arthroplasty

Total wrist arthroplasty is effective at relieving pain in patients with rheumatoid wrist arthritis. However, in spite of recent advances, wrist arthroplasty is associated with a high complication rate. In order to minimize complications such as loosening, migration, and dislocation, wrist arthroplasty should only be performed in patients who place low demands on their wrists. In addition, arthroplasty is only indicated in wrists with good bone stock that will support an implant. Furthermore, the patient must have functioning wrist flexors and extensors to benefit maximally from wrist arthroplasty. It is important to discuss complications such as infection, loosening, migration and dislocation with the patient, as well as the postoperative rehabilitation and long-term limitations that will be placed on wrist use. A number of implant designs are available worldwide. The most commonly used implants consist of cobalt chrome metal components, often with titanium plasma spray on the stems to improve osseointegration, and ultra-high molecular weight polyethylene on metal articulations. Because wrist implants are continually modified and refined, the details of the surgical technique change and the implant manufacturer's specific recommendations should be followed. The general steps of the operation are described below.

The dorsal wrist capsule is exposed as described above (Fig. 19.43). A distally based U-shaped capsulotomy is created, leaving a cuff of capsule on the radius for closure (Fig. 19.44). Radiocarpal and mid-carpal synovectomies are performed. A transverse carpal osteotomy is made, removing 2 mm of the head of the capitate, the proximal pole of the hamate, the proximal half of the scaphoid, and the entire triquetrum and lunate. With the wrist flexed, the surface of the radius is prepared using a guide and a burr or saw (Fig. 19.45). Next, a guide-wire is drilled into the radius. It should be in line with the medullary canal, with a starting point about 2–3 mm volar to the dorsal lip of the radius and near the interfossal ridge.

Fig. 19.43 A radially based retinacular flap has been elevated, exposing the extensor tendons. Synovectomy is being performed.

Fig. 19.44 A wrist capsulotomy has been made. The capsulotomy is U-shaped, and is distally based, providing full exposure of the wrist joint.

The distal radius is then sequentially broached, keeping the broach aligned with the medullary canal. After broaching, the radial trial component is placed and impacted. If it is proud, further broaching or burring of the radius may be required. Next, the radial trial is removed, and the carpus is prepared. This step varies depending upon the implant used. After

Fig. 19.45 An osteotomy has been made at the distal end of the radius. Note the saw-guide held in place with two K-wires.

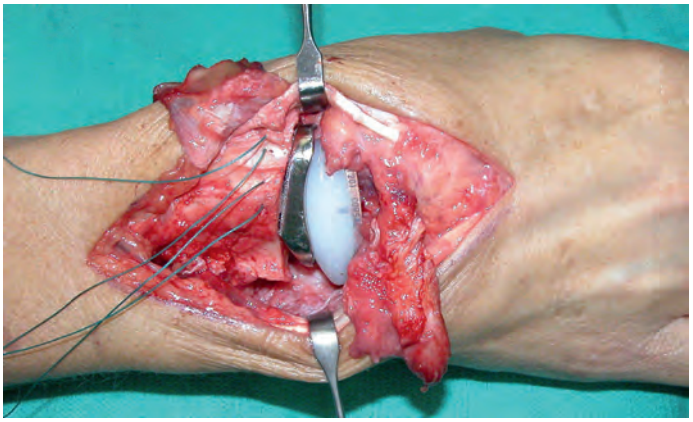

Fig. 19.46 The radial and carpal components have been seated, and the joint reduced. Final position of the implant.

preparing the carpus, a trial reduction is performed with both the radial and carpal trial components. Articulation and range of motion are checked. Trials are removed, the wound is copiously irrigated, fresh towels are placed, and gloves are changed. The radial implant is placed first and impacted, and its position checked with fluoroscopy. Next, the carpal component(s) is placed and impacted, and the joint reduced (Fig. 19.46). Hardware position and alignment are checked with fluoroscopy (Fig. 19.47). Depending upon the implant design, carpal screws may be placed. Joint stability and ROM are checked, and final X-rays are taken. The tourniquet is let down, hemostasis is achieved, and the retinaculum is closed with the EPL transposed.

Postoperative care

The patient is splinted in 30° of extension for 2 weeks. ROM begins at 2 weeks under the guidance of a therapist, and protection of a removable splint for the next 6–8 weeks. Strengthening begins at 4–6 weeks. Patients are given a 20-lb lifting restriction, and sports and other heavy activities are prohibited. It is crucial for the patient to take preoperative antibiotics before dental, urologic, and gastrointestinal procedures, etc.

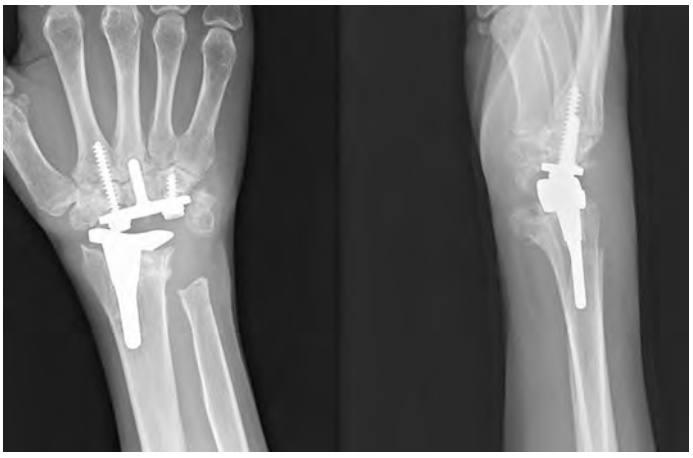

Fig. 19.47 PA and lateral radiographs demonstrating good position and alignment of the prosthesis.

Outcomes, prognosis, and complications

Total wrist arthroplasty effectively relieves wrist pain. However, the surgeon and patient are accepting a higher complication rate in order to preserve wrist motion. Major complications include implant instability or dislocation, migration, infection, fracture, loss of alignment, and persistent pain.

Secondary procedures

Although revision arthroplasty may be attempted, failed total wrist arthroplasty is most reliably treated with complete wrist arthrodesis. Wrist arthrodesis after failed total wrist arthroplasty is not straightforward, due to scarring and loss of bone stock. Difficulty with fixation and delayed union are not uncommon.

Hints and tips

- Total wrist arthroplasty is a "high risk–high reward" operation. The patient is accepting a relatively high complication rate for the chance to preserve wrist motion.
- The patient must be aware of lifetime limitations on upper extremity use.
- The patient must be instructed in taking antibiotics prior to dental, urologic, GI, and other invasive procedures or surgeries after total wrist arthroplasty.

Operations for the hand and fingers

MCP synovectomy and soft tissue reconstruction

Synovectomy and soft-tissue reconstruction of the MCP joints is a temporizing operation, and synovitis and deformity usually recur. It is only indicated in patients with persistent synovitis that does not respond to at least 6 months of maximum nonoperative management who have radiographically intact joints, correctable deformities, and substantial dysfunction. Patients with adequate function should not undergo MCP synovectomy and soft-tissue reconstruction, regardless of the presence of synovitis or deformity.

A transverse incision is made over the dorsal aspect of the MCP joints. Dissection is carried down to the extensor mechanism over each joint, using longitudinal spreading to protect the dorsal veins and sensory nerves. Often, the extensor tendon has subluxated ulnarly, and there may be attenuation or destruction of the radial sagittal band. The ulnar sagittal band is incised longitudinally, adjacent to the extensor tendon. A 15-blade is then used to separate the extensor mechanism from the underlying joint capsule. The capsule, which is usually very thin, is then incised transversely with a 15-blade, exposing the MCP joint. Synovial pannus is removed with a curette or small synovial rongeur. (It should be noted that PIP synovectomy can be performed as well for painful synovitis that is unresponsive to medical management, as demonstrated in Figs. 19.48 and 19.49).

The finger is checked for intrinsic tightness. The PIP joint is passively flexed while the MCP joint is alternately held in flexion, and then hyperextension. Increased resistance to PIP flexion when the MCP is held in hyperextension indicates

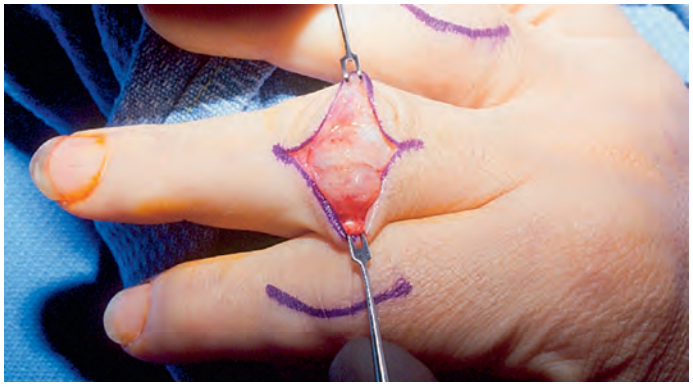

Fig. 19.48 A slightly curved incision has been made over the dorsal aspect of the PIP joint, and skin flaps have been elevated. The synovial pannus can be seen protruding ulnar to the central slip.

Fig. 19.49 Excision of the synovial pannus, working in a proximal to distal direction.

intrinsic tightness. In addition, ulnar sided intrinsic tightness is evaluated by testing the PIP joint with the MCP ulnarly versus radially deviated. If intrinsic tightness is present, an ulnar intrinsic release and cross-intrinsic transfer are performed.

On both sides of the finger, the soft tissue is elevated off the lateral bands using tenotomy scissors. The ulnar lateral band is divided distally and freed proximally to the musculotendinous junction. It is then transferred to the radial lateral band of the adjacent finger and secured with a modified Pulvertaft weave (Fig. 19.50). The cross-intrinsic transfer should be tensioned with the finger in neutral alignment. In the small finger the abductor digiti minimi is released with a 15-blade at its musculotendinous junction. Finally, the extensor tendons are mobilized radially and relocated centrally over the MCP joints. The radial sagittal band of each joint is imbricated. The MCP joints are then passively ranged. If the extensor mechanism tends to re-subluxate, or if the radial sagittal band reconstruction is not secure, the extensor tendon should be sutured directly to the underlying joint capsule at the base of the proximal phalanx.

Postoperative care

A splint is applied with the MCP joints extended and in neutral radio-ulnar alignment. Active ROM in a dynamic MCP extension splint is begun once pain and edema have improved. A resting splint that holds the MCPs extended and in neutral alignment should be worn at night and at other times. Splinting can be weaned after 6–8 weeks, although night-time splinting may be continued indefinitely.

Outcomes, prognosis, and complications

Recurrence of synovitis and deformity should be expected over time. Fig. 19.51 demonstrates a patient before and 1.5 years after MCP synovectomy and cross-intrinsic transfer.

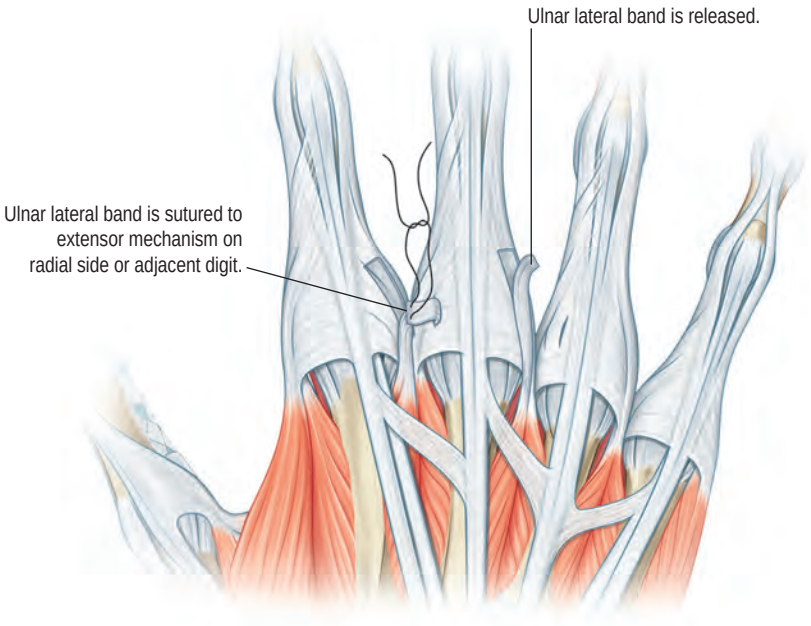

Fig. 19.50 The ulnar lateral bands of the index, long and ring fingers are divided distally, and transferred to the radial lateral bands of the adjacent long, ring, and small fingers. The abductor digiti minimi of the small finger is divided.

Fig. 19.51 Preoperative (above) and postoperative (below) views of both hands after cross-intrinsic transfers.

Secondary procedures

Recurrent synovitis and deformity that are painful or adversely affect hand use are indications for arthroplasty.

MCP arthroplasty (silicone)

MCP arthroplasty is indicated in patients who have pain or substantial loss of function due to MCP deformity and arthritis (Video 19.2 ▶). If the patient has reasonable hand function without pain, arthroplasty is not indicated regardless of the degree of deformity. PyroCarbon implants or surface replacement arthroplasty (SRA) implants can be used in rheumatoid patients in certain situations (Figs. 19.52 & 19.53). However, because of the soft-tissue laxity and joint instability associated with RA, silicone arthroplasty is generally preferred (Fig. 19.54). A silicone implant acts as a spacer and internal mold that becomes encapsulated, and thereby provides some degree of alignment stability. A number of silicone MCP implants are commercially available. Although there are some minor differences in design, the surgical techniques are similar.

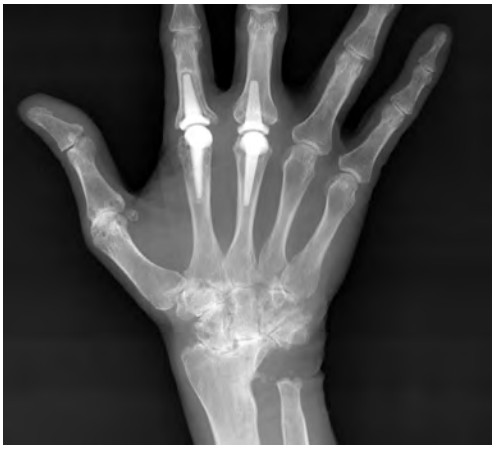

Fig. 19.52 Index and long MCP arthroplasties with PyroCarbon implants. The use of PyroCarbon implants should be limited to patients without soft-tissue instability.

Fig. 19.53 MCP arthroplasty with surface replacement implant. The proximal component is made of cobalt-chrome, and the distal radiolucent component is made of ultra-high-molecular-weight polyethylene (UHMWPE).

A transverse incision is made across the dorsal aspect of the MCP joints. If only one joint is undergoing arthroplasty, a longitudinal incision can be used. The extensor mechanism is exposed as described above. Because of the alignment of the fingers, arthroplasty is performed at the index finger and

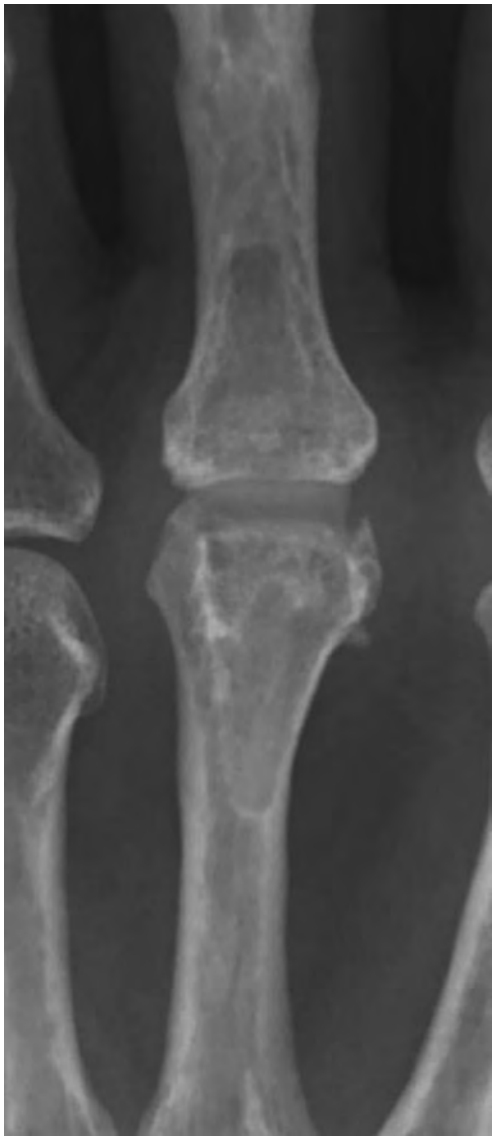

Fig. 19.54 MCP arthroplasty with a silicone implant. The implant is relatively radiolucent, but the broached regions of the metacarpal and proximal phalanx that are occupied by the stems of the implant are visible on radiographs. The barrel of the implant which serves as a spacer between the two bones can be seen.

progresses ulnarly. A longitudinal incision is made in the ulnar sagittal band adjacent to the extensor tendon. The extensor mechanism is elevated off the joint capsule, and the extensor tendon is retracted radially. If intrinsic tightness is contributing to ulnar deviation, an ulnar intrinsic release can be performed as described above. The capsule is incised longitudinally with a 15-blade and synovectomy is performed. The ulnar collateral ligament is released by separating its proximal insertion from the lateral aspect of the metacarpal head. If possible, the radial collateral ligament is preserved. The MCP joint is then maximally flexed, exposing the metacarpal head. A starter awl is used to open the medullary canals of the metacarpal and proximal phalanx, and fluoroscopy is used to confirm appropriate alignment (Fig. 19.55). In order to center the awl in the medullary canal, the entrance point should be in the dorsal third of the articular surface (Fig. 19.56). A transverse osteotomy is made in the metacarpal head just distal to the insertion of the collateral ligaments. The proximal phalanx is then brought into extension, and a transverse osteotomy is created at the proximal phalanx base, resecting only articular cartilage and subchondral bone (Fig. 19.57). Conservative osteotomies should be made initially, as more bone can be resected later if necessary. The medullary canals of the metacarpal and proximal phalanx are broached sequentially until an appropriately sized implant can be placed (Fig. 19.58). Trials are used to select an implant that matches the diameter of the medullary canals and covers the entire exposed bony surface, but that does not overhang. When broaching the medullary canals, the broach should be oriented in such a way as to minimize the rheumatoid deformity. For example, in the index finger, the rectangular broach should be positioned high on the dorsal ulnar side of the base of the proximal phalanx, and low on the radial palmar side. This helps bring the finger into supination when the implant is placed, and prevents pronation deformity. The small finger broaching should be done in the opposite manner to prevent supination deformity. After broaching is completed, a rasp is used to smooth all cortical surfaces that may come in contact with the implant. The trial is then placed and the joint is reduced (Fig. 19.59). The transverse barrel should seat against both osteotomy sites, but should not be compressed. The joint is then passively ranged. If the implant is compressed during extension, further bone resection is required. There should be no bony impingement with flexion and extension. The trial is removed, and the wound is copiously irrigated. Using fresh powder-free gloves, the final silicone implant is placed. The radial collateral ligament is imbricated using 3-0 Ethibond sutures. If release of the radial collateral ligament was required, it must be sutured back to the periosteum or to bone holes created prior to implant placement. The capsule is closed, and the radial sagittal band is imbricated, centralizing the extensor tendon. A cross intrinsic transfer may be performed as described above.

Of note, some patients with severe MCP disease are poor candidates for implant arthroplasty. For example, longstanding volar MCP subluxation or dislocation can result in erosion and remodeling of the base of the proximal phalanx to the extent that it cannot accommodate the stem of an implant. In these patients, a volar plate interposition arthroplasty is a reasonable alternative. The volar plate is released palmarly from its origin on the metacarpal through a separate palmar incision, while maintaining the attachment to the base of the proximal phalanx. The metacarpal head is resected as for implant arthroplasty through a dorsal approach. The joint is reduced, and the proximal end of the volar plate is anchored to the dorsal cortex of the metacarpal. The volar plate serves two purposes, acting as interposed soft tissue, and also suspending the base of the proximal phalanx to resist recurrent palmar subluxation.

Clinical tip

- When performing an MCP arthroplasty, if the dorsal base of the proximal phalanx is too eroded to support an implant, a volar plate arthroplasty should be performed. This will interpose soft tissue into the arthroplasty space, and suspend the proximal phalanx.

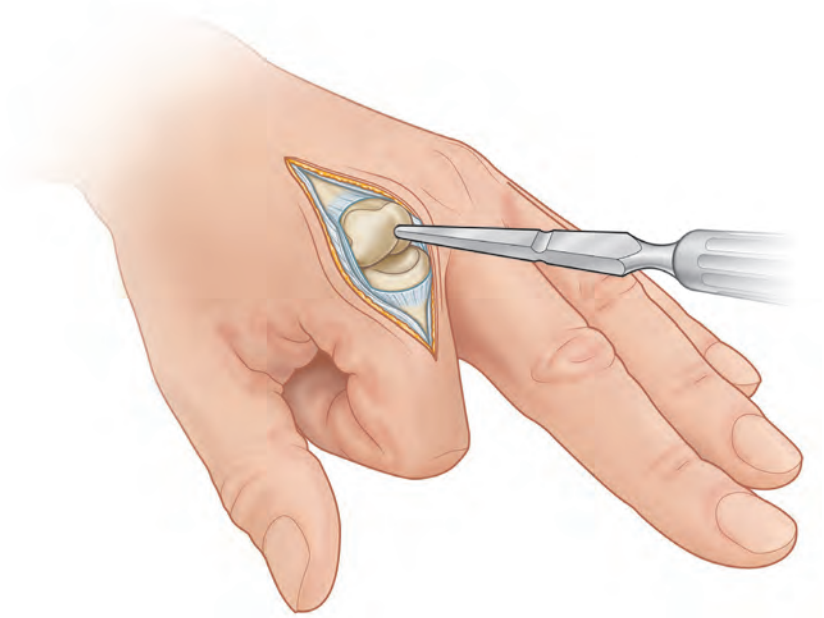

Fig. 19.55 A starter awl is used to open the subchondral bone at the head of the metacarpal and at the base of the proximal phalanx, in order to gain access to the medullary canal.

Postoperative care

Postoperatively, the wrist is splinted in 20° of extension, and the MCPs are splinted in extension and slight radial deviation. The IP joints are left free. Once edema and pain have improved, active motion with the guidance of a therapist is initiated. The patient wears an MCP extension splint in between exercises, and a dynamic MCP extension splint may be used for exercises if needed. Modifications of splinting position are frequently required, depending on the severity of the preoperative deformity, and on patient progress after surgery. Splinting is weaned at 6 weeks.

PIP arthroplasty

PIP arthroplasty can effectively relieve pain and improve alignment, while preserving joint mobility in patients with PIP arthritis. However, PIP arthroplasty is less reliable than MCP arthroplasty in terms of stability and correction of deformity. PIP arthroplasty should therefore be avoided in the index finger, which must resist strong ulnar deviation forces during pinch. It is most effective in patients with pain due to arthritis, who have relatively good soft tissue.

The procedure is similar to that for MCP arthroplasty described above. A dorsal longitudinal incision is made over the PIP joint, and skin flaps are elevated at the level of the extensor mechanism. The central slip is divided longitudinally from the mid-portion of the proximal phalanx to the central slip insertion, without disrupting the central slip insertion. The joint is flexed and a transverse capsulotomy is made. The collateral ligaments should be preserved if possible. If collateral ligament recession is required for adequate exposure of the joint, the collateral ligaments are repaired prior to skin closure. A transverse osteotomy is made in the head of the proximal phalanx just distal to the collateral ligament insertion. An osteotomy is not required at the base of the middle phalanx, but osteophytes should be removed and the articular surface smoothed. Bony resection should be conservative, and further resection can be performed later if required. A starter awl is used to open the medullary canals, and fluoroscopy is used to confirm correct alignment. Broaches are then used to sequentially broach up the medullary canals of the proximal and middle phalanges. Trials are used to select the appropriate implant size as described above. The appropriately sized trial is placed, the joint is reduced and ranged, and checked for instability or impingement. If required, further bony resection and re-broaching is performed. The trial is removed and bone edges are smoothed. The wound is copiously irrigated, gloves are changed, and the final implants are inserted. If required, the central slip and collateral ligaments are reattached to bone using sutures passed through bone holes drilled with a Kirschner wire. The bone holes should be created and the sutures passed prior to placing the final implant. The divided central slip is approximated with absorbable sutures, and the skin is closed.

Fig. 19.56 In order to be in line with axis of the medullary canal, the starting point should be created at the junction of the middle and dorsal third of the articular surface.

Postoperative care

Patients begin motion postoperatively, as soon as edema and pain are improved. Splinting is continued for at least 6 weeks postoperatively. The position and type of splinting required vary substantially, depending upon the preoperative deformity and patient's postoperative progress.

Outcomes, prognosis, and complications

Although the outcomes reported in the literature are variable, silicone MCP arthroplasty has been demonstrated in multiple studies to effectively treat pain, correct ulnar drift, improve

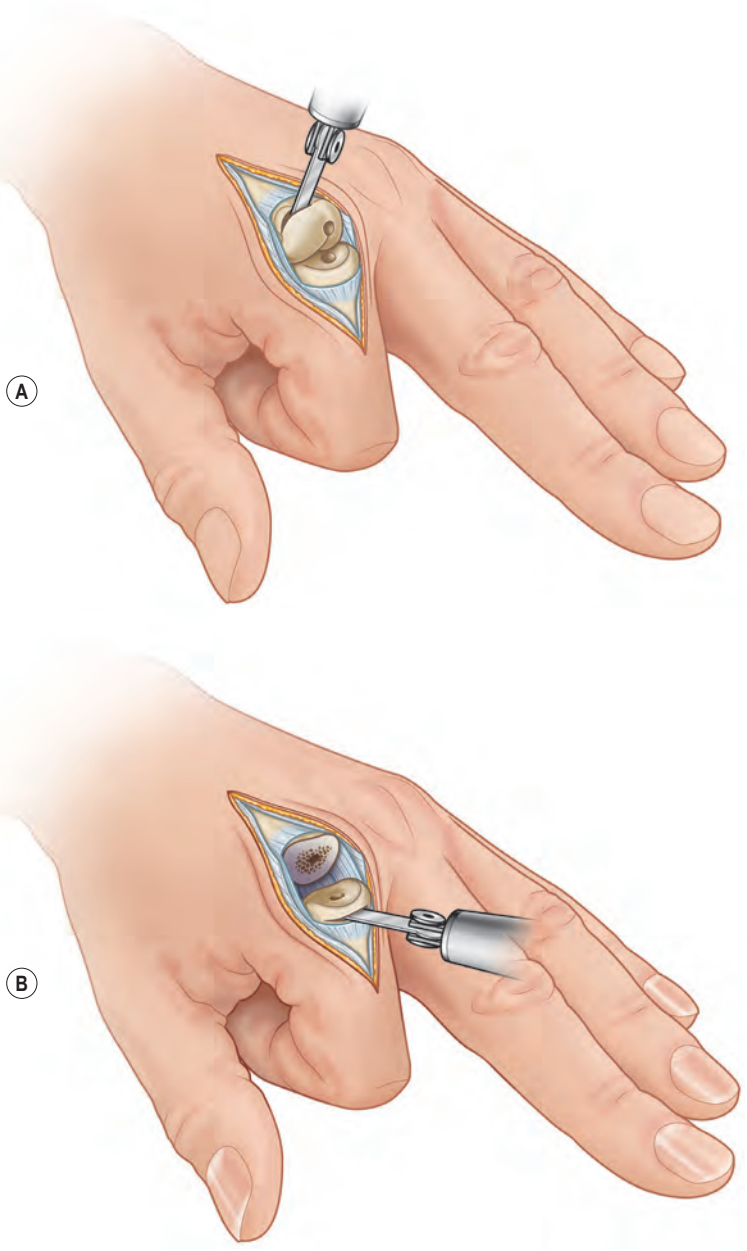

Fig. 19.57 A sagittal saw is used to create osteotomies of the metacarpal head and base of proximal phalanx. Conservative osteotomies should be made at first, and revised if needed. The collateral ligaments should be preserved if possible.

MCP joint arc of motion, and improve appearance. These effects are often maintained for years, although slow deterioration usually occurs. At the PIP joint, arthroplasty typically relieves pain, but is not as effective at correcting deformity or improving motion. Potential complications include recurrence of deformity, extension lag or loss of flexion, fracture of silicone implant, dislocation of implant, silicone synovitis, and infection. Recurrence may be due to soft tissue changes, implant fracture, or inappropriate positioning of implant.

Secondary procedures

Revision arthroplasty after implant failure is possible, but should be reserved for patients with loss of hand function that is directly correlated to the failure of the implant. Often, overall upper extremity function is decreased not because of implant failure, but because of ongoing changes at the wrist, elbow, or shoulder. Furthermore, a fractured implant often continues to function as a spacer, and the patient may not notice a change in joint function. When revision arthroplasty is performed, it is important to correct any issues that may have contributed to implant failure, such as soft tissue deforming forces, sharp bony edges, or inadequate bone resection.

Hints and tips

- Pyrolytic carbon or other surface replacement arthroplasties should be reserved for patients with stable joints and normal ligaments and soft tissue.
- Most RA patients who require MCP or PIP arthroplasty should have silicone rather than surface replacement arthroplasty.
- The surgeon should start with conservative osteotomies and broaching. More bone can always be resected if needed.

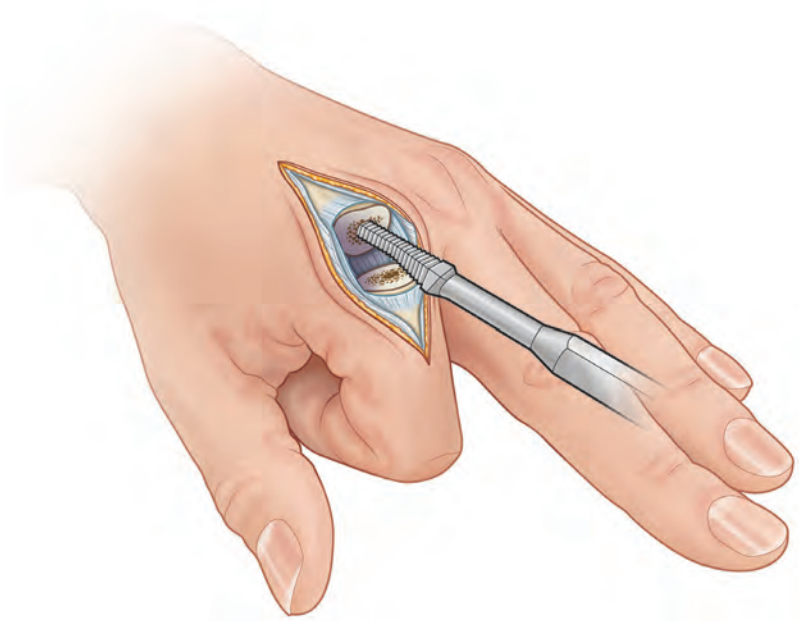

Fig. 19.58 The medullary canals are sequentially broached.

MCP and IP arthrodesis

Arthrodesis of the MCP or IP joints is a reliable method for treating refractory pain due to arthritis. Although motion is sacrificed, the complication rate of arthrodesis is less than that of arthroplasty, making it an attractive option in some clinical situations. Arthrodesis is most commonly indicated at the index or long finger PIP joint, where the ability to resist strong ulnar deviation forces during pinch is crucial.

The joint is exposed as described above for arthroplasty. The collateral ligaments can be divided in order to improve joint exposure. With the joint flexed, a rongeur is used to remove all articular cartilage and subchondral bone from the opposing articular surfaces, creating flat opposing cancellous surfaces. The flat cancellous surfaces must be created in such a way that when they are apposed, there is full contact between the two surfaces with the joint in the desired amount of flexion, without radial or ulnar deviation. Next, two parallel 0.035 or 0.045-inch K-wires are drilled across the joint, entering the cortical bone dorsally at least 1 cm proximal to the arthrodesis site, and angled volarly into the medullary canal of the distal bone. The K-wires should be advanced until they enter cortical or subchondral bone distal to the osteotomy site. Next, a 0.045-inch K-wire is used to create a transverse hole in the distal bone, 1 cm distal to the arthrodesis site. A 24-gauge stainless steel wire is passed through the transverse hole in the distal bone. Both ends of the wire are then turned proximally, crossed over the dorsal aspect of the arthrodesis site and wrapped around the K-wires, creating a figure-of-eight (Figs. 19.60 & 19.61). The free ends are twisted down

Fig. 19.59 Final position of the implant.

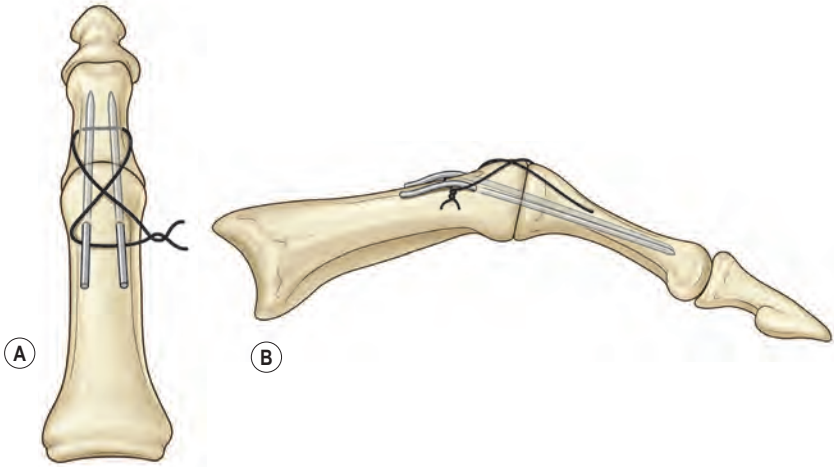

Fig. 19.60 K-wire and stainless steel wire configuration for tension band arthrodesis of the PIP joint.

with a needle driver until strong compression is achieved. The excess wire is then cut and bent down against the bone. The two K-wires are retracted 2 mm proximally, bent 90° and cut, and then tapped back in to prevent a sharp protruding K-wire. The extensor mechanism is repaired, and the skin is closed. For the DIP joint, because fusion in a flexed position is not necessary, a headless compression screw provides effective fixation (Fig. 19.62).

Postoperative care
